Table 5: Effect of directionality on forensic camera model identification. The original SPAM features average horizontal and vertical information (symmetrization). Skipping this step improves the classification accuracy for small images.

Resolution	SPAM [80] (symmetrized)	Proposed variant (not symmetrized)
Full resolution	0.9972	0.9972
256^2	0.9722	0.9728
128^2	0.9041	0.9342

An advantage of feature-based methods is that we can measure the information lost by symmetrization. Figure 12 plots the L2 distance between the submodels of different directionality that are averaged in the original SPAM features as a function of the directionality score. We call this distance "stress." The two submodels are most similar for directionality scores close to zero. Stress increases with image directionality. Taken together, this provides the link between the directionality score, symmetrization in feature space, and accuracy.

6 Effect on synthetic image detection

GAN and diffusion-based synthetic image generators are known to introduce weak but detectable periodic artifacts [19]. They are explained by the repeated upsampling during image synthesis and therefore appear largely symmetrical [30]. Little attention has been paid to asymmetries in these artifacts. We show that synthetic images do contain directional traces, which CNN-based "fake-or-real" detectors tend to exploit.

We train CNN detectors for two synthetic image generators: DALL·E Mini [24] and Stable Diffusion XL (SDXL) [81]. For the real images, we use ALASKA2 and rotate each image by a random multiple of 90 degrees to remove directional bias. To create fake images, we pass the real images through the autoencoders of the two synthetic image generators. Compared to generating images from text prompts, this approach allows us to create real–fake pairs with matching scene content. This eliminates the possibility of spurious results due to shortcuts caused by a scene bias [38]. As detailed in Appendix D, this approach leaves the same synthesis artifacts as the typical text-to-image pipepline. 80% of the images are used for training, 10% for validation, and 10% for testing. We ensure that both real and fake images of the same scene are in the same

Table 6: CNN-based synthetic image detectors exploit directional artifacts introduced by the autoencoders of GANs.

Autoencoder	Orientation	Acc.	TNR	TPR
DALL·E Mini	original	1.000	1.000	0.999
	rotated	0.989	0.999	0.979
Stable Diffusion XL	original	1.000	1.000	1.000
	rotated	0.674	1.000	0.349

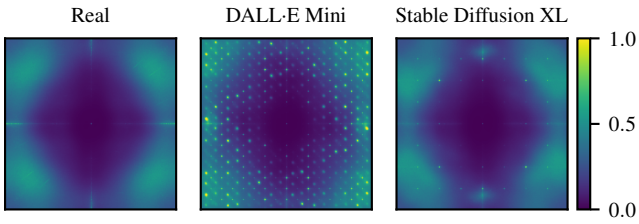

Figure 13: Power spectra of noise residuals from real images, the DALL·E Mini autoencoder, and the Stable Diffusion XL autoencoder. The last stages of generative models leave asymmetric artifacts that do not appear in real images.

split. We train an EfficientNet-B0 as binary classifier with cross-entropy loss, ImageNet pretraining, learning rate 10^{-4}, batch size 32, and dropout rate 0.25.

Table 6 reports that both detectors achieve an accuracy of 1.0. The accuracy drops when the test images are rotated by 90 degrees. As can be seen from the true negative rate (TNR) and true positive rate (TPR), the performance loss is largely due to fake (positive) images being misclassified as real (negative). For the DALL·E Mini autoencoder, the TPR drops from 0.999 to 0.979, which means that 2.1 % of fake images are classified as real. For the SDXL autoencoder, the TPR even drops to 0.349, which means that almost two out of three fake images are classified as real. Rotated real images are correctly classified, i.e., the TNR remains near-perfect after rotation.

Directional artifacts can be observed in the power spectrum after averaging the noise residuals from 1 000 randomly selected images [19]. Figure 13 compares the randomly rotated ALASKA2 (left) to our DALL·E Mini (center) and SDXL (right) images. In ALASKA2, no directional pattern can be observed. Conversely, DALL·E Mini shows asymmetric dot patterns. SDXL introduces a high-frequency artifact on the vertical axis, which is not present on the horizontal axis.

Our experiments in this section demonstrate that synthetic images contain directional statistics. They are related to the autoencoder of synthetic image generators, but their root cause is yet unknown. As many recent detectors for synthetic images do not rotate their training images [21, 42, 90, 98, 99], these detectors may be less reliable on rotated test images. An attacker can generate an image of a rotated scene and manually rotate it back to reduce the chances of being caught.

7 Related work

Previous work in the security field has touched on the directionality of images, but the results are scattered. Westfeld [100] reports improved steganalysis by scanning images along a space-filling Hilbert curve. While it breaks up directionality, the method is justified by increased locality. Franz et al. [31–33] develop statistical models of flatbed scanner images. They observe directional differences between successive scans and attribute it to the variability of line sensor elements and the mechanical tolerances. None of this applies to the area sensors in today's smartphones and digital cameras. A common forensic task on these sensors is to determine the configuration of the color filter array. The fact that this pattern depends on the camera orientation has been studied [60]. Recent work observed directional artifacts in DALL·E 2, but did not investigate further [4].

Popular feature descriptors in steganalysis [35, 63, 80] and image forensics [14] use directional high-pass filters to extract noise residuals or count co-occurrences in horizontal and vertical directions. They exploit sign and mirror symmetries to obtain a compact feature vector. Several early works made the simplifying assumption that image statistics are non-directional; examples include the subtractive pixel adjacency model (SPAM) ("the effect of portrait/landscape orientation is negligible" [80, p. 3]), the spatial rich model ("the statistics of natural images do not change after rotating the image by 90 degrees" [35, p. 5]), and the JPEG rich model ("assuming the statistics of natural images do not change after mirroring about the main diagonal" [63, p. 2]). Such assumptions can be traced back to early quantitative detectors of LSB replacement steganography ("What holds when scanning an image horizontally ought to hold, in general, when scanning vertically." [59, p. 13]). While a lower feature dimensionality reduces the risk of overfitting and multicolinearity [102], it ignores the natural directional properties of images. Two more recent steganalysis feature descriptors, the phase-aware rich models (PHARM) [48] and the Gabor filter residuals (GFR) [95], do not average over orientations, but without giving a reason or supporting evidence. Some applications may ignore directionality when the orientation is known a priori or when the error rate is low enough to analyze the image in all four orientations, e.g., in PRNU matching.

The practices regarding rotation augmentation are inconsistent among subfields. In steganalysis, rotation augmentation is common [10, 55, 101]. In camera model identification and synthetic image detection, the majority of related work avoids rotation, with two exceptions [44, 74]. We did not find reflections on these choices, let alone comparisons. Rotation augmentation has been adopted from computer vision [67], where images are often downscaled and rotated by only a few degrees. However, these operations involve resampling which suppresses the signal of interest for security applications [55].

Overall, directionality of image statistics seems tangen-

tial to all of these works. While the security implications of certain image processing operations have received some attention recently (e.g., adversarial scaling [85]), a comprehensive treatment of directionality has been lacking.

8 Discussion

Directionality matters. This is the two-word summary of our multi-domain, multi-method study on the causes and effects of directionality in digital images in security applications.

This research has led to a number of new insights, primarily into the effects but also the causes of directionality. We are the first to report directional bias in popular benchmark image databases. We also point out that DCT implementations in popular JPEG libraries leave directional traces. For color images, directional chroma subsampling and asymmetric quantization tables add more directional traces. Across the three security applications studied, detectors trained on one image orientation do not naturally generalize to rotated images. In steganalysis, we found that the main cause for this is asymmetric quantization tables, followed by directional scene bias in the dataset. CNN-based fake-or-real detectors are susceptible to pick up directional traces left by the autoencoders in the last stage of generative models. Several feature descriptors used in steganalysis and image forensics average horizontal and vertical statistics. We found that a forensic camera model classifier benefits from keeping the directions separate, especially for small images.

Rotation augmentation requires more thought than is devoted in the extant literature. Our results lead to the following recommendations. If generalization to rotated images is desired, use rotation augmentation. To maximize performance on a directional dataset, avoid rotation augmentation. On small datasets, rotation augmentation can reduce overfitting but directionality-preserving transformations are preferable.

A qualitative observation is that many causes of directionality relate to legacy conventions and practices. While old standards "never die," and are notoriously hard to replace, contemporary implementations of standards could depart from outdated defaults and instead use settings that do not leave new or amplify existing directional traces.

Limitations While we claim to have captured the dominant causes of directionality in raw-to-image conversion, our stocktaking is probably incomplete. A careful study of the literature reveals more idiosyncrasies of specific devices that may cause directionality. For example, the meanwhile historical Fujifilm J50 reportedly shifts the PRNU by seven pixels in horizontal direction depending on the exposure time [40].

Although the experimental setups in Sections 4, 5, and 6 closely replicate selected related work published in prominent venues, these scenarios only evaluate a single dataset, compression setting, and detector architecture. The effect of directionality may be larger or nonexistent in different scenarios. Additionally, we trained and evaluated our CNNs with JPEG images that were *de*compressed with default settings, i.e., the ISLOW inverse DCT. Switching to the float DCT would slow down the training and the numerical differences are tiny. Real-world applications built with the popular TensorFlow framework might deviate much more since `tf.io.decode_jpeg` defaults to the IFAST DCT method.[6] The CNN detectors in Sec. 6 are tailored to *un*compressed synthetic images. In practical applications, suspect images are often post-processed, scaled, and compressed. We intentionally chose uncompressed images to avoid potential inferences from directional effects of subsequent processing. Further experiments with more diverse setups are needed to quantify which factors interact with directionality.

Possible extensions Directionality relates to rotation by 90 degrees. Is there a similar paper to be written on horizontal and vertical flipping? Clearly, natural images may contain biases, e.g., a bright sky at the top and darker areas at the bottom. Some processes intentionally flip images, e.g., webcams make users feel like they are looking into a mirror. To show that directionality is still special, we retrain all CNNs from Fig. 1 without flipping augmentation, and evaluate their accuracy with flipped images. In all cases, the performance on flipped images matches the performance on the original images. This suggests that flipping matters less than rotation.

Reproducibility Our code for measuring directionality is available at https://github.com/uibk-uncover/directionality.

9 Concluding remark

We close with the conjecture that gravitation is the root cause of directionality in digital images. Human preference for landscape orientation has impacted scene composition as well as technology. This is likely due to the horizontal arrangement of mammalian eyes, which itself might have evolved to make our prehistoric ancestors more secure against predators that move on the surface [5].

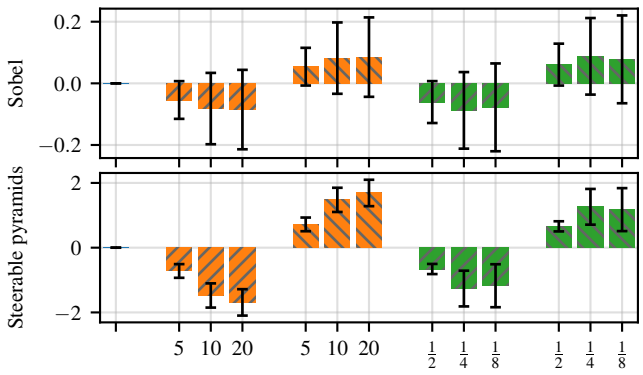

Figure 14: Comparison of Sobel filters (top) and steerable pyramids (bottom) for five types of test data. Both detectors indicate the dominant image direction, but the steerable pyramids are more precise, as indicated by the tighter error bars.

A Data

The experiments in this paper draw on multiple databases, summarized in Tab. 7. BOSSBase (grayscale) and ALASKA2 (color) are popular in the steganography and steganalysis literature. From ImageNet, we use training set. The Dresden, VISION, and Forchheim databases are popular in the forensics community for benchmarking camera device or model identification. Camera annotations make them ideal for camera-specific statistics and the study of prevalent compression patterns. From the Dresden database, we use the natural scene subset. From the Forchheim database, we use the camera-original subset. Additionally, we acquired 201 flat-field frames with a Sony Alpha 6600 and a Nikon D850.

Table 7: Databases used for illustrating the causes and effects of directionality

Name	Purpose	Format	# images
BOSSBase [6]	Steganalysis	NC	10 000
ALASKA2 [16]	Steganalysis	NC	80 005
ImageNet [25]	Image recog.	JPEG	1 281 141
Dresden [39]	Forensics	JPEG	16 961
VISION (flat) [91]	Forensics	JPEG	4 167
VISION (nat) [91]	Forensics	JPEG	7 565
Forchheim [44]	Forensics	JPEG	3 851
Own (flat)	-	NC	402

NC = never compressed

B Comparison of directionality scores[7]

This section compares two directionality detectors based on the Sobel filter and steerable pyramids. We generate 1 000 *symmetric* synthetic images of size 512^2, consisting of of cosine patterns with randomized amplitude and additive noise. We produce four directional variants using horizontal/vertical smoothing and horizontal/vertical downscaling.

Figure 14 shows the average directionality scores of the Sobel (top) and the steerable pyramids directionality detectors (bottom). As expected, horizontal/vertical smoothing (orange) or downscaling (green) leads to negative/positive directionality scores. The errors bars show that steerable pyramids are more precise than the Sobel-based detector.

[7] A longer description is available in an arXiv version of this paper.

Table 8: A CNN multi-class classifier for forensic camera model identification cannot maintain its accuracy on rotated test images. Rotation augmentation overcomes this limitation.

Training setup	Accuracy original	Accuracy rotated
no-rot	0.941	0.845
aug-rot	0.932	0.929

C CNN-based camera model identification

This part has been moved to the appendix to make space for the SPAM feature descriptor, which allows us to directly measure the "stress" caused by explicit symmetrization. The headline result in Fig. 1 use a CNN-based method for better comparability across applications. Here we describe the experiment and report on the effect of rotation augmentation.

We replicate the setup of [44], who train an EfficentNet-B5 as 27-class classifier on the Forchheim dataset, and pay particular attention to factors that affect directionality. We verified that 22 cameras stored their images in canonical orientation and set the EXIF orientation flag (cf. Sec. 3.4). The other cameras stored rotated images without orientation metadata. We use all images as stored to preserve the compression direction.

Each image was subdivided into non-overlapping patches of size 256^2. From each image, we select the 100 patches with the highest quality according to a heuristic quality metric [9]. This approach discards non-informative regions, e.g., consisting of homogeneous pixels. We trained on randomly cropped sub-patches of size 64^2, using an initial learning rate of 10^{-5}, and a dropout rate of 0.25. The learning rate halves whenever the validation loss stagnates for 500 epochs. Training ends when the validation loss does not improve for 1000 epochs.

We evaluate two setups. In the *no-rot* setup, the training patches are randomly flipped along the vertical and horizontal axis. In the *aug-rot* setup, the training patches are additionally rotated by a random multiple of 90 degrees, as in [44].

Table 8 reports the results. In the *no-rot* setup, the CNN achieves an accuracy of 0.941. The rightmost column reports the accuracy after rotating the test images by 90 degrees in counter-clockwise direction. The drop in accuracy by 9.6 %-pts. shows that the images contain directional information,

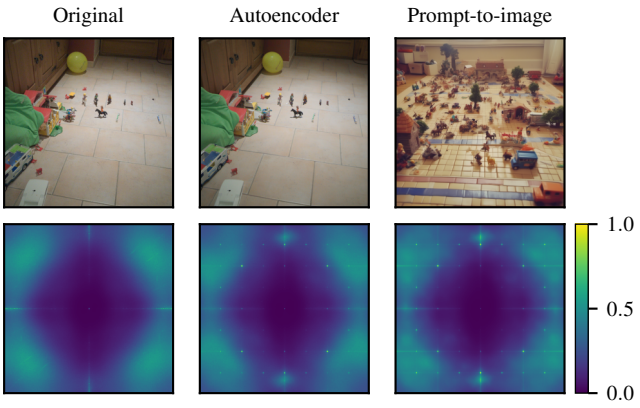

Figure 15: Passing a real image through SDXL's autoencoder inserts the same frequency-domain artifacts as in images generated from text prompts while preserving the scene content.

which the CNN has learned to exploit. In the *aug-rot* setup, the CNN achieves a slightly lower accuracy of 0.932 but generalizes to rotated test images.

D SDXL autoencoder vs. text-to-image

Today's synthetic image generators split the image generation into a semantic and a perceptual part [88]. The perceptual part consists of an autoencoder that provides a compact image representation and can reconstruct images from this representation. The semantic part consists of a generative model that synthesizes the semantic content of the image in the autoencoder's compact representation. The autoencoder's decoder fills in the perceptual details while decompressing the generated representation to an image.

We considered compressing the ALASKA2 dataset to text prompts with the CLIP interrogator[8] and reconstructing a synthetic ALASKA2 dataset from the text prompts. Working with a small subset, we found that some of the generated images were surprisingly close to the original images. In many cases, however, the text prompts encouraged an artistic style or hallucinated animals. We were concerned that this might introduce scene bias and discarded this approach.

Our fake images in Sec. 6 were created by passing real images through the generators' autoencoder. Figure 15 demonstrates that this approach leaves the same artifacts as synthesizing images from text prompts. The top row shows a real image from ALASKA2 (left), the image after compression and decompression via the SDXL autoencoder (center), and an image synthesized from a text prompt (right). The bottom row shows the power spectrum after averaging 1 000 noise residuals. The autoencoder image has the same scene content as the original image, but shows the same artifacts as images synthesized from text prompts. The artifacts in the right column appear slightly sharper because SDXL produces 1024^2 images while the autoencoder maintains the 512^2 image resolution. This shows that synthesis artifacts are introduced by the autoencoder, as also observed in related work [23].

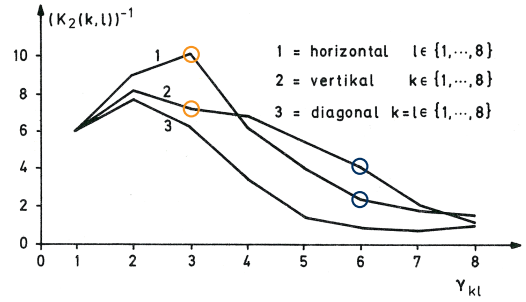

Figure 16: Psychovisual thresholding experiments revealed different contrast sensitivity profiles for horizontal, vertical, and diagonal DCT basis functions. Figure reproduced from [70, p. 138]. The circles are our own annotations, relating to the quantization factors highlighted in Fig. 10.

Figure 17: Orientation-filtered stimuli used in neuroscience. Images reproduced with kind permission of the authors [41].

E Measurement of human contrast sensitivity

Human contrast sensitivity to the 64 DCT basis functions was measured by Lohscheller in the early 1980s [70, pp. 122–142]. Figure 16 shows the measured contrast sensitivity for the horizontal, vertical, and diagonal DCT basis functions. The values are averages of 18 human subjects. Note that horizontal and vertical sensitivity are different and the order changes between low and high frequencies. These measurements are reflected in the standard JPEG quantization table (Fig. 10), which is still widely used today.

F Horizontal edges in human face perception

Goffaux et al. confirmed that human brains prefer horizontal contours when recognizing human faces [41]. They presented orientation-filtered stimuli images to study participants in fMRI scanners. These images are reproduced in Fig. 17. The strongest activity in high-level face-specialized ventral regions of the human brain was observed in the condition where horizontal edges were preserved, as in the third image.

Information Flow Control in Machine Learning through Modular Model Architecture

Abstract

In today's machine learning (ML) models, any part of the training data can affect the model output. This lack of control for information flow from training data to model output is a major obstacle in training models on sensitive data when access control only allows individual users to access a subset of data. To enable secure machine learning for access-controlled data, we propose the notion of information flow control for machine learning, and develop an extension to the Transformer language model architecture that strictly adheres to the IFC definition we propose. Our architecture controls information flow by limiting the influence of training data from each security domain to a single expert module, and only enables a subset of experts at inference time based on the access control policy. The evaluation using large text and code datasets show that our proposed parametric IFC architecture has minimal (1.9%) performance overhead and can significantly improve model accuracy (by 38% for the text dataset, and between 44%–62% for the code datasets) by enabling training on access-controlled data.

1 Introduction

Recent studies [9, 10, 48] showed that large machine learning (ML) models can leak sensitive information that was in their training data through their inference-time output. This inference-time leakage introduces a new security/privacy concern when different users have access to different (training) data. For example, consider a scenario where a company trains an in-house code-completion model [21] with its proprietary code repositories, when individual employees have access to different subsets of the repositories based on their team or projects. The company faces a dilemma—if the model is trained with all the repositories, employees may be able to learn about the code that they do not have permission to access; if only trained with repositories that everybody has access to, the model quality will degrade. It would be ideal if the model can generate different outputs to different employees, by selectively leveraging training data that they have access to. Unfortunately, today's ML models mix information from all training data during the training process, and cannot selectively utilize a subset of training data.

To address this problem, we introduce the notion of information flow control (IFC) to machine learning. Instead of treating all training data uniformly, we partition the training dataset into multiple *security domains*. During inference, a trained ML model takes an *access policy* that represents which security domains are accessible by the current user and ensures its output does not leak any training data that the user cannot access. The goal of IFC in this ML setting is to develop a training process, an inference process, and a model architecture that can honor the access policy at inference time by guaranteeing no leakage of information from inaccessible training data to the model output. We define the problem through the lens of non-interference (NI), and present IFC as a new challenge that ML systems should address.

Deep learning models are notoriously difficult to understand or control even though they perform well in practice. In that sense, IFC in parametric deep neural networks may seem infeasible at a glance. We show that information flow can be controlled at the model architecture level. Our approach trains a separate, small sub-module, called an *expert* for each security domain, so that each security domain's data only influences a single expert. Then, we develop a secure *gating* function that is used at run-time to activate only a small number (k) of the most relevant, accessible experts for each user query considering the user's access policy. Once the gating function picks the top-k experts, the final output is generated by *aggregating* the outputs/parameters of the k experts. To ensure non-interference (NI), the gating and aggregation decisions only use information from accessible security domains.

While people studied modular model architectures [27, 30, 44] for non-security purposes, we found that designing a secure modular architecture for IFC introduces a new set of technical challenges. For IFC, in addition to only using accessible experts at inference time, the gating decisions (choosing

*Work done while at Cornell University.
†Work done while at Meta.

which experts to activate) and aggregation methods (combining information from the different activated experts) must also satisfy non-interference. This condition implies that gating and aggregation functions cannot be learned from the entire training data, as is the case with many of today's ensemble or mixture-of-experts (MoE) models. Moreover, the access policy is only given at run-time, and the decisions must be made quickly with only information from the accessible domains, which may change for each query. Additionally, the gating function must scale to a large number of security domains, which may be dynamically added or removed over time. We address these challenges by designing three new secure gating functions, and two secure expert aggregation methods based on output ensembling and parameter merging. The secure gating functions allow our IFC architecture to handle both cases when the target domain of an input is known and unknown, and a large number of security domains.

We implement our IFC design by extending two Transformer language models (GPT-2 and OPT) with our secure architecture, and evaluate them with real-world text [3] and code [12] data with simulated security domains. The evaluation results show that our proposed architecture can improve the accuracy (perplexity) by 38–62%, while strictly following the given access policy. When multiple experts are evaluated in parallel, the execution time of the secure IFC model is also close to the insecure baseline, adding at most 1.9% latency. The proposed parametric IFC architecture can also be useful for attribution, as only a small subset of activated experts influence the output, and machine unlearning, as it allows an easy removal of a security domain.

In summary, our technical contributions are as follows:

1. We introduce information flow control for ML and formally define non-interference in the ML context.
2. We propose modifications to the general Transformer architecture to enable information flow control. We propose fast, effective, and scalable gating functions and expert aggregation methods to enable information from multiple accessible security domains to be efficiently combined at run-time, improving the output quality while strictly enforcing non-interference from inaccessible domains.
3. We evaluate our approach with large corpuses of text [3] and code [12] datasets and show that we can enable secure use of access-controlled data with low performance overhead. The ability to securely use in-domain training data can significantly improve model accuracy compared to the baseline that is only trained on public data.

2 Information Flow Control (IFC) in ML

Here, we discuss information flow control (IFC) for machine learning (ML), including the motivation, a formal definition, and high-level approaches to realize it. The next section introduces a concrete realization of IFC for language models.

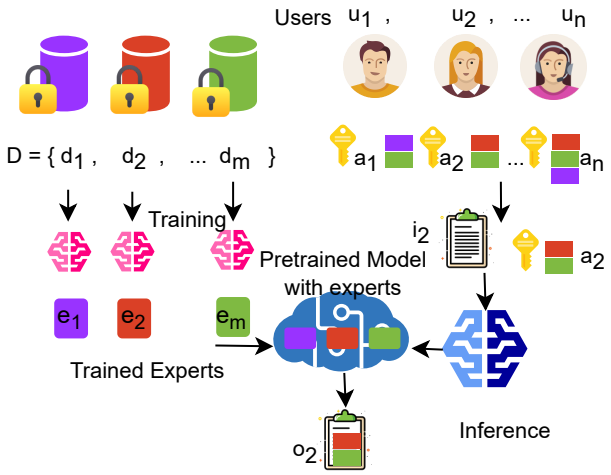

Figure 1: Information flow control (IFC) in machine learning.

2.1 Objective and Setup

The goal of IFC in ML is to ensure that a machine learning output only depends on a subset of training data that a user has access to. Figure 1 illustrates the setup and how IFC changes training and inference for ML. We assume a setting where the training data set D is partitioned into m different *security domains*, i.e., $D = \{d_1, d_2 \ldots d_m\}$. There are n users ($u_1 \ldots u_n$), each with an *access policy* ($a_1 \ldots a_n$), which defines which subset of security domains out of D are accessible to each user. At inference time, a user (say user u_2) provides an input (i_2) and an access policy (a_2) to the model. Then, the model with IFC capability needs to ensure that the corresponding output (o_2) depends only on the domains from D that are present in the access policy a_2.

2.2 Example Use Cases for IFC in ML

The ability to control information flow from training data to model outputs is important in many use cases where different users can only access different subsets of the training data. Below, we briefly discuss example use cases.

AI Coding Assistant. In order to provide more relevant suggestions, a code completion model for a coding assistant can be trained using code from a company's internal repositories. However, code repositories typically have access control, and individual engineers only have access to a subset of repositories. A code completion model needs to honor the access restrictions and only suggest code based on the repositories that a particular user has access to at inference time. The security domains for code repositories can be delegated based on projects or organizations. In this paper, we study this case by treating a Github repository as a security domain so that it can have its own access permission.

AI for Writing/Summarizing Documents. A language model (LM) can be used to provide text suggestions when writing or summarizing documents with sensitive content, such as company internal memos, project reports, military

documents, etc. The language model can perform better if it can leverage related (sensitive) documents that the user has access to. For instance, when writing a project report, a language model accessing other documents from the same project will provide more tailored suggestions. However, we need to ensure that the model's suggestions do not leak any information from other inaccessible documents. For example, access to company documents may be limited based on projects or organizations, and individual users may have access to a different set of projects or organizations. In this case, the documents from the same project/organization can be put into a separate security domain. We use the Pushshift.io dataset to simulate such use cases.

AI-based Q/A on Access Controlled Materials. The recent advances in large language models (LLMs) showed a potential for use in search or Q/A engines (e.g., ChatGPT, Bing Chat). While these models are only trained on public domain data today, it is likely that the LLM-based search or Q/A engines will also be applied to answer questions based on access controlled data such as pay-walled content (e.g., Wall Street Journal, New York Times, etc), internal corporate documents, etc. In such cases, the LLM may need to incorporate the access controlled data for the best performance. However, in order to prevent unintended leakage of access controlled data, the model should be able to ensure that its output only depends on the subset of the training data that a particular user is allowed to access.

2.3 Extending IFC Definition to ML

We define IFC in ML by extending the notion of non-interference (NI) in the traditional information flow control.

Traditional Non-Interference (NI). Non-Interference [22] is a security policy commonly used in information flow control to limit the influence between security levels. Let D represent the machine state, and let d_L and d_H be the projection of the machine state D to the low sensitivity and high sensitivity parts, respectively. Let $=_L$ be the function that compares the low sensitivity parts of the state, i.e., $D =_L D'$ iff $d_L = d'_L$. Let $(P, D_1) \Downarrow D_2$ be the execution of a program P starting with machine state D_1 and terminating with the machine state D_2. Given this, Non-Interference for a deterministic program P is defined as follows [22]:

$$\begin{aligned}\forall D_1, D'_1 : D_1 =_L D'_1 \wedge \\ (P, D_1) \Downarrow D_2 \wedge \\ (P, D'_1) \Downarrow D'_2 \Rightarrow \\ D_2 =_L D'_2\end{aligned}$$

In other words, a deterministic program P satisfies Non-Interference if, given the same initial low sensitivity machine state, its transformation of the low sensitivity machine state is the same regardless of the high sensitivity machine state.

Non-Interference for Machine Learning. We define non-interference in machine learning below. A generalized definition for probabilistic protection is presented in Section 5.

Definition Let $D = \{d_1 \ ... \ d_m\}$ be a dataset partitioned into m security domains. For a given user u_i, we define the user's *access policy* $a_i \subseteq \{1, \ldots, m\}$, which specifies a set of domains accessible by u_i. For two datasets $D = \{d_1, \ldots, d_m\}$ and $D' = \{d'_1, \ldots, d'_m\}$, let $=_{a_i}$ be the comparison operator such that $D =_{a_i} D'$ iff $d_j = d'_j$ for all $j \in a_i$. Let $\mathcal{M}_D(a_i, \boldsymbol{x}) \Downarrow o$ denote the inference algorithm for a model $\mathcal{M}$ that was trained on dataset D, which performs inference for request $\boldsymbol{x}$ with access policy a_i and the inference result being a distribution o over all possible outputs. We say that $\mathcal{M}$ satisfies Non-Interference (NI) with respect to access policy a_i if for all queries $\boldsymbol{x}$ the following holds:

$$\begin{aligned}\forall D, D' : D =_{a_i} D' \wedge \\ \mathcal{M}_D(a_i, \boldsymbol{x}) \Downarrow o \wedge \\ \mathcal{M}_{D'}(a_i, \boldsymbol{x}) \Downarrow o' \Rightarrow \\ o = o'\end{aligned}$$

This definition prohibits protected data from influencing the output (or their likelihoods, when the output is probabilistic). Our definition is also *termination sensitive*, meaning that the termination behavior (when the output generation will be finished) is not influenced by the protected data as well.

2.4 Parametric and Non-Parametric IFC

The main technical challenge in IFC for ML comes from the difficulty in controlling or tracking the information flow through the trained model parameters. One approach to sidestep this challenge is to only use non-parametric methods to leverage sensitive data: instead of using sensitive data for training model parameters, the data is protected using the traditional access control or IFC mechanisms and only retrieved and incorporated to an ML model at inference time. For example, retrieval augmented generation (RAG) [5, 28, 36, 39] showed that incorporating retrieved data as a part of the input context of a language model is an effective way to complement a parametric language model (LM), especially for knowledge-intensive tasks such as question answering.

Parametric training (fine-tuning) and non-parametric RAG are complementary in their nature and we believe that both will be important in achieving the state-of-the-art AI/ML capabilities going forward. In that sense, we need IFC for ML to be able to handle both parametric training and non-parametric retrieval augmentation. As non-parametric IFC can largely leverage existing access control and IFC techniques, in this paper, we focus on enabling IFC for parametric models.

The following discussion further elaborates why we believe that both parametric and non-parametric IFC will be necessary to fully utilize sensitive data in ML.

Complementary Capabilities. Today, RAG is primarily considered as a way to further improve LMs in addition to fine-tuning rather than replacing fine-tuning. RAG allows

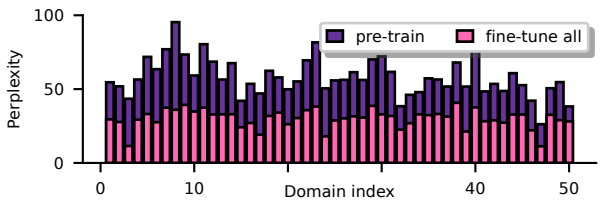

Figure 2: Pre-trained GPT-2 evaluated on 50 datasets from Pushshift.io consistently underperforms fine-tuned GPT-2.

more recent information to be added/updated without retraining, improving attribution and enabling faster adaptation/customization. On the other hand, fine-tuning is generally considered to be necessary for deeper adaptation of LLM behaviors such as changing writing style/tones and adding new domain-specific knowledge, terminologies, etc. Today's RAG approaches also increase the context length of LMs and thus inference costs, especially when knowledge from multiple sources is needed to be assembled [18, 60]. These costs fundamentally limit the amount of new information that can be incorporated at inference time in practice. Intuitively, adding a small amount of information to the context can work well for some tasks such as generating answers to specific questions. Yet, fine-tuning will likely be more effective in learning from a large amount of data, merging knowledge from multiple domains, etc.

Need for Parametric Training in RAG. Studies in RAG found that off-the-shelf parametric models often struggle to leverage additional retrieved information at inference time [54] and parametric fine-tuning is still needed. For more effective RAG models, the encoder model that generates embedding vectors for search and the decoder model that generates outputs need to be trained/fine-tuned [28, 31], making our work still relevant.

Models w/o RAG. While generative models can often benefit from retrieved data at inference time, many ML models will likely remain mostly parametric. For example, it is not clear how retrieval augmentation can be used to allow image classification models to leverage classified images. For such parametric models, we need the parametric IFC capability.

2.5 Comparison with Differential Privacy

Differential Privacy (DP) [16] is another method to ensure privatization of sensitive data. A randomized algorithm is said to be differentially private if it produces similar output regardless of whether the sensitive data was included in the algorithm's database. Unlike IFC which allows users with different access policies to selectively benefit from different subsets of security domains within the protected data, DP limits all users from benefiting from all protected data. Moreover, IFC achieves zero leakage, unlike DP which still leaks data (captured by its privacy parameters, e.g., ε).

Furthermore, DP typically aims to protect individual data samples (i.e., example-level DP), and the privacy protection becomes weaker when a group of samples are correlated and must be protected together [37] (e.g. multiple texts in a security domain). Applying DP to protect a group of data requires group-level DP [17], which amplifies the privacy parameter ε by the size of the group and thus hurts utility proportional to the size of the group. Recent studies on DP-finetuning of GPT-2 [7, 41, 55] have shown noticeable accuracy loss of between 1% and 40%, even with example-level DP, at a moderate privacy parameter ($\varepsilon = 8$). The utility loss will be drastically amplified when a group of data in each security domain must be protected together, as our security domains are large (3K–900K samples per domain in Pushshift dataset).

Nevertheless, we note that DP may be more applicable than IFC in certain scenarios. For example, if there are a very large number of security domains, say one domain per each user for millions or billions of users, user-level DP can be a natural way to guarantee data privacy with moderate utility loss. In comparison, achieving IFC using our approach would require training one adapter per user, which can be prohibitively expensive to scale.

2.6 Limitations of Naive IFC Solutions

Here, we discuss a few simple approaches to leverage sensitive training data with access restrictions in parametric models, and discuss why these coarse-grained approaches available today are unlikely to be sufficient in practice.

Train Only on Public Data. One simple option is to use a model trained only on public data, which intuitively cannot leak any sensitive data. However, models trained only on public data cannot perform specific tasks well compared to fine-tuned models. Figure 2 shows the perplexity (the measure of accuracy; lower is better) of GPT-2 on data from 50 different subreddits (security domains) from Pushshift.io. We see that the model fine-tuned on (potentially sensitive) additional data significantly outperforms the same model trained with only public data.

Fine-tune a Model for Each Access Policy. We can fine-tune a new model for each possible access policy. For m domains, this requires fine-tuning at most 2^m different models. The exponential growth makes this approach impractical unless m is very small.

Fine-tune One Model for Each Security Domain. Another option is to fine-tune one model for each security domain (only train m models), and choose one of the models that a user has access to at run-time. However, our experiment later (Section 4.5) shows that this approach is sub-optimal, and a user with access to multiple domains can significantly improve the model's output quality by using multiple domains at the same time.

2.7 Our Approach: IFC through Modular Architecture

At a high-level, IFC for a parametric model needs the following three components:

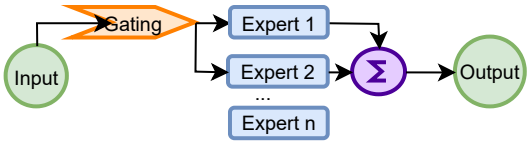

Figure 3: Parametric IFC through modular model architecture. The influence of each security domain is limited to one expert. A *gating function*, at inference time, decides which of the experts should be activated for a given input. The activated experts are aggregated either though ensembling their outputs or aggregating the parameters.

1. **Parameter Isolation.** During training, there must be a way to isolate parameters influenced by different security domains. We refer to these isolated parameters as *experts*.
2. **Secure Gating.** With a large number of security domains, it is infeasible and ineffective to use all accessible domains. At inference, a secure gating function needs to determine which of the accessible domains are relevant to the current input in a way that does not use information from the inaccessible domains. We refer to this process as *gating*.
3. **Secure Expert Aggregation.** Finally, the information from the domains chosen during gating needs to be combined to produce one output. This act of combining information from the different chosen domains can also only use information from accessible domains. We refer to this step as *aggregation*.

To enable more fine-grained parametric IFC, we propose an approach based on a modular model architecture as shown in Figure 3. In this approach, we separately train a different expert with data from each security domain to ensure parametric isolation. Then, at run-time, once we have the user's input and access policy, we use a secure gating algorithm to find the top-k best-suited experts permitted by the access policy. Once we have our top-k experts, we use them in our aggregation scheme to produce one final output for the user. Each of these steps is carefully designed to ensure no information is leaked from domains that are not allowed by the access policy.

While there have been previous studies on modular ML model architectures [27, 30, 44], the previous designs largely investigated modularity in the context of improving inference efficiency. We found that designing a modular architecture for IFC introduces a new set of technical challenges.

Secure Real-time Gating. IFC presents unique challenges to gating that have not been explored before. In traditional modular architectures such as Mixture of Experts (MoE) [44], gating functions used to determine expert relevance are often learned during model training using information from the entire training set. Such learned gating functions cannot enforce isolation of inaccessible experts and cannot be used for IFC. This is because information from training data can leak through which experts are activated and how the experts are aggregated even if only accessible experts are activated at run-time. Moreover, because the access policy is only available at run-time, gating decisions in IFC cannot heavily rely on offline computation and thus need to quickly rank accessible domains at run-time only using information from said accessible domains. In all, we must now construct a real-time gating scheme that is fast, incorporates domain access restrictions, scales to a large number of domains, and maps the user's limited text input to relevant domains. We address this challenge for LMs by developing three different secure real-time gating schemes in Section 3.5.

Secure Expert Aggregation. For high accuracy, the expert aggregation scheme needs to assign different weights to different experts depending on their relevance. For IFC, the expert aggregation needs to be performed efficiently at run-time in a way that prevents the weights from leaking information from inaccessible domains.

Scalability and Modularity. The traditional MoE architecture is only designed for a relatively small number of experts. To allow scalability to a larger number of security domains, we need to carefully design the expert model architecture so that each expert has a relatively small number of parameters. For the same reason, instead of activating all accessible domains, we want our gating function to only activate a small number of the (top-k) most relevant experts. Finally, to efficiently support dynamic changes in security domains, gating decisions and aggregation methods should be able to quickly handle adding or removing security domains without re-training.

The security, modularity, and scalability constraints above significantly limit the information that can be used to make gating/aggregation decisions, the size of each expert, and the number of experts that can be activated (k). It is a significant challenge to achieve high accuracy under this constrained environment. In the following section, we describe our IFC design for LMs and show that our proposed design can significantly improve the accuracy while enforcing non-interference compared to a pre-trained model.

3 IFC for Transformer Language Models

In this section, we describe how to adapt an existing Transformer architecture in language models (LMs) for information flow control (IFC). To ensure non-interference efficiently, we carefully choose an expert model architecture and develop secure gating and aggregation techniques for both cases when the domain of an input is known and unknown.

3.1 Background: Transformer-based LM

This paper focuses on language models which perform the next token prediction—the task of predicting the next most probable *token* for any given sequence of tokens. For language modeling, the accuracy is measured with *perplexity*, an exponentiation of the negative log likelihood of the text. Lower perplexity implies better performance.

The current state-of-the-art language models use Transformers [4, 14, 43, 50, 51, 57, 62, 63]. Figure 4 shows a typical decoder-only Transformer model architecture (GPT-2 [50]). The model takes input texts represented as a sequence of

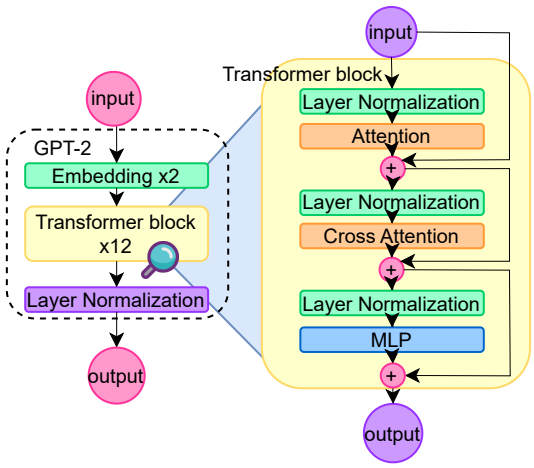

Figure 4: A typical Transformer-based language model (LM) architecture (based on GPT-2).

tokens. These input tokens are passed through embedding layers, followed by Transformer blocks and a normalization layer. Each of the Transformer blocks consist of attention layers and an MLP layer, interspersed with normalization layers.

3.2 Overview of IFC for Parametric LM

Figure 5 shows a high-level overview of our scheme. During **domain-aware training**, we start with a baseline model pre-trained with public data. We fine-tune the pre-trained model with data from each of the m security domains and get m experts $e_1 ... e_m$. Training experts is done by fine-tuning only a subset of the parameters using data from each security domain. These modified parameters of the model constitute the "experts", while the rest of the parameters remain unchanged. The effect of the data from each security domain is limited to parameters within one expert, thus enforcing parameter isolation (Section 2.7). We discuss different expert architecture choices in Section 3.3.

Our **access-policy-aware inference** consists of two main steps: gating and aggregation. The **gating** function selects the top-k most relevant experts the user can access by taking in two (or three) inputs: a) the user u_i's access policy a_i, b) a sequence of text tokens $\boldsymbol{x} = \{\boldsymbol{x_1} ... \boldsymbol{x_T}\}$, and c) an *optional* label l that indicates which of the m domains the input is closest to content-wise. The **aggregation** step uses the selected k experts $\{e_1 \ ... \ e_k\}$ to produce a single high-quality output. We explore two approaches for aggregation: aggregating the expert outputs and aggregating the expert parameters.

Providing the domain label l can be straightforward and useful in many cases. For example, when working on a particular project, other documents from the same project are likely to be the most relevant and may all be in the same security domain. In such cases, we use a gating algorithm called `gate-known`, which utilizes a pre-computed accuracy matrix to determine the top-k experts accessible as per a_i that are most relevant to domain l. When the domain label is not provided, we determine the most relevant domains based on the previous input tokens (`gate-pairwise` and `gate-cluster`). These algorithms sample some tokens from the user's input (*sample text*), convert it to a vector, and find the top-k best matching experts to this sample vector through either a *pairwise* distance comparison or a *clustering* algorithm.

3.3 Expert Model Architecture Choices

There are many potential choices for experts. For resource efficiency, it is better to only fine-tune a small number of parameters. For accuracy, it may be better to train more parameters. Below are the different options we explored:

1. **Fully Fine-tune.** For the best accuracy, we can fine-tune all parameters of separate copies of the model using data from each security domain to create experts.
2. **MLP.** We freeze all layers except for the MLP layers in each Transformer (Encoder/Decoder) layer. Each domain expert only differs in its MLP weights.
3. **First $\frac{N}{2}$ Decoder Layers.** We fine-tune only the first $\frac{N}{2}$ of the N Decoder blocks and freeze the rest.
4. **Last $\frac{N}{2}$ Decoder Layers.** We freeze the first half of the Decoder blocks and fine-tune the rest.
5. **Adapter.** Adapters are blocks consisting of a few layers that are added to a pre-trained Transformer for efficient model fine-tuning [29]. We insert additional adapter blocks and only fine-tune them with the security domain data.

We evaluated these expert architecture options in Section 4 using GPT-2 as our representative model, and chose the adapter as the main option in this study. For this setup, we place an adapter block right before the MLP layer in each of the Transformer blocks and only train the adapters for each domain. While the expert architecture is important for storage overhead and fine-tuning time, the rest of the scheme can work for any expert architecture choice.

3.4 Domain-Aware Training

During training, we take the text data in each of the m security domains in D, and train one expert per security domain (Algorithm 1). Note that the training algorithm that produces an expert e_j only depends on the domain data for that expert, i.e., d_j. This means that the experts are trained independent of each other, and can be added or removed from the final model as needed, allowing us to make our model *modular*.

3.5 Access-Policy-Aware Gating

In order to optimize accuracy and scalability, we only activate a small number (k) of experts that are accessible as per the

Algorithm 1: Training algorithm for IFC.

Input: Training Data $D = \{d_1, d_2 \ ... \ d_m\}$
Output: Trained Experts $e_1 \ ... \ e_m$
(1) **for** $j \leftarrow 1$; $j \leq m$; $j \mathrel{+}= 1$ **do**
(2) $\quad e_j \leftarrow \texttt{train}(d_j)$

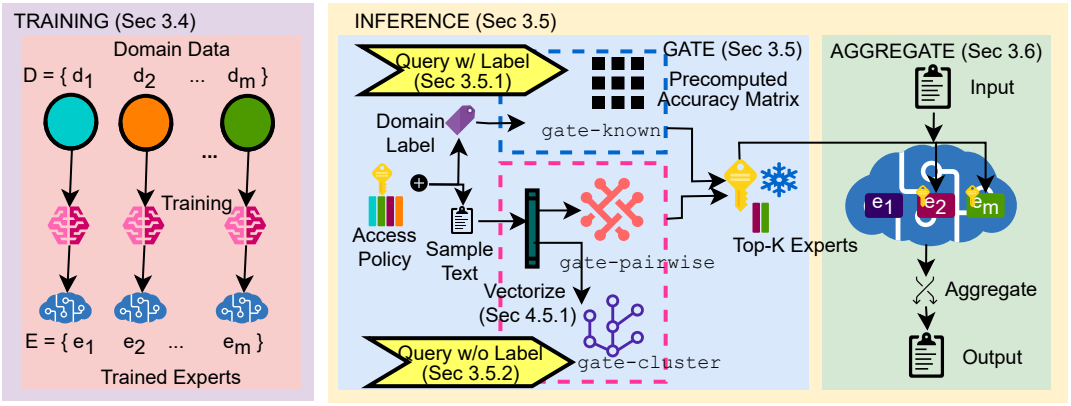

Figure 5: The overview of the proposed Parametric IFC scheme for a Transformer-based language model.

user's access policy a_i, and relevant to the given input $\boldsymbol{x}$. If we use *all* accessible experts, the outputs from irrelevant experts can hurt the accuracy. Also, a large number of activated experts can incur significant resource overhead. Thus, we limit the aggregation to the top-k closest experts.

3.5.1 Known Domain Label

Algorithm 2 (`gate-known`) shows how we choose the top-k experts when the domain label l is given by the user. In the offline phase of the algorithm, we evaluate each of the domain experts (e_1 ... e_m) on a small amount of held out text from each security domain (w_1 ... w_m) to obtain an all-to-all accuracy matrix (M) (Line 1). The rows of M pertain to the security domain of the held out text, and the columns pertain to the experts that is used to evaluate the text. This allows us to see how well each expert performs on text from each domain.

During inference, when the domain label l is provided with the user's access policy a_i, `gate-known` first ensures that l is one of the user's accessible domains[1] (Lines 2-3) and uses l to select the most relevant domains from the accuracy matrix M. The function then uses the access policy a_i as a mask to filter out the inaccessible experts. This step is important to ensure inaccessible experts are removed from the top-k consideration. The final outcome is a list of accessible experts ranked by their performance on domain l (Line 4). We then select the top-k experts from this ordered list.

Note that this gating algorithm only uses information from accessible domains, and the gating decisions do not leak information about inaccessible domains.

3.5.2 Unknown Domain Label

When the domain label l is not provided, we use a part of the user's input (specifically, the first c tokens) as a sample text to estimate top-k experts that are the most relevant. The simplest way to determine relevant experts is to run the sample

[1]To ensure that a user cannot learn any information about an inaccessible domain, an error is returned and the inference is aborted if a user provides the label l for an inaccessible domain.

Algorithm 2: Gating w/ a domain label (`gate-known`).

Input: User input $\boldsymbol{x_1}$ ... $\boldsymbol{x_T}$, access policy a_i, domain label $l \in D$
Output: Model output o_c ... o_T
Hyperparameters: k

```
// Offline Phase
(1) M ← perplexity_matrix({e1...ek}, {w1...wk})
// Online Phase
(2) if not accessible(l) then
(3)     abort;
(4) e1 ... ek ← top_k(gate(ai, l, M))
(5) for t ← 1; t ≤ T; t += 1 do
(6)     ot ← aggregate(xt, e1 ... ek)
```

text through each expert and compare the resulting perplexity. However, this approach is too expensive for a real-time gating function. Instead, we compare the vectorized sample text with the vectorized representation of each domain (Algorithm 3). First, we convert the sample text $\{\boldsymbol{x_t}$ ... $\boldsymbol{x_{t+c-1}}\}$ to a vector representation (Line 2). This vector is passed to the `gate` function, which outputs the top-k experts from the accessible domains a_i. We explore two alternatives of the `gate` function in Line 3, provided by `gate-pairwise` (Algorithm 4) and `gate-cluster` (Algorithm 5). As we will elaborate later, both gating functions are carefully designed to ensure non-interference. Once these experts $\{e_1$ ... $e_k\}$ are determined, the tokens after the sample text, i.e., $\boldsymbol{x_{>t+c}}$, and the selected experts $\{e_1$ ... $e_k\}$ are fed into an `aggregate` function (Section 3.6) to produce an output $o_{>t+c}$ (Lines 4-5). The most relevant k experts are re-evaluated after every r tokens in the user's input, in order to account for the domain shift in the user's inputs over time.

The `vectorize` function (Line 2, Algorithm 3) converts a text to its vector representation. Popular methods to vectorize text include simpler approaches such as Bag of Words [33] (and its variants like TF-IDF and BM25), n-gram vectors [47], and more sophisticated approaches involve encoder models like BERT [14]. While easier and more efficient to imple-

Algorithm 3: Gating w/o domain labels (`gate-unknown`).

Input: User input $x_0 \ldots x_T$, access policy a_i
Output: Model output $o_c \ldots o_T$
Hyperparameters: r, c, k

(1) **for** $t \leftarrow 1$; $t \leq T$; $t \mathrel{+}= r$ **do**
(2) $\quad v' \leftarrow$ `vectorize` $(x_t \ldots x_{t+c-1})$
(3) $\quad e_1 \ldots e_k \leftarrow$ `gate` (v', a_i)
(4) $\quad$ **for** $t' \leftarrow t+c$; $t' \leq t$; $t' \mathrel{+}= 1$ **do**
(5) $\quad\quad o_{t'} \leftarrow$ `aggregate` $(x_{t'}, e_1 \ldots e_k)$

Algorithm 4: Pairwise gating function (`gate-pairwise`).

Input: c tokens from user input $x_t \ldots x_{t+c-1}$, access policy a_i
Output: Top-k experts $e_1 \ldots e_k$
Hyperparameters: k, c

`// Offline Computation`
(1) **for** $j \leftarrow 0$; $j \leq m$; $j \mathrel{+}= 1$ **do**
(2) $\quad v_j \leftarrow$ `vectorize` (d_j)
`// Online Phase`
(3) **def** `gate` (v', a_i)
(4) $\quad \bigcup_{n \in a_i}\{\varphi_n\} \leftarrow$ `pairwise` $(v', \bigcup_{n \in a_i}\{v_n\})$
(5) $\quad \bigcup_{n \in a_i}\{\varphi'_n\} \leftarrow$ `score` $(\bigcup_{n \in a_i}\{\varphi_n\})$
(6) $\quad e_1 \ldots e_k \leftarrow$ `top_k` $(\bigcup_{n \in a_i}\{\varphi'_n\})$

ment, the simpler techniques have many shortcomings [26] (e.g., Word2Vec cannot work with tokens outside of the training vocabulary). Thus, we use pre-trained BERT [14], which is an encoder model that converts each text-token to a 768-dimensional embedding vector. For multiple tokens, we compute an average over all tokens in the text to obtain a single 768-dimensional vector. For the user's sample text, BERT is run at the inference time to obtain its embedding vector. For each security domain, we pre-compute a representative embedding vector offline with BERT using its training data.

The `gate-pairwise` function (Algorithm 4) picks the top-k most relevant experts by comparing the pairwise distance between the vectorized sample text and the representative vector of each accessible domain. First, the representative vector $v = \{v_1, v_2 \ldots v_m\}$ for each domain is calculated offline (Line 1-2). During inference, a pairwise cosine similarity score (φ) between the sample text vector v' and every single domain vector that is accessible to the user $\bigcup_{n \in a_i}\{v_n\}$ is calculated to get a list of similarity scores $\bigcup_{n \in a_i}\{\varphi_n\}$ (Line 4). Note that the similarity scores are not computed with inaccessible domains to prevent information leakage. A higher similarity between v' and any domain vector v_n suggests that the user's text is similar to that particular domain, and the corresponding expert is likely to be useful. We then adjust the resulting cosine similarity rankings of the accessible domains using the `score` function (discussed below) to get a list of adjusted similarity scores ($\bigcup_{n \in a_i}\{\varphi'_n\}$). We select experts with the top-k highest adjusted similarity scores (Line 6).

The `gate-cluster` function (Algorithm 5) is a more efficient alternative than `gate-pairwise` which performs a

Algorithm 5: Cluster gating function (`gate-cluster`).

Input: c tokens from user input $x_t \ldots x_{t+c-1}$, access policy a_i
Output: Top-k experts $e_1 \ldots e_k$
Hyperparameters: k, c, s

`// Offline Computation`
(1) **for** $j \leftarrow 0$; $j \leq m$; $j \mathrel{+}= 1$ **do**
(2) $\quad v_j \leftarrow$ `vectorize` (d_j)
(3) $C_0 \ldots C_s \leftarrow$ `compute_clusters` $(v_1 \ldots v_m)$
`// Online Phase`
(4) **def** `gate` (v', a_i)
(5) $\quad c_1 \ldots c_s \leftarrow$ `cluster_centers` $(C_1 \ldots C_s, a_i)$
(6) $\quad C_i \leftarrow$ `nearest_cluster` $(v', c_1 \ldots c_s, a_i)$
(7) $\quad \bigcup_{n \in C_i \cap a_i}\{\varphi_n\} \leftarrow$ `pairwise` $(v', \bigcup_{n \in C_i \cap a_i}\{v_n\})$
(8) $\quad \bigcup_{n \in C_i \cap a_i}\{\varphi'_n\} \leftarrow$ `score` $(\bigcup_{n \in C_i \cap a_i}\{\varphi_n\})$
(9) $\quad e_1 \ldots e_k \leftarrow$ `top_k` $(\bigcup_{n \in C_i \cap a_i}\{\varphi'_n\})$

linear search over m domains and scales poorly with a large m. Instead, `gate-cluster` introduces a hierarchical search, being more suitable when m is large. During the offline phase, `gate-cluster` clusters the domain vectors into s clusters of similar domains $D = \{C_0 \ldots C_s\}$, where $\bigcap_{j=0}^{s} C_j = \phi$ and $\bigcup_{j=0}^{s} C_j = D$ (Line 3). During inference, the `gate` function first computes the centers $c_1 \ldots c_s$ of each cluster based on the accessible domains (Line 5). These cluster centers are then used to calculate the cosine similarity with the sample text vector v' to find the closest cluster with at least one accessible domain (Line 6). While the clusters themselves are allocated offline, the cluster centers for each of the clusters need to be computed online to ensure that inaccessible domains do not influence the closest cluster selection. Within this closest cluster C_i, we compute the pairwise cosine similarity between v' and each accessible domain vector in the cluster C_i to get a list of scores $\bigcup_{n \in C_i \cap a_i}\{\varphi_n\}$ (Line 7). We again adjust the scores using the `score` function and pick k experts with the highest scores (Line 9).

The `score` function (Algorithm 4, Line 5; Algorithm 5, Line 7) adjusts the similarity scores by considering the quality of each expert. The initial cosine similarity score only captures the semantic similarity between the sample text and the domain's text, but fails to take into account how well the expert corresponding to the domain was trained. Even when the cosine similarity is low (the domain is not close to the sample text), experts pertaining to domains with a large number of samples sometimes provide a better output as they are trained better. The `score` function adjusts the cosine similarity score φ_n by taking into account the amount of training data for each domain (Equation 1). We introduce a term $S_n \in [0,1]$, which represents the fraction of training samples out of all accessible samples that belong to domain n. S_n is close to 1 for domains with more training data. We add S_n multiplied with $\lambda \in [0,1]$ to get the adjusted score, where λ is a hyper-parameter that controls the influence of the domains' training data size. If λ

is close to 1, domains with more samples are preferred.

$$S_n = \frac{\text{count}(d_n)}{\sum_{j=1}^{len(a_i)} \text{count}(d_j)}, \quad \varphi'_n = \text{score}(\varphi_n) = \varphi_n + \lambda S_n \quad (1)$$

3.6 Expert Aggregation

When the top-k experts are selected, they are aggregated to produce a single output (Algorithm 2, Line 6; Algorithm 3, Line 5). We explore two ways of aggregation: ensembling the expert outputs and merging the expert parameters.

The first option is to ***ensemble the outputs*** from the k experts. We first run the user's input at time t ($\boldsymbol{x_t}$) through the selected k experts (e_1 ... e_k), and combine the resulting k outputs ($o_{t,1}$ ... $o_{t,k}$) to give a final output o_t at time t. We employ an approach similar to DeMix [27], which exploits Bayesian probabilities to estimate the likelihood of each of the k experts being a good fit for the input $\boldsymbol{x_t}$ (Equation 2) and uses these likelihoods as weights to aggregate the k outputs (Equation 4). The likelihood, expressed as a posterior probability over domains, can be calculated using Bayes' rule [27]:

$$P(d_t = j|\boldsymbol{x_t}) = \frac{P(\boldsymbol{x_{<t}}|d_t = j) \times P(d_t = j)}{P(\boldsymbol{x_{<t}})} \quad (2)$$

$$= \frac{P(\boldsymbol{x_{<t}}|d_t = j) \times P(d_t = j)}{\sum_{j'=1}^{k} P(\boldsymbol{x_{<t}}|d_t = j') \times P(d_t = j')}. \quad (3)$$

We assume a uniform domain prior (i.e., uniform $P(d_t = j)$) — that is, no one domain is inherently more likely than another. Our experts already output the probability of tokens conditioned on the respective experts ($P(\boldsymbol{x_{<t}}|d_t = j)$). These domain likelihoods are used to aggregate the outputs of each of the k experts to get the final output:

$$o_t = \sum_{j=1}^{k} o_{t,j} \times P(d_t = j|\boldsymbol{x_t}). \quad (4)$$

This method does not require training and uses information only from accessible domains, allowing easy addition/removal of domains while ensuring non-interference.

Another option is to ***merge the parameters*** of the k experts and feed the user's input to this combined expert. This has the advantage of reducing the number of experts that need to be run at inference. The weights that we use for parameter merging are simply a normalized version of the top-k scores returned by our gating algorithms. This parameter aggregation approach is inspired by the recent studies on combining parameters in model training [32, 40, 58]. While the approach is similar, we apply the parameter merging at inference time and show that it can also be used to combine multiple experts. With regards to IFC, since the top-k experts are all accessible according to the user's access policy, merging parameters from these already accessible experts does not lead to any leakage from inaccessible security domains.

4 Evaluation

4.1 Experimental Setup

Baseline NLP Models. We use GPT-2 [50] and OPT [63] as two representative Transformer-based language models to evaluate our approach. Given the architecture-agnostic properties of our approach, we believe that the proposed information flow control framework can also be applied to other state-of-the-art Transformer-based models [14, 43, 51, 62].

Datasets. We use two datasets, the Pushshift.io dataset [3], and Codeparrot's Github-Code dataset [12]. The former is used to train GPT-2, while the latter is used for OPT. Pushshift [3] is an actively maintained collection of all Reddit comments and posts from 2005. We simulate security domains by treating different subreddits as different domains. While we only use public content from Pushshift.io, a similar platform may want to have access control for different groups, so that each user has access to only a subset of groups. The setup is also representative of a general case where the security domain and the content have a correlation (e.g., different projects forming their own security domain). We set the number of domains to $m = 50$ for our experiments with Pushshift, which corresponds to 50 different subreddits. For the Pushshift experiments, we use all comments from the 50 subreddits over the time-span of August 2021 to August 2022. The domain sizes range from $\approx$ 19k tokens in the smallest domain to $\approx$ 500M tokens in the largest.

Our second dataset is Codeparrot's Github-Code dataset [12]. This dataset is a collection of open-source code from different repositories spanning various licenses on GitHub. We use data from MIT licensed repositories from 5 different programming languages: Python, JavaScript, C, C++ and Java. We take the largest MIT licensed repositories from these languages to get a total of 79 domains, where each security domain spans a single code repository. More details of the datasets are in Appendix A.

Baseline Schemes. We use two baselines to compare our algorithms with: a) pre-trained GPT-2/OPT and b) GPT-2/OPT fine-tuned on the data from all domains combined together. The first ensures non-interference, as none of the inaccessible domains' data is used for training and thus cannot be leaked during inference. The second represents an insecure baseline, which provides the best case accuracy that can be achieved using all access-controlled data for fine-tuning.

Figure 2 shows the perplexity when the test sets from each of the domains are evaluated for the baselines a) and b) for the Pushshift dataset. We see that the pre-trained model does not perform well, showing the average perplexity over all domains of 55.5. The average perplexity is significantly improved to 29.8 for the model fine-tuned on all 50 domains. This suggests that using in-domain data when possible can significantly improve model accuracy. For all experiments that follow, improvement is shown as the normalized perplexity over the pre-trained model.

Param	Description
m	Number of security domains
k	Number of experts to activate
r	Number of tokens to process after which we re-evaluate top-k experts
c	Number of tokens in sample text
s	Number of clusters used for `gate-cluster`
λ	Factor by which we penalize the experts of small domains

Table 1: Description of the hyper-parameters.

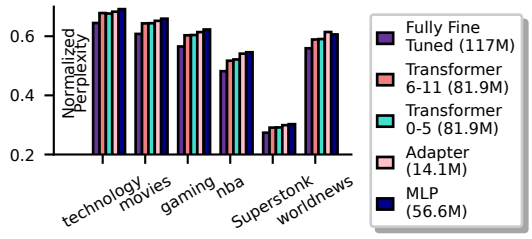

Figure 6: Accuracy of different expert model architectures (Section 3.3). The number of trainable parameters is shown in the legend. The y-axis shows the perplexity normalized with respect to pre-trained only model. A lower value represents a bigger drop in perplexity, and thus a larger improvement.

Parametric IFC schemes and hyper-parameters. We evaluate the three proposed algorithms for gating: `gate-known`, `gate-pairwise`, and `gate-cluster` together with output ensembling as our aggregation scheme (unless noted otherwise). For `gate-known`, we use the subreddit group/code-repository that the query was originally from as the user-provided domain label l. Table 1 summarizes the hyper-parameters for our IFC schemes. We use the following as the default values: $k = 3$, $r = 500$k, $c = 10$k, $s = 10$, and $\lambda = 0.4$. An ablation study over these hyper-parameters is provided in Appendix B

4.2 Impact of Expert Architecture

To evaluate different expert architecture choices (discussed in Section 3.3), we trained all 5 architectures with GPT-2 on the 5 largest domains in the Pushshift dataset, and evaluated the performance of the respective experts on the validation sets of said domains. Figure 6 shows the results. The y-axis represents the normalized perplexity with respect to the pretrain-only model. A lower value represents a higher drop in perplexity and therefore a larger improvement in accuracy.

We notice that all five architecture options lead to a 30% to 70% perplexity improvement depending on the domain, with the fully fine-tuned expert outperforming other architectures, albeit by a maximum margin of 0.1%. However, as seen in the legend, the fully fine-tuned expert also uses considerably more trainable parameters than the other architectures. In contrast, the adapter uses the smallest number of trainable parameters, but still performs quite well (only 0.1% worse in the worst case scenario). Given this, for the following experiments, we use adapters as our expert architecture.

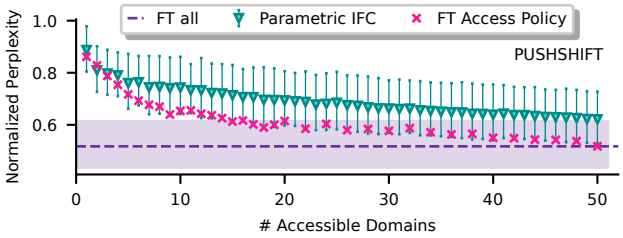

Figure 7: The normalized perplexity as a function of the number of accessible domains for our parametric IFC scheme. Perplexity is normalized to the pre-trained model, and each point and error bar represents the geometric mean/standard deviation over all domains $\times$ gating algorithms $\times$ access policies. "FT Access Policy" represents perplexities evaluated for a random subset of access policies where the model was fully fined tuned on all *accessible data* for each policy. The horizontal line and shaded regions represent the geometric mean/standard deviation of the insecure, fully fine-tuned model.

4.3 Model Accuracy

To understand the accuracy impact of the IFC scheme, we evaluate the perplexity of the language model using the test sets of all 50 domains in the Pushshift dataset and 79 domains in the Codeparrot dataset under a large number of access policies. For this study, we randomly selected 500 access policies from all 2^{50} possible combinations for the Pushshift dataset, and 790 out of 2^{79} for the Codeparrot dataset. The policies cover all possible number of accessible domains (1 to 50 and 1 to 79 respectively). There are about 10 policies for a given number of accessible domains. Since the 79 domains in Codeparrot span 5 different programming languages, we depict our results for each programming language individually.

Each of the graphs in Figures 7, 8, 9, 10, and 11 shows how the normalized perplexity varies as more domains become accessible for the Pushshift dataset and repositories in the CodeParrot dataset. The y-axis shows the perplexity normalized to the pre-train only model (lower is better). We divide all the evaluated access policies into bins indicating the number of accessible domains. Each point in the figures shows the geometric mean over multiple access policies and multiple domains for a given number of accessible domains. We also show the geometric mean of the normalized perplexity of the fully fine-tuned (insecure) model, which uses the training data from all domains. The shaded regions and error bars represent one geometric standard deviation.

Impact of the Number of Accessible Domains. Figures 7 and 8 show that over all possible gating schemes and access policies, the accuracy with IFC improves as the number of accessible domains increases. Even with just one accessible domain in the Pushshift dataset (Figure 7), the perplexity is reduced by 11.5% on average compared to the model that is pre-trained on public data only. When all domains are accessible, the perplexity is reduced by about 38%, close to the ideal 48% improvement of the fully fine-tuned model. For

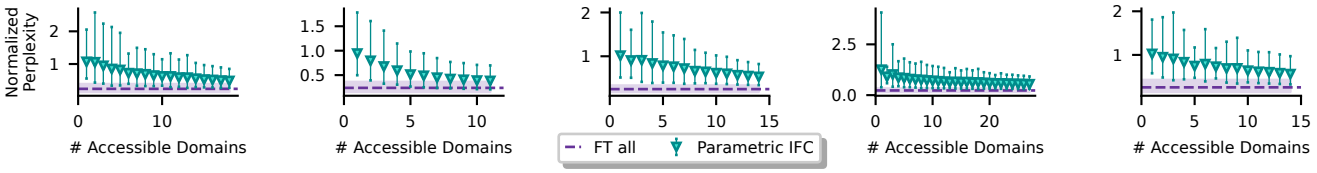

Figure 8: The normalized perplexity as a function of the number of accessible domains for each programming language in Codeparrot.

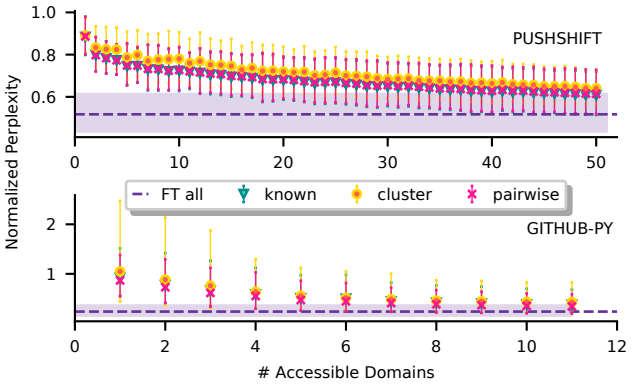

Figure 9: Impact of different gating algorithms.

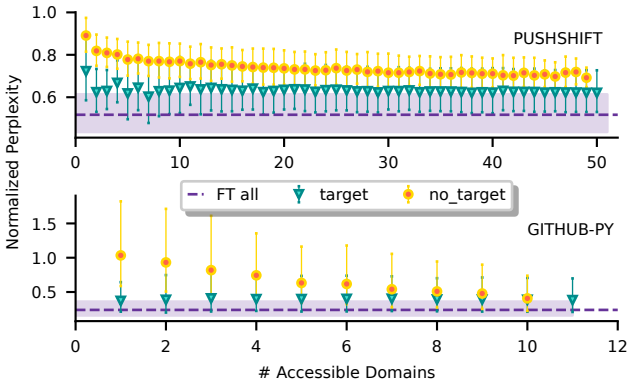

Figure 10: Effect of including vs. excluding target domain.

the Codeparrot dataset (Figure 8), we see an improvement of $44-62\%$ when all domains are accessible, with the fully fine-tuned model at roughly 75% improvement for all coding languages. Note again that full fine-tuning is an insecure baseline that leaks data from inaccessible domains.

Figures 7 and 8 show higher perplexities when only few domains are accessible. The low accuracy is because the accessible experts are less likely to be useful for a given input when there are only a few, not because our approach is ineffective for a small number of domains. To illustrate this, we fine-tuned a separate model for each access policy (for 50 out of the 500 policies in Figure 7). We see the same trend of lower accuracy for fewer accessible domains, with accuracy improving as more domains become accessible.

Impact of Gating Algorithm. Figure 9 separates the results from Figure 7 by the gating algorithm used. This result shows that all gating schemes are effective at selecting relevant experts. `gate-known`, which has extra knowledge of the domain label, performs the best as expected. Also, `gate-pairwise` performs better than `gate-cluster`; however, the differences are relatively small. The average difference is 3% and 9% between the two for both the Pushshift dataset and the Python subset of the Codeparrot dataset respectively.

Including vs. Excluding Target Domain. We additionally evaluate settings when the security domain that is the most relevant to the user input (i.e., target domain) is *inaccessible*. We do so by excluding the subreddit/repository the input query was selected from. This simulates the case where the user queries a new domain that the model is not trained on yet. Figure 10 demonstrates the differences in the two cases where the target domain is accessible or inaccessible.

When the number of accessible domains are small, the gap between the two cases (target domain included vs. excluded) is large. This is because when the target domain is excluded, the model cannot find an expert that directly matches the user query's domain. However, the gap decreases as more domains become accessible, showing the proposed scheme's ability to aggregate less related experts to improve the output when the most relevant domain is unavailable. Interestingly, the maximum improvement ($\approx 40\%$ and $\approx 63\%$ for Pushshift and Python-Codeparrot, respectively) is only slightly lower (by 8% and 4% for Pushshift and Python-Codeparrot) when the target domain is excluded compared to when the target domain could be accessible. This shows that when enough experts are accessible, many non-target experts can almost fully compensate for the lack of the target expert.

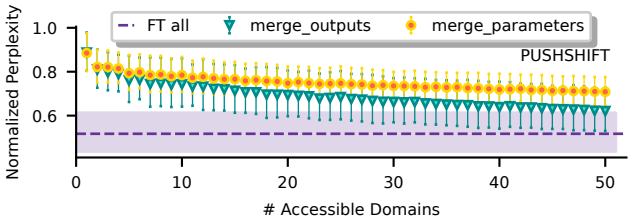

Figure 11: The accuracy comparison between the two expert aggregation methods: output ensembling and parameter merging (GPT-2 for the Pushshift dataset).

Output vs. Parameter Aggregation. The results so far show that output ensembling works well as the expert aggregation scheme. In order to understand the potential to avoid running multiple experts, we also tested the parameter merging approach for GPT-2 with the Pushshift dataset. Figure 11 compares the normalized perplexity of output ensembling and parameter merging. Here we see that the maximum improve-

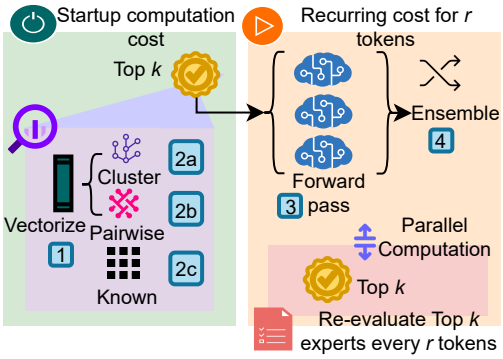

Figure 12: A breakdown of the inference run-time when evaluating a sequence of input tokens. The startup part runs only once, while the recurring part runs for every sequence of r tokens.

ment from output ensembling is 38%, whereas that from parameter merging is only 29%. Thus, while parameter merging can also improve perplexity over the pre-train only baseline and may be used as an efficient aggregation option, the result suggests that output ensembling is more effective, especially when a large number of domains are accessible. We leave in-depth studies on parameter merging to future work.

4.4 Performance and Resource Usage

Use Case Scenarios. The run-time of our scheme depends on the use case. Generative use cases can be roughly divided into two categories: single token generation (e.g., next word prediction) and batch token generation (e.g., document paraphrasing, question/answering, summarization, etc.).

Run-time Overhead. We show the flow of both use cases in Figure 12 (here, we only evaluate output aggregation). In both cases, the run-time cost can be divided into two parts — a startup cost and a recurring cost. The startup cost involves picking the initial top-k experts for the first batch of the user provided tokens. The startup cost has to be incurred before we can run our model to provide predictions. The recurring cost involves evaluating input text tokens with the top-k experts and aggregating the outputs. This process is repeated as long as the user keeps providing input. As discussed in Section 3, we re-evaluate the top-k experts after every r tokens to handle the changing nature of text . The re-evaluation can be done in parallel with the model execution for the current sequence of tokens and does not add additional latency.

Forward Pass. Table 2 shows the breakdown of the run-time and memory usage for different model sizes and use cases. The result suggests that the largest contribution to the overall latency comes from the forward pass on the model. It is therefore important that in the case of output aggregation, we run the forward pass on each of the k experts in parallel to reduce the latency. This issue would not be faced in parameter aggregation as the top-k experts would be merged into one, resulting in a single forward pass. Both vectorizing and aggregation algorithms have comparatively small latencies.

Gating Algorithms. The table also shows the performance comparison between `gate-cluster` and `gate-pairwise`. As expected, the hierarchical search with clustering (`gate-cluster`) is faster than the pairwise search (`gate-pairwise`) for the same number of domains (m). However, the run-time overhead of both gating algorithms is small compared to the forward pass latency. For security domains up to tens of thousands, `gate-pairwise` can be used with no noticeable impact on the end-to-end latency. For a very large number of security domains, `gate-cluster` provides a more scalable solution.

For `gate-cluster`, the table also shows that the number of clusters (s) and the number of domains (m) need to be balanced for low latency. `gate-cluster` shows poor performance when the number of clusters is either too large or small because it performs tiered sorting; first sorting to find the best cluster, then sorting to find the top-k experts within the cluster. With too many clusters, the search for the best cluster is slow. When there are only a small number of very large clusters, the search within a cluster takes long.

$$\text{top}(k) = \text{gate}(m) + \text{vectorize}(c)$$
$$\text{time} = \text{top}(k) + \max\left\{\begin{array}{c}(\text{forward-pass}() + \text{aggregate}()) \times r \\ \text{top}(k)\end{array}\right\} \times \frac{n}{r} \quad (5)$$

End-to-End Performance. Given the run-time of each component in Table 2, the end-to-end latency can be calculated as shown in Equation 5. Table 3 shows the end-to-end latency of `gate-pairwise` with GPT-2 (large) model for three different use cases that generate a different number of tokens: next-word prediction (1 token), next-phrase prediction (10 tokens), and document paraphrasing (500 tokens). We show the performance of `gate-pairwise` as it represents the slowest gating algorithm. The average latency is obtained by generating 1,000 tokens for each task for a large number of security domains (10,000). The average memory usage per GPU is shown, since the memory capacity of each GPU is often the limiting factor in running a large language model. The results show that the overall overhead of the proposed parametric IFC scheme is reasonable even for a large number of security domains; the worst-case latency overhead is only 1.9%, and the worst-case memory usage overhead is 13%.

4.5 Ablation Study: Activated Experts

Here, we study how sensitive our scheme is to the number of activated experts. A study of some of the other parameters in Table 1 is provided in Appendix B. In the following experiments, we run our schemes with 150 different access policies on the validation sets of all 50 domains of the Pushshift dataset.

Figure 13 shows how the number of optimal experts (k) changes with the number of accessible domains for ≈ 150 access policies. The bottom graph in Figure 13 demonstrates the trend only for access policies where the target domain is not accessible. In the top graph, the result indicates that using more experts (larger k) is beneficial when only a very small

Component / Complexity	Variable	Runtime (s) / Memory (MiB)				
3 Forward Pass O(n)	Model Size (1k Tokens)	Small 7.45 / 612	Medium 13.8 / 1635	Large 21.1 / 3175	XL 27.5 / 6272	- -
	Num Tokens (GPT-2 Large)	1 0.166 / 3618	10 0.354 / 3627	100 2.19 / 3251	500 10.4 / 3213	1k 21.1 / 3175
1 Vectorize O(n)	Context Size	<512 7.87E-03 / 1206	1024 1.57E-02 / 2412	2048 3.13E-02 / 2412	5120 7.82E-02 / 2412	10240 1.56E-01 / 2412
4 Output Aggregation O($n(2k+1)$)	Num Tokens (3 Experts)	1 2.37E-04 / 260	5 3.13E-04 / 263	512 6.58E-03 / 554	1024 1.31E-02 / 849	- -
	Num Experts (1024 Tokens)	2 9.73E-03 / 651	3 1.31E-02 / 849	4 1.64E-02 / 1045	5 1.97E-02 / 1241	- -
2b `gate-pairwise` O($m*\log(m)$)	Num Domains	100 6.27E-03 / 2.40	1k 1.90E-02 / 12.9	10k 1.62E-01 / 94.0	100k 1.72 / 940	1M 17.0 / 9375
2a `gate-cluster` O($s*\log(s)+s+\frac{m}{s}*\log(\frac{m}{s})$)	Num Domains (10 Clusters)	100 1.24E-03 / 2.17	1k 6.43E-03 / 11.6	10k 3.16E-02 / 99.5	100k 3.06E-01 / 962	1M 3.10 / 9561
	Num Clusters (1M Domains)	10 1.85 / 9610	100 1.72E-01 / 9162	1k 1.45E-01 / 9349	10k 1.78 / 9674	100k 22.8 / 9803

Table 2: The run-time and memory usage of each component in our scheme with varying parameter values. We change one parameter at a time while keeping the other parameters constant. The constant parameter is shown inside a parenthesis. The theoretical complexity is shown in the first column with n referring to the number of tokens being evaluated. For descriptions of the other variables, refer to Table 1.

Use Case	Latency (s) / Memory (MiB)		
	Our Case	Baseline	Overhead
Next Word Prediction (1)	0.167 / 4051	0.166 / 3618	1.006 / 1.12
Next Phrase Prediction (10)	0.358 / 4060	0.354 / 3627	1.011 / 1.12
Document Paraphrasing (500)	10.6 / 3646	10.4 / 3213	1.019 / 1.13

Table 3: The average latency and memory usage to generate 1, 10, or 500 tokens. The average latency is computed by generating 1k tokens. The average memory usage is shown for one GPU (our scheme uses 3 GPUs in parallel for $k = 3$). The experiments use GPT-2 Large and `gate-pairwise` with the following parameters: $m = 10{,}000$, $k = 3$, $r = 200$, and $c = 100$.

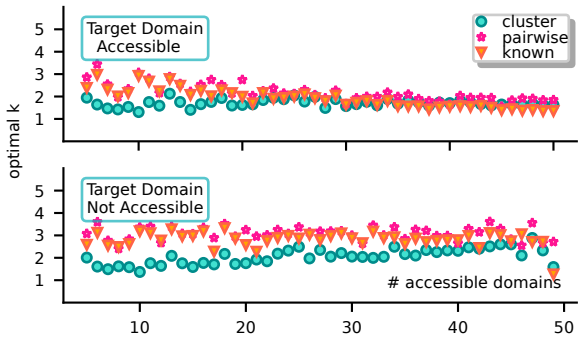

Figure 13: The optimal k value as a function of the number of accessible domains for 150 access policies (top graph). Each data point is the geometric mean over 3×50 (access policy, domain) combinations. The bottom graph shows a sub-sample of the 150 access policies where the test domain is inaccessible.

number of domains are accessible. When only a few domains are accessible, it is unlikely that any of the accessible domains are directly related to the text being evaluated, and hence it is useful to have multiple relevant experts. On the other hand, as more domains become accessible, it is more likely that one of the accessible experts is trained with the data close to the input text, and can already provide high accuracy without other experts. Finally, in the bottom graph, when the input's domain needs to be estimated or is not part of the accessible experts, then $2-4$ experts are needed for the best accuracy. In particular, this scenario benefits from more experts overall—which is expected since no single expert is "best" for the test domain.

4.6 Limitations

While our approach provides strict security guarantees, there are a few limitations. First, frequent and unpredictable input domain shifts from the user can lead to sub-optimal gating (and lower accuracy) in our approach when the input domain label is not provided. Second, output ensembling uses k-times as many resources, each to run the k experts. While this may be solved by parameter merging, our experiments show that parameter merging does not perform as well as output ensembling. Future work is needed to address these limitations.

5 Future Work: Quantitative IFC

The strict non-interference that we use in this paper can be generalized to allow a limited amount of information leakage from inaccessible training data to a model output. Doing so can improve inference accuracy for queries that are out-of-domain for a given access policy. We generalize the definition of non-interference to ε-non-interference (ε-NI) below, which limits information leakage from inaccessible domains in $D - a_i$ to $\varepsilon > 0$ in a similar manner to differential privacy [17].

ε-Non-Interference. Let the dataset D, access policy a_i and

relation $=_{a_i}$ be as defined in Section 2.3. An inference algorithm $\mathcal{M}$ satisfies ε-Non-Interference (ε-NI) with respect to access policy a_i if for all queries $\boldsymbol{x}$ and all output sets O the following holds:

$$\begin{aligned}\forall D, D' : D =_{a_i} D' \wedge \\ \mathcal{M}_{\mathcal{D}}(a_i, \boldsymbol{x}) \Downarrow o \wedge \\ \mathcal{M}'_{\mathcal{D}}(a_i, \boldsymbol{x}) \Downarrow o' \Rightarrow \\ e^{-\varepsilon} \leq \frac{P(o \in O)}{P(o' \in O)} \leq e^{\varepsilon}\end{aligned}$$

Our definition of ε-NI is closely related to that of private prediction [15]. However, one key difference is that the notion of adjacency is not with respect to single training examples, but of entire sets of domains. For instance, D is adjacent to all datasets D' (i.e., $D =_{a_i} D'$) where data from the accessible domains $j : j \in a_i$ are the same. The notion of adjacency used in subsample-and-aggregate style protocols such as PATE [49] and SubMix [20] can be viewed as a special case of our definition, restricted to singleton inaccessible domains.

In general, ε-NI offers more flexibility than differential privacy due to the fact that the access policy only considers predetermined subsets of data (i.e., domains) that may be known ahead of time. It may be possible to design specialized inference mechanisms that satisfy ε-NI while providing high utility. We leave the exploration and design of such mechanisms for future work.

6 Related Work

Mixture of Experts. Mixture-of-expert (MoE) language models have been studied extensively, especially in the context of efficient model scaling. These models also tend to employ gating and ensembling, however their methods do not enforce the strict isolation that is needed for Parametric IFC. Chen et al. [11] propose to optimize multi-task learning through co-operation and specialization between different modular experts in an MoE setting. Tang et al. [56] study the significance of clustering as a pre-processing step to aid routing inputs to specific experts. Work has also been done in developing MoE schemes with a large number of experts [38, 53], but using learned routing. There have also been efforts in controlled generation [13, 35, 42]—i.e., controlling various attributes (such as sentiment) of the generated text, as opposed to blind generation that most LLMs support today.

Retrieval Augmented Generation There have been several prior works exploring retrieval augmented generation, especially in the case of knowledge intensive tasks like question answering [5, 28, 36, 39]. However, IFC in ML is a new area of research with very limited prior literature. There has been concurrent work in retrieval-based IFC [59], although to the best of our knowledge, we are still the first to define and propose IFC for parametric models, which we believe is a critical missing component in enabling IFC for full ML models.

Machine Unlearning. Another related area in ML is machine unlearning, which seeks to remove the traces of certain data from a trained model. One approach is to apply a model update that removes the influence of the sample to be unlearned [8, 19, 23, 52]. Another solution uses a sharding+ensembling based mechanism for unlearning [6]. While related, machine unlearning is different from information flow control; machine unlearning aims to handle infrequent removal of an arbitrary subset of training data whereas information flow control aims to control the influence of training data for each query using security domains defined at training time. When coarse-grained unlearning is acceptable, the modular architecture that we propose can also be useful for unlearning as it supports adding or removing security domains after training.

Federated Learning: Federated Learning (FL) [45] trains a model with data disaggregated across multiple parties. In FL, each party trains a model locally using its private data and sends it to an aggregator, which aggregates the model to produce a generalized model. While FL eliminates the need to collect raw data at a centralized location during training, it still produces a single model that contains information from all the training data [34, 46], requiring further protection if the information leakage must be limited [46, 61, 64]. It would be interesting future work to complement FL with IFC by using FL to train experts for individual security domains. Such a hybrid design has the potential to provide unique privacy-enhancing properties both during the training of experts (through FL) and inference (through IFC).

Differential Privacy: Differential Privacy (DP) can be applied to ML training [1] and inference [15] to prevent training data from leaking through the trained model [2, 24, 25]. In particular, recent works adopted differentially private training methods [7, 41, 65] and inference methods [20] for large language models to protect training data. As discussed in Section 2.5, DP training provides an orthogonal protection to IFC, and the two are not directly comparable.

7 Conclusion

In this work, we present the concept of Information Flow Control (IFC) in machine learning, including a mathematical formulation of the problem. We then propose a method to provide IFC for parametric ML models and show how the IFC capability can be supported through modest modifications for a Transformer-based language model. The evaluation results based on the datasets from Pushshift.io and Codeparrot show that the proposed parametric IFC architecture can enable strong control of information flow from training data to model outputs with low overhead.

A Dataset

Figures 14 and 15 show a relationship dendogram of the Codeparrot and Pushshift domains, showing how closely related different domains are. The color coding indicates the clusters that we use for `gate-cluster`, implying that our clustering algorithm naturally clusters closely related domains.

B Ablation Study (cont'd)

B.1 Sample Text Length

Figure 16 shows the number of tokens in the sample text that is needed to correctly identify each of the 50 domains in the Pushshift dataset. The result shows that a fair number of domains can be identified correctly with as few as 128 tokens. However, there are a few domains that need as many as 8k tokens to be identified, indicating that there are multiple

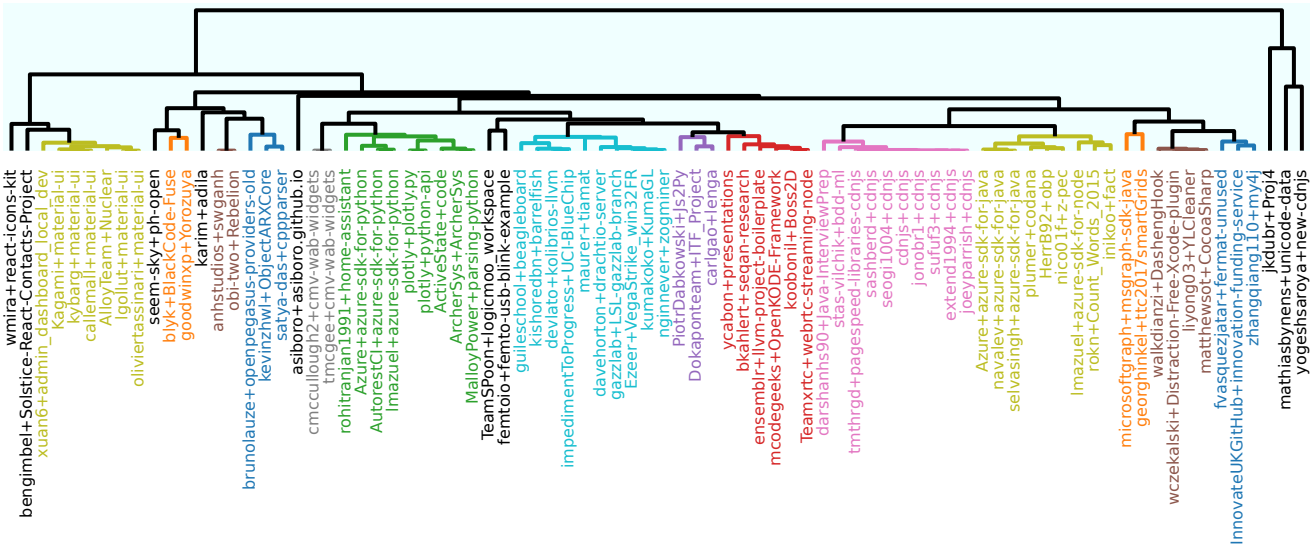

Figure 14: A dendogram of the Codeparrot dataset representing how closely related each of the security domains are to each other. Furthermore, the color codes represent the clusters that these domains are divided into for `gate-cluster`.

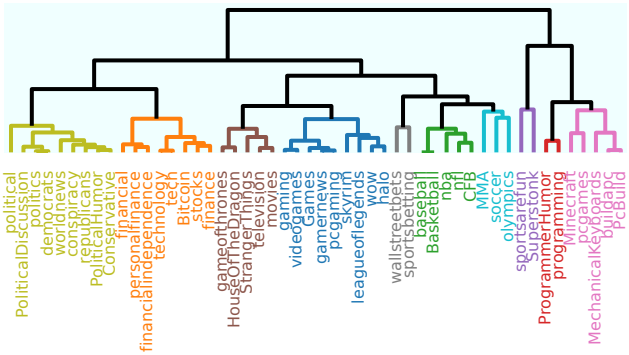

Figure 15: A dendogram representing how closely related each of the 50 domains from our Pushshift dataset are to each other. Furthermore, the color codes represent the clusters that these domains are divided into for `gate-cluster`.

domains that are quite similar. It is also interesting to note that there is no clear correlation between the number of tokens needed to identify a domain and the size of the domain.

B.2 All Accessible Experts vs Top-K

We evaluate two naive schemes of turning on all accessible experts and compare it with our scheme in Figure 17. Here, we assume that all 50 experts in the Pushshift dataset are accessible, and thus ensemble all 50 experts to evaluate each of the test datasets. We see that giving equal weights to all 50 experts performs the worst. Intelligently weighing all 50 experts based on their relevance to their test dataset performs better, however, the best performance comes from activating just the top-K out of all 50 experts and weighing the K experts based on their relevance, which is the technique employed in our IFC framework.

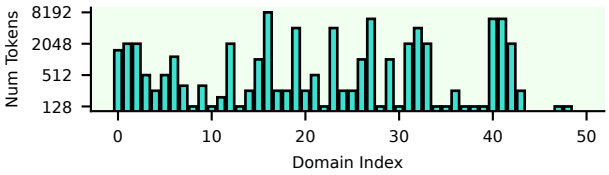

Figure 16: The minimum number of tokens needed to correctly identify each of the 50 domains in the Pushshift dataset. Domains are sorted from largest to smallest.

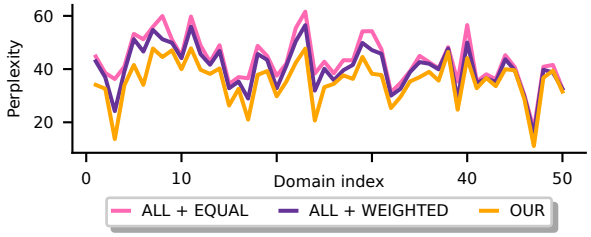

Figure 17: Evaluating all 50 Pushshift domains with our top-k scheme and comparing it to two naive algorithm of turning on all 50 experts with a) equal weighting (ALL + EQUAL), b) with our weighing scheme (ALL + WEIGHTED). We see that choosing only the top-K experts and weighing them intelligently (OUR) performs superior to both.

POPSTAR: Lightweight Threshold Reporting with Reduced Leakage

Abstract

This paper proposes POPSTAR, a new lightweight protocol for the private computation of *heavy hitters*, also known as a private threshold reporting system. In such a protocol, the users provide input *measurements*, and a report server learns which measurements appear more than a pre-specified threshold. POPSTAR follows the same architecture as STAR (Davidson et al., CCS 2022) by relying on a helper randomness server in addition to a main server computing the aggregate heavy hitter statistics. While STAR is extremely lightweight, it leaks a substantial amount of information, consisting of an entire histogram of the provided measurements (but only reveals the actual measurements that appear beyond the threshold). POPSTAR shows that this leakage can be reduced at a modest cost ($\sim 7\times$ longer aggregation time). Our leakage is closer to that of Poplar (Boneh et al., S&P 2021), which relies however on distributed point functions and a different model which requires interactions of two non-colluding servers to compute the heavy hitters.

1 Introduction

Telemetry is essential for assessing the proper functioning of applications and operating systems. For example, a vendor would like to record which events lead to a crash to mitigate potential bugs. The desire to minimize the amount of collected information in this process has led to the emergence of *private telemetry* solutions to compute simple statistics $M(s_1, s_2, \ldots)$ of the users *measurements* $\{s_i\}$, such as their *sum* $\sum s_i$ or their *heavy hitters*, i.e., the set of measurements which appear more than a pre-defined threshold t times. In these systems, we expect the provider to only learn $M(s_1, s_2, \ldots)$, whereas the users learn nothing. While this is a special case of multi-party computation (MPC), rather than using generic off-the-shelf solutions, we aim for lightweight solutions that require no interaction among the users, while tolerating some amount of leakage. This work will propose a new approach for the private computation of heavy hitters. Prior to introducing our contribution, however, we start with some background.

Two-server aggregation. Single-server solutions have primarily emerged in the context of Federated Machine Learning [9, 12, 26, 27]. They require multiple rounds of interaction, and consequently need to be robust to client dropouts. In contrast, a number of lightweight telemetry systems like Prio [17] (for sums) and Poplar [13] (for heavy hitters) instead rely on *two non-colluding* servers. Clients only send a single message to each server. Such systems are the subject of an IETF standardization [21], have been generalized [19], and have seen real-world deployment. Crucially, however, the recipient of the aggregation results (e.g., a browser vendor) needs to enlist an external entity trusted not to be colluding, willing to tolerate the same storage cost, and interact during the aggregation protocol. Needless to say, this can be challenging and expensive, as confirmed by the recent deployment [4] of Prio as part of Google/Apple's exposure notification platform (GAEN). Even if a third party specializes in acting as the second server for a number of services, its workload would scale with the number of services supported, and would need to *interact* every time a service recovers the output statistics.

An alternative model is offered by STAR [18], a system for the private computation of heavy hitters which in turn extends earlier telemetry systems based on anonymous tokens [22]. Here, servers operate *independently*. The first server, which we refer to as the *randomness server*, merely implements an oblivious pseudorandom function (OPRF). In contrast, the provider runs a *report server* which obtains reports (computed by the clients with help of the randomness server), and recovers the heavy hitters without interacting with the randomness server. Due to the lack of coordination, the randomness server is now more likely to be implemented by a third-party service. The problem with STAR, however, is that its leakage is substantial–in fact, an anonymized version of the entire frequency histogram for the inputs $\{s_i\}$ is revealed, but only the actual measurements appearing beyond a certain threshold are revealed.

In this paper, we ask the following question: *Can we reduce the leakage of STAR while preserving its architecture and without significantly impacting its efficiency?*

Our contributions. We present a new threshold reporting system, POPSTAR, to compute heavy hitters which increases privacy in the STAR system at a moderate cost. Our system, not unlike STAR and Poplar, will still leak information. For a truly passive corrupted report server, our leakage is similar to that of Poplar when reporting totally *random* measurements, without the need of the expensive interactions between two non-colluding servers. We also show the effect of active attacks to be limited.

Our randomness server remains relatively simple (although not as simple as that of STAR), and our report server is roughly seven times as slow as that of STAR under suitable parameter choices. We note that our randomness server is computationally ($\sim 70\times$) heavier than our report server, however the main benefit is its simplicity and that of being independent. We also discuss in Section 8.3 potential optimizations to speed up the randomness server.

We give a full security analysis of our system: we provide a functionality that captures its leakage precisely, and prove our protocol to implement it. We also give an empirical analysis of the leakage and propose a heuristic mechanism to provide differential privacy. Finally, we benchmark an implementation of the components of our system.

2 Overview of POPSTAR

Overview of STAR. We start with an overview of STAR [18] before introducing the key ideas behind POPSTAR. For starters, STAR's randomness server implements an *oblivious PRF* (OPRF), used to associate with every potential *measurement* $s \in \{0,1\}^*$ a randomly chosen degree t *polynomial* $p_s(X) \in \mathbb{F}[X]$ over a finite field $\mathbb{F}$. In particular, each client querying s to the randomness server will learn the *same* polynomial $p_s(X)$, whereas the randomness server learns nothing about either of s or the polynomial obtained by the client within this interaction.

A client's report for a measurement s has the form

$$\mathsf{rep} = [r, p_s(r), \mathsf{Enc}(p_s(0), s)] \ ,$$

where Enc here denotes the encryption procedure of a symmetric encryption scheme, $r \in \mathbb{F}$ is uniformly chosen, and $p_s(X)$ is the polynomial associated with s previously obtained from the randomness server. If the report server then obtains $t+1$ reports for the same measurement s, associated with distinct r values (which is the case with overwhelming probability), the value $p_s(0)$ can be reconstructed via simple interpolation, and the value s can be recovered via decryption from any of the reports.[1] A client, when ready, sends the report directly to the report server (or, as we explain below, to an intermediate mixing server first to eliminate the origin and timing information of the report).

[1] It is often useful to additionally encrypt application-dependent metadata, along with s, but we omit this for the sake of brevity.

The problem is that the report server now accumulates reports for potentially different measurements, but cannot recognize which reports are associated with the same measurement. For this reason, STAR includes a *tag* $\mathsf{tag}(s)$ in the report as well—such a tag is also computed from an independent OPRF evaluation with the randomness server, and crucially, tags are deterministic functions of s and unlikely to collide. With overwhelming probability, any $t+1$ reports with the same tag can be used to reconstruct $p_s(0)$ efficiently via interpolation, and then decrypt the associated ciphertexts.

However, tags add unwanted leakage, as the server can now build histograms *for the tags*, and while the associated measurement s is only revealed for tags appearing more than t times, the histogram information associated with unrevealed inputs is important information we ideally want to hide.

POPSTAR to the rescue: Reducing leakage. We are now ready to explain our approach to reducing leakage in POPSTAR. The main idea is that the randomness server will associate with every possible string $y \in \{0,1\}^{\leq \ell}$ of length at most ℓ an independent (pseudo)random polynomial $p_y(X)$ of degree t. Here, ℓ is a parameter which we will (empirically) show to be related to the privacy offered by the system–we hence often refer to it as the *privacy parameter*.

By interacting with the randomness server, the client *obliviously* obtains ℓ polynomials

$$p_{y_1}(X), p_{y_1 y_2}(X), \ldots, p_{y_1 y_2 \ldots y_\ell}(X)$$

associated with the ℓ prefixes of a (pseudo)random string $y(s) = y_1 y_2 \ldots y_\ell$ which is, in turn, derived from s. The client also obliviously obtains tags $\mathsf{tag}(y_1), \mathsf{tag}(y_1 y_2), \ldots, \mathsf{tag}(y_1 y_2 \ldots y_\ell)$. Crucially, querying the same s multiple times (by multiple clients) will yield the same polynomials (and tags), whereas querying distinct measurements $s \neq s'$ will very likely lead to different sequences of polynomials/tags that partially overlap up to the length of the longest common substring of $y(s)$ and $y(s')$. For example, if $\ell = 4$, $y(s) = 0000$ and $y(s') = 0010$, interacting with the randomness server on input s will reveal the polynomials

$$p_0(X), p_{00}(X), p_{000}(X), p_{0000}(X)$$

whereas on input s' the revealed polynomials are

$$p_0(X), p_{00}(X), p_{001}(X), p_{0010}(X) \ .$$

POPSTAR's report for a measurement $s \in \{0,1\}^*$ has form

$$\mathsf{rep} = \left[r, p_{y_1}(r), \mathsf{tag}(y_1), \mathsf{ct}^{(1)}, \ldots, \mathsf{ct}^{(\ell+1)}\right] \ ,$$

where $r \in \mathbb{F}$ is randomly chosen, and

$$\mathsf{ct}^{(i)} = \mathsf{Enc}(p_{y_1 \ldots y_i}(0), p_{y_1 \ldots y_i y_{i+1}}(r) \parallel \mathsf{tag}(y_1 \ldots y_i y_{i+1}))$$

for $i = 1, \ldots, \ell - 1$. The ℓ-th ciphertexts encrypts $p_s(r) \parallel \mathsf{tag}(s)$, where $p_s, \mathsf{tag}(s)$ are computed from an

independent OPRF evaluation with the randomness server. The final ciphertext encrypts s.

$$\mathsf{ct}^{(\ell+1)} = \mathsf{Enc}(p_s(0), s) \ .$$

Now, the report server is always able to "peel off" an additional encryption layer from a report for s with $y(s) = y_1 y_2 \ldots y_\ell$ whenever more than t reports for a prefix $y_1, \ldots, y_i$ have been received.

While the costs of managing reports are higher in POPSTAR than in STAR, our implementation shows that they remain within feasible range. For example, aggregating 1 million reports takes 136.1 seconds, which is roughly 7× slower than STAR. The randomness server is however more complex and less efficient than in STAR–in fact, after extensive benchmarks, the best performing solution we provide is still based on garbled circuits. Still, even here the end-to-end running time of one client interaction with the randomness server is dominated by network latency ($\sim 50ms$), rather than local computation times. In POPSTAR, such an interaction takes 2 round trips whereas in STAR, 1 round trip. Hence, we estimate it to be 2× to 3× slower than STAR.

Security Analysis. Our approach substantially reduces leakage compared to STAR. A passive server in particular learns:

1. All strings $y' = y_1 \ldots y_i$ such that $> t$ reports are for a measurement s such that $y_1 \ldots y_{i-1}$ is a prefix of $y(s)$.
2. For each such string y', which reports are for a measurement s such that y' is a prefix of $y(s)$.

This leakage profile resembles that of Poplar, which however uses *either* the measurement itself in lieu of $y(s)$, or a deterministic hash of s, which makes our system stronger in this one dimension. However, in contrast to (2) above, each of the two Poplar servers cannot link a particular report to its contribution, and hence only learns *how many* reports are for a measurement s such that y' is a prefix of $y(s)$, but not *which reports*. As in STAR, we mitigate this by introducing an abstract *mixing server* which is used by the clients when submitting their reports. This could be an actual third-party service, or could be implemented heuristically by having all users coordinate sending their reports at pre-specified times using anonymous communication tools such as ToR.

Another attack by a malicious report server is to maliciously spawn clients and interact with the randomness server. However, this attack is rather ineffective due to the randomness of the mapping between s and $y(s)$, and can intuitively only help uncover extra information about random processes up to a small depth. Also, the effect of this attack can be mitigated via rate limiting measures on the randomness server.

We give a detailed functionality capturing the security of POPSTAR in Section 7.1 (and which we use then to prove security in the full version), [2] and then interpret it empirically in Section 7.2. We also propose a heuristic mechanism to provide differential privacy in Section 7.3.

[2] https://eprint.iacr.org/2024/320

Robustness against malicious client input. POPSTAR as described above is not very robust. For example, a malicious client may include in its report wrong evaluations of the polynomials, causing interpolations by the report server to produce wrong decryption keys. Any honest report containing a ciphertext that is supposed to be decrypted by those keys will be affected. We note that STAR is also not robust against such malicious reports–while clients can verify that the polynomial is correct (using e.g., a *verifiable* OPRF), the report server cannot generally check that the reports contain legitimate evaluations of the polynomial.

We describe a robust variant of POPSTAR in Section 6 that prevents malicious clients' reports from affecting honest reports, assuming the randomness server behaves honestly.

3 Preliminaries

General notations. For a natural number $n \in \mathbb{N}$, we write $[n]$ to represent the set $\{1, \ldots, n\}$. We write $x \| y$ to denote the concatenation of two strings x, y. For a tuple S and an index set I, we write S_I to mean the subset indexed by I.

Shamir's secret sharing. Although not explicitly using Shamir's secret sharing scheme, POPSTAR relies on the same underlying idea of sharing a secret via polynomial evaluation, and reconstructing the secret via interpolation.

We briefly describe Shamir's scheme over a finite field $\mathbb{F}$, and its correctness and privacy guarantees. They directly translate to properties of polynomial interpolation.

In the following, $M \in \mathbb{N}$ is the number of share holders, $t \in [M]$ is a threshold, and $E = (\mathsf{pt}_1, \ldots, \mathsf{pt}_M)$ is a tuple of distinct points in $\mathbb{F}$.

- $Y \leftarrow \mathsf{Share}^{t,E}(k)$ outputs shares $Y = y_1, \ldots, y_M$ of the secret $k \in \mathbb{F}$, computed as $y_i = f_k(\mathsf{pt}_i)$, where $f_k(x) = k + c_1 \cdot x + \ldots + c_t \cdot x^t$, and $c_1, \ldots, c_t \leftarrow \mathbb{F}$.
- $k \leftarrow \mathsf{Recon}^{t,E}(I, Y_I)$ outputs the secret k, reconstructed from a subset of $> t$ shares Y_I as $k = f_k(0)$ where $f_k = \mathsf{Interpolate}(E_I, Y_I, t)$.

Lemma 1. *Fix any number $M \in \mathbb{N}$, threshold $t \in [M]$, and distinct points $E = (\mathsf{pt}_1, \ldots, \mathsf{pt}_M) \subseteq \mathbb{F}$. Let $Y = (y_1, \ldots, y_M) \leftarrow \mathsf{Share}^{t,E}(k)$ be shares of a randomly sampled secret $k \leftarrow \mathbb{F}$.*

1. *Any subset of $> t$ shares Y_I indexed by $I \subseteq [M]$ can recover the correct secret: $k = \mathsf{Recon}^{t,E}(I, Y_I)$.*
2. *Any subset of $\leq t$ shares $Y_{I'}$ indexed by $I' \subseteq [M]$ leaks no information about the secret: $(E, I', Y_{I'}) \equiv (E, I', U)$, where U denotes random values over $\mathbb{F}$.*

Symmetric key encryption with key commitment. An encryption scheme with key commitment guarantees that a ciphertext may be only decrypted with the same key used to produce it. In particular, the decryptor either learns the correct plaintext or recognizes a decryption failure.

We describe a simple scheme for encrypting l-bit messages in the random oracle model, based on the simple padding idea in [2]. Let $H_E : \{0,1\}^* \to \{0,1\}^{l+\lambda}$ be a hash function modeled as a random oracle.

- $\mathsf{Enc}(k, \mathsf{msg})$ samples a random string $r \leftarrow \{0,1\}^\lambda$, and outputs $\mathsf{ct} = (r, c)$ where $c = H_E(k \| r) \oplus (0^\lambda \| m)$.
- $\mathsf{Dec}(k, \mathsf{ct})$ parses $\mathsf{ct} = (r, c)$, and computes $(v^* \| m^*) = c \oplus H_E(k \| r)$. It outputs m^* if $v^* = 0^\lambda$, and $\perp$ otherwise.

In addition to key commitment, the usual correctness and IND-CPA security holds for the above scheme.

Concretely in our evaluations, we use AES-GCM with the padding fix described in [2].

Garbled circuit [10] (GC). We use a simplified syntax.

- $(\widehat{C}, K = \{k_0^{(i)}, k_1^{(i)}\}_{[m]}) \leftarrow \mathsf{Garb}(1^\lambda, C)$: given a Boolean circuit $C : \{0,1\}^m \to \{0,1\}^n$, outputs a garbled circuit $\widehat{C}$ and m pairs of keys K corresponding to the inputs to C.
- $C(x) = \mathsf{Eval}(\widehat{C}, K_x)$: evaluates the garbled circuit $\widehat{C}$ using m keys K_x, which are selected from K according to an input $x \in \{0,1\}^m$.

Correctness and privacy guarantees the evaluator learns $C(x)$ and nothing else. [3] POPSTAR uses GC to implement an oblivious double PRF protocol (Figure 4), between a client and the randomness server.

Oblivious transfer (OT). An OT protocol runs between a sender and a receiver with the following interface.

- $\mathsf{OT}^l.\mathsf{send}(\{\mathsf{msg}_0^{(i)}, \mathsf{msg}_1^{(i)}\}_{i\in[l]})$. The sender inputs l pairs of messages $\mathsf{msg}_0^{(i)}, \mathsf{msg}_1^{(i)}$ for $i = 1, \ldots l$.
- $\{\mathsf{msg}_{x_i}^{(i)}\} \leftarrow \mathsf{OT}^l.\mathsf{receive}(x)$. The receiver inputs a choice vector $x \in \{0,1\}^l$, and receives one message from each pair chosen by the corresponding bit of x.

Security guarantees that the receiver learns only the messages chosen by x, while the sender learns nothing about x.

POPSTAR uses OT together with a GC scheme introduced above to implement the oblivious double PRF protocol (Figure 4). Concretely, we use the OT protocol of [15].

[3] More precisely, the evaluator also learns the topology of C.

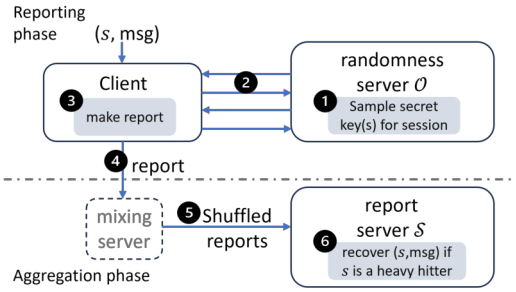

Figure 1: POPSTAR architecture. The server $\mathcal{O}$ samples fresh secret key(s) for each session. In the reporting phase, each client computes a report by interacting with the server $\mathcal{O}$, and sends it to the mixing server. In the aggregation phase, the server $\mathcal{S}$ obtains shuffled reports, and locally recovers heavy hitters and their associated messages.

4 System Overview and Threat Model

4.1 System Overview

Figure 1 illustrates the system model of POPSTAR. We explain it in more detail below.

The basic threshold reporting system. The basic system consists of a set of clients $P_1, P_2, \ldots$, a randomness server $\mathcal{O}$, and a report server $\mathcal{S}$. We envision the system run in recurring sessions, during which each client computes a report of a measurement s and a message msg with the help of the server $\mathcal{O}$, and sends it to the server $\mathcal{S}$. The server $\mathcal{O}$ should learn nothing, and the server $\mathcal{S}$ should only learn the measurements reported more than t times.

The threshold t is a system parameter set appropriately depending on the application scenario and the duration of each session. We emphasize that the server $\mathcal{S}$ should not be able to aggregate reports from different sessions.

Clients do not communicate among themselves and the two servers $\mathcal{S}$ and $\mathcal{O}$ do not communicate with each other. Clients communicate with both servers through private and authenticated asynchronous channels (e.g., both servers deploy TLS for this purpose, and have each a certificate).

Hiding client identities through a mixing server. In many applications, it is desirable to hide client identities associated with each report from the server $\mathcal{S}$, as well as the timing of each report. For this, we will assume the availability of an abstract mixing server that collects reports from the clients during each aggregation session, shuffles them randomly, and delivers them to the server $\mathcal{S}$ in one shot (See Figure 1).

The abstract mixing server could be implemented by an actual third-party service, or heuristically by having the clients to coordinate sending their reports at pre-specified times through anonymous communication tools such as ToR.

An alternative suggested in [18] is to also rely on the randomness server $\mathcal{O}$ for this purpose. In more detail, we let the server $\mathcal{O}$ act as an oblivious HTTP proxy between the clients and the server $\mathcal{S}$, which strips away identifying information from client messages containing their reports, batches them until the end of the aggregation session, and delivers all messages in a shuffled order in one shot.

4.2 Threat Model and Security Goals

We consider a static malicious adversary who initially corrupts a subset of the participants, and controls them throughout the session. As in prior works [13, 18], we assume the two servers $\mathcal{O}$ and $\mathcal{S}$ *do not collude*. More specifically, we only consider three scenarios: (1) a corrupted server $\mathcal{S}$ with colluding clients; (2) corrupted clients only; (3) a corrupted server $\mathcal{O}$ with colluding clients. We explain the security goals and guarantees of POPSTAR in each scenario below. Section 7.1 will also describe a functionality $\mathcal{F}_{\mathsf{report}}$ that captures the security of POPSTAR precisely, but here we limit ourselves to an informal overview.

Corrupted server $\mathcal{S}$ with colluding clients. In this scenario, the goal is to protect privacy of honest clients' inputs, i.e., their measurements and associated messages.

POPSTAR guarantees that if an honest client's measurement is not a heavy hitter, and not among the ones reported by the corrupted clients, then its input is hidden from the adversary, except for a small leakage. (Each colluding client may choose to make a report of an arbitrary measurement s^*.)

Section 7.1 captures the leakage precisely, and Section 7.2 compares with prior works in detail. In short, POPSTAR has a leakage similar to the hashing variant of Poplar, and much smaller than STAR.

We note that a baseline attack by a malicious server $\mathcal{S}$ in POPSTAR (and also in STAR) is to spawn many colluding clients, and use each of them to statically target a different measurement s^*. This will cause the malicious server to identify reports by honest clients' that are on s^*, which will lose privacy. (Of course, this only happens if the malicious server can guess an s^* for which a report is being made.) This attack is somewhat unavoidable in this model, and also affected STAR. We do not try to address this attack within POPSTAR, but argue it can be mitigated by other means in practice. (See the remark on "client rate limiting".)

Corrupted clients only. In this scenario, the goal is to prevent maliciously generated reports from damaging the aggregation results, e.g., causing some measurements to be unrecoverable, even if there are $> t$ honest reports of them.

We first present a very efficient construction of POPSTAR without trying to defend against such malicious reports. We then describe a robust variant (Section 6) that minimizes the effect of malicious reports.

The robust variant of POPSTAR guarantees that malicious reports get discarded from the final aggregation results, while ensuring that honest reports are still counted.

Corrupted server $\mathcal{O}$ with colluding clients. In this scenario the goal is to protect the privacy of honest clients' inputs.

POPSTAR completely hides honest clients' inputs from the adversary, irrespective of whether the measurements are heavy hitters or not.

POPSTAR has very limited guarantee against malicious reports from corrupted clients, and faulty reports from honest clients caused by a malicious server $\mathcal{O}$. Essentially, the adversary may cause any subset of the honest reports to be discarded from the final aggregation results.

Remark on colluding servers $\mathcal{S}$ and $\mathcal{O}$. POPSTAR is designed with two non-colluding servers in mind. However, we note that even when they collude, POPSTAR still provides limited privacy (see Section 5.1). In contrast, Poplar [13] has no privacy when the servers collude.

Remark on client rate limiting. As noted in the case of a corrupted server $\mathcal{S}$, privacy of POPSTAR relies on the assumption that the adversary cannot collude or spawn too many malicious clients, nor sending multiple queries through one colluding client to the server $\mathcal{O}$.

We envision enforcing one query per session from the clients by requiring them to register accounts with the server $\mathcal{O}$, who limits the number of interactions per account.

To prevent the adversary from registering multiple accounts, one could use usual measures making the creation of multiple accounts expensive (e.g., requiring multiple e-mail addresses, distinct authentication factors, etc).

5 Protocol Description

5.1 Threshold Reporting Protocol

The POPSTAR protocol (Figure 1) consists of a reporting phase, where each client computes a report with the help of the server $\mathcal{O}$ and sends it to the mixing server, and an aggregation phase, where the report server obtains reports from the mixing server and locally recovers the heavy hitters. We focus on the more efficient non-robust variant in this section. We describe the robust variant in Section 6, and propose a heuristic mechanism to provide differential privacy in Section 7.3.

The algorithmic descriptions of each client and the report server are given in Figure 2 and 3. Below we first introduce the cryptographic tools used, and the interfaces implemented by the randomness and the mixing servers. We then describe the two phases in more detail. Finally, we analyze the correctness and privacy of the protocol. (Formal security definitions can be found in Section 7.1 and proofs in the full version.)

Cryptographic primitives. The protocol uses the symmetric key encryption scheme $(\mathsf{Enc}, \mathsf{Dec})$ with key commitment described in Section 3. It also uses two hash functions (modeled as random oracles): (1) $H_s : \{0,1\}^* \to \{0,1\}^\lambda$, (2) $H_p : \{0,1\}^* \to \mathbb{F}^{t+1} \times \{0,1\}^\lambda$ where $\mathbb{F}$ is a λ-bit field. The output of H_p is a degree t polynomial f and a tag.

The randomness and the mixing server interfaces. The randomness server $\mathcal{O}$ implements two interfaces $\mathsf{OPRF}, \mathsf{ODPRF}$ short for oblivious (double) PRF. We give details of the implementations in Section 5.2.

- $u \leftarrow \mathsf{OPRF}(x)$. Each client can call $\mathsf{OPRF}(x)$ with an λ-bit string input, and obtain a single λ-bit string.
- $v^{(1)}, \ldots, v^{(\ell)} \leftarrow \mathsf{ODPRF}(x)$. Each client can call $\mathsf{ODPRF}(x)$ with an λ-bit string input, and obtain ℓ λ-bit strings.

The former result u is supposed to be a PRF evaluation: $u = F(\mathsf{sk}, x)$, where sk is known only to the server $\mathcal{O}$. The latter results $v^{(1)}, \ldots, v^{(\ell)}$ are supposed to be PRF evaluations $v^{(d)} = F'(\mathsf{sk}', \mathsf{prefix}(u', d))$, where $u' = F'(\mathsf{sk}', x)$, and $\mathsf{prefix}(u', d)$ denotes the first d bits of u', padded appropriately. sk' is known only to the server $\mathcal{O}$.

The abstract mixing server implements two interfaces.

- $\mathsf{Mix.send}(R)$. Each client can call $\mathsf{Mix.send}(R)$ to send its report to the mixing server.
- $\{R_j\} \leftarrow \mathsf{Mix.collect}()$. The report server $\mathcal{S}$ can call $\mathsf{Mix.collect}()$ to collect reports sent by the clients, in a randomly shuffled order.

The reporting phase. During the reporting phase, each client who wishes to report a measurement s and an associated message msg independently and asynchronously executes the following steps (formally described in Figure 2).

First, the client hashes its measurement to a λ-bit string $x = H_s(s)$, and calls the ODPRF and OPRF interfaces of the server $\mathcal{O}$ with the input x to obtain evaluation results $v^{(1)}, \ldots, v^{(\ell)}, u$. The client hashes, using H_p, the evaluation results into $\ell+1$ degree t polynomials $f^{(1)}, \ldots, f^{(\ell)}, f^{(\ell+1)}$, each associated with a tag.

Next, the client derives a secret key $k^{(d)} = f^{(d)}(0)$ from each polynomial, and a Shamir's secret share (Section 3) of the key $y^{(d)} = f^{(d)}(\mathsf{pt})$. The evaluation point pt is chosen at random for each report so that pt does not leak anything about the client identity, and also does not collide with other client's choices with overwhelming probability.

Finally, the client creates a chain of encryptions. The first key $k^{(1)}$ is used to encrypt the second share, together with the second tag: $\mathsf{ct}^{(1)} \leftarrow \mathsf{Enc}(k^{(1)}, \mathsf{tag}^{(2)} \,\|\, y^{(2)})$, and so on. The final key $k^{(\ell+1)}$ is used to encrypt the measurement and the message: $\mathsf{ct}^{(\ell+1)} \leftarrow \mathsf{Enc}(k^{(\ell+1)}, s \,\|\, \mathsf{msg})$. The report consists of the ciphertexts, the first share and tag, and the evaluation point: $R = (\mathsf{pt}, \mathsf{tag}^{(1)}, y^{(1)}, \mathsf{ct}^{(1)}, \ldots, \mathsf{ct}^{(\ell+1)})$. The client sends it to the mixing server using the interface $\mathsf{Mix.send}(R)$.

$\mathsf{POPSTAR\text{-}Client}^{\ell,t}(s, \mathsf{msg})$

$\mathsf{Mix.send}(R = (\mathsf{pt}, \mathsf{tag}^{(1)}, y^{(1)}, \mathsf{ct}^{(1)}, \ldots, \mathsf{ct}^{(\ell+1)}))$

Figure 2: The client pseudocode of POPSTAR.

The aggregation phase. During the aggregation phase, the server $\mathcal{S}$ collects the reports received by the mixing server using the interface $\{R_j\}_{j\in[m]} \leftarrow \mathsf{Mix.collect}()$, and executes the following steps (formally described in Figure 3).

First, the server $\mathcal{S}$ divides the reports into depth-1 subgroups according to the depth-1 tags included in each report, discarding the ones with size $\le t$.

Next, for each depth-1 subgroup $G^{(1)}$, the server uses the shares $\{y_j^{(1)}\}_{j\in G^{(1)}}$ and evaluation points $\{\mathsf{pt}_j\}_{j\in G^{(1)}}$ included in the reports to derive a key $k^{(1)}$ by polynomial interpolation. The server decrypts the depth-1 ciphertexts $\{\mathsf{ct}^{(1)}\}_{j\in G^{(1)}}$ in the group using $k^{(1)}$, discarding reports R_j for which $\mathsf{ct}_j^{(1)}$ fails to decrypt. Note that by using an encryption scheme with key commitment, the server recognizes decryption failures and avoids proceeding with garbage results. A successful decryption of $\mathsf{ct}_j^{(1)}$ recovers the depth-2 tags and shares $\mathsf{tag}_j^{(2)}, y_j^{(2)}$ for report R_j. After recovering a depth-2 tag and share for each report in the group $G^{(1)}$, the server divides it further into depth-2 subgroups, discarding the ones with size $\le t$.

The server proceeds analogously for each depth-2 subgroup $G^{(2)}$, further dividing it into depth-3 subgroups, and so on. In the end, the server obtains a list of depth-$(\ell+1)$ subgroups, each with size $> t$.

Finally, for each depth-$(\ell+1)$ group $G^{(\ell+1)}$, the server decrypts the depth-$(\ell+1)$ ciphertexts in it, discarding the ones that fails. A successful decryption of $\mathsf{ct}_j^{(\ell+1)}$ recovers

a measurement s and a message msg_j for report R_j. If the reports in the group contain the same measurement, then the server adds it and associated messages to the aggregation results. Otherwise, the server discards the group.

Figure 3: The report server $\mathcal{S}$ pseudocode of POPSTAR.

Correctness. We note three facts of the aggregation phase. (1) A subgroup with size $> t$ is decrypted successfully. (2) Reports on the same measurement are put into the same depth-d subgroup, for all $d \in [\ell+1]$. (3) Reports on different measurements are put into different depth-$(\ell+1)$ subgroups.

First, a depth-d subgroup contains only reports with the same $\mathsf{tag}^{(d)}$. Hence, the shares $y_j^{(d)}$ in this group are evaluations on the same degree t polynomial $f^{(d)}$ uniquely associated with $\mathsf{tag}^{(d)}$, and the ciphertexts $\mathsf{ct}_j^{(d)}$ are encrypted under the key $k^{(d)} = f^{(d)}(0)$. Interpolation of the $> t$ shares recovers $f^{(0)}$ and $k^{(d)}$. Hence, decryptions for the group are successful.

Second, note that the tags $\mathsf{tag}^{(1)}, \ldots, \mathsf{tag}^{(\ell+1)}$ in a report of s are deterministically derived from s. Hence, reports of the same s share the same $\mathsf{tag}^{(d)}$, and are put into the same depth-d subgroup for all $d \in [\ell+1]$.

Third, note that the final tag $\mathsf{tag}^{(\ell+1)}$ in a report of s is derived as $f^{(\ell+1)}, \mathsf{tag}^{(\ell+1)} = H_p(u \,\|\, s)$, where H_p is modelled as a random oracle. With overwhelming probability, different s leads to different $\mathsf{tag}^{(\ell+1)}$.

We can now conclude correctness. For any measurement s with $> t$ reports, the subgroups containing these reports all have size $> t$ by fact (2), hence are successfully decrypted by fact (1). The final depth-$(\ell+1)$ subgroup contains only reports of s by fact (3), hence s and the associated messages are added to the aggregation results.

Privacy. We informally argue privacy for reports of non-heavy hitter measurements against the report server $\mathcal{S}$. (See Section 7.1 for formal security definitions and the full version for proofs.)

First consider the server $\mathcal{S}$ without colluding clients. A report of some measurement s can be divided into two parts: (1) the final ciphertext, $\mathsf{ct}^{(\ell+1)}$, encrypting s and a message under the secret key $k^{(\ell+1)}$, and (2) the rest of the report, encrypting (through a chain of ciphertexts) a share of the key $y^{(\ell+1)}$. The final ciphertext $\mathsf{ct}^{(\ell+1)}$ remains secure against the server $\mathcal{S}$ when there are $\leq t$ reports of s, because $\leq t$ shares of the key $k^{(\ell+1)}$ leaks no information about it.

Next, when the server $\mathcal{S}$ colludes with some clients, each such client allows it to target a certain measurement s^* and directly learn the secret key $k^{*(\ell+1)}$ used for encrypting s^*. In more detail, the colluding client is allowed one call to the interface $u^* \leftarrow \mathsf{OPRF}(x^*)$ with $x^* = H_s(s^*)$. It then derives $k^{*(\ell+1)}$ from u^*. Reports of s^* lose privacy, while reports for non-heavy hitters $s \neq s^*$ remain private. We emphasize the server $\mathcal{S}$ only chooses targeted measurements s^* during the reporting phase, before seeing any honest client's reports.

Finally, we note that by observing how reports are grouped together during the aggregation phase, the server $\mathcal{S}$ learns a small amount of leakage of the non-heavy hitter measurements. This is because the tags in a report of some s are deterministically derived from s. We capture the leakage precisely in our formal security definition (Figure 6), and give a detailed comparison with the leakages in prior works in Section 7.2. Briefly, our leakage is similar to that of the hashing

variant of [13] (Poplar), and much smaller than that of [18] (STAR).

Limited privacy against colluding servers $\mathcal{S}$ and $\mathcal{O}$. Observe that a client's report is derived deterministically from its measurement s and interactions with the corrupted server $\mathcal{O}$. So a baseline attack by the adversary is to guess s and verify against the client's report. We argue this is the best it can do in the random oracle model. If the measurements contain sufficient entropy, the adversary cannot efficiently guess correctly.

First note the client's input $x = H_s(s)$ to the ODPRF and OPRF protocols is a hash of s, which looks random to the adversary without guessing s. The interactions with the server $\mathcal{O}$ as well as the derived keys $k^{(1)}, \ldots k^{(\ell+1)}$ and ciphertexts $\mathsf{ct}^{(1)}, \ldots, \mathsf{ct}^{(\ell)}$ reveal nothing beyond the hash x.

Next note that the encryption key $k^{(\ell+1)}$ is derived as another hash of s, which looks random to the adversary without guessing s. This ensures the final ciphertext $\mathsf{ct}^{(\ell+1)}$ reveals nothing about s, unless the key $k^{(\ell+1)}$ is recovered through guesses of s or more than t reports of s.

Remark on a "Lite" variant. In [18], the authors also propose a "Lite" variant of STAR, where its randomness server is replaced with a public hash function. The privacy guarantee of this variant is weaker, which relies on the client measurements having high entropy. We note that an analogous variant of POPSTAR can be naturally derived by replacing the server $\mathcal{O}$ with public hash functions.

5.2 Implementing the Randomness Server

The randomness server $\mathcal{O}$ implements two interfaces, OPRF and ODPRF (see Section 5.1). The former can be implemented by any oblivious PRF protocol (OPRF), e.g., the one of [24], or by a simpler variant of the ODPRF protocol below.

To implement the latter, the server $\mathcal{O}$ samples a secret key $\mathsf{sk} \leftarrow \{0,1\}^\lambda$ for each aggregation session, and listens for client messages. Upon receiving init from a client, the server $\mathcal{O}$ executes the ODPRF (Figure 4) protocol with the client using sk as its input. At the end of the aggregation session, it deletes sk.

The ODPRF protocol. The protocol has three steps.

1. The server $\mathcal{O}$ defines a circuit C such that $C(\mathsf{sk}, x)$ computes ℓ λ-bit strings $v^{(1)}, \ldots, v^{(\ell)}$ exactly as required by the interface. It computes a garbled circuit (GC) $\widehat{C}_{\mathsf{sk}}$ of $C(\mathsf{sk}, \cdot)$ together with λ pairs of inputs keys $\{k_0^{(i)}, k_1^{(i)}\}$.
2. The server $\mathcal{O}$ and the client run an oblivious transfer (OT) protocol OT^λ. The server calls $\mathsf{OT}^\lambda.\mathsf{send}(\{k_0^{(i)}, k_1^{(i)}\})$ to send the input keys, and the client calls $K_x = \{k_x^{(i)}\} \leftarrow \mathsf{OT}^\lambda(x)$ to receive input keys corresponding to x.

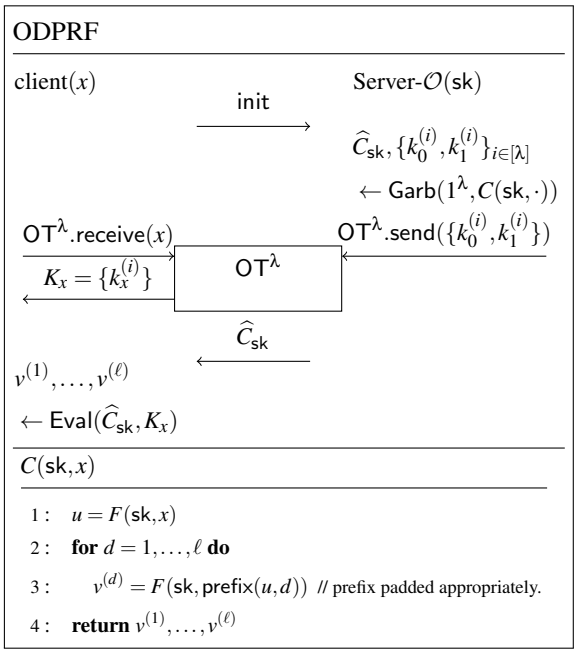

Figure 4: The oblivious double PRF protocol.

3. The server $\mathcal{O}$ sends the garbled circuit $\widehat{C}_{\mathsf{sk}}$ to the client, who locally evaluates it to obtain the results $v^{(1)}, \ldots, v^{(\ell)} = C(\mathsf{sk}, x)$.

Correctness follows directly from that of the GC scheme and the OT protocol. (See Section 3.) Privacy guarantees that the client's input x and the server's secret key sk are hidden from each other. This also follows directly from the security of the GC scheme and the OT protocol.

We note that compared to a generic maliciously secure 2PC protocol computing C, our protocol does not enforce the server $\mathcal{O}$ to send the correct garbled circuit corresponding to $C(\mathsf{sk}, \cdot)$. We make this relaxation for better efficiency.

The observation is that the client's outputs from the ODPRF protocol only affect how its report is grouped during the aggregation phase, but not the privacy of the report.

Concrete Choice of F. We instantiate F with the LowMC [3] block-cipher with 128-bit keys and blocks, and 64-bit data security. LowMC is designed to minimize the number of AND gates in its circuit, which in turn minimizes our garbled circuit (with free-XOR) size and computation.

According to the parameter calculation script, [4] our instantiation of F has 1638 AND gates. Hence, the circuit C computing the double PRF evaluations has $1638 \cdot (\ell+1)$ AND gates.

[4] https://github.com/LowMC/lowmc

6 The Robust Variant

We describe a robust variant of our protocol to minimize the effect of malicious reports from corrupted clients, assuming the randomness server $\mathcal{O}$ behaves honestly.

Recall that during the aggregation phase (Figure 3), for $d \in [\ell+1]$, the server $\mathcal{S}$ groups reports according to their revealed depth-d tags. For each group $G^{(d)}$ of size $> t$, it interpolates the revealed depth-d shares to obtain a secret key $k^{(d)}$, and decrypts the depth-d ciphertexts in the group.

A malicious report R_i^* in the group may affect the process in three ways.

1. It may contain a wrong share $y_i^{*(d)} \neq f^{(d)}(\mathsf{pt}_i)$, where $f^{(d)}$ is the polynomial uniquely associated with the $\mathsf{tag}^{(d)}$ for this group. The server $\mathcal{S}$ may derive a wrong key $k^{*(d)}$ as a result, and fail at decrypting all ciphertexts in the group.

2. It may contain a wrong ciphertext $\mathsf{ct}^{*(d)}$ that fails to decrypt under the correct key for this group. The server $\mathcal{S}$ drops the malicious report R_i^* as a result.

3. When $d = \ell+1$, it may contain a $(\ell+1)$-th ciphertext decrypting to a different measurement s^* from the honest reports in the group. The server $\mathcal{S}$ skips the group as a result.

We describe how to prevent (1) and (3) below. We don't prevent (2), as it only results in the malicious report R_i^* being discarded.

Preventing (3). At high level, we prevent (3) by allowing the server $\mathcal{S}$ to verify that a decrypted measurement s indeed belongs to its depth-$(\ell+1)$ group. To this end, we augment the OPRF interface implemented by the randomness server $\mathcal{O}$ with *verifiability*. (We show how to implement this interface using a verifiable oblivious PRF protocol in the end.)

- $(u, \pi_x) \leftarrow \mathsf{VOPRF}(x)$. Each client can call $\mathsf{VOPRF}(x)$ to obtain a λ-bit evaluation result u, and a proof π_x.

The result u is supposed to be a PRF evaluation $u = F(\mathsf{sk}, x)$ as before, and the proof π_x is supposed to be verifiable against a public key pk by an algorithm Verify: $b \leftarrow \mathsf{Verify}(\mathsf{pk}, u, x, \pi_x)$. We assume a PKI setup where every client and the report server $\mathcal{S}$ learns pk.

During the reporting phase (Figure 2), each client calls $(u, \pi_x) \leftarrow \mathsf{VOPRF}$ in place of $u \leftarrow \mathsf{OPRF}(x)$ (line 3), and encrypts u, π_x in addition to its measurement and message in the depth-$(\ell+1)$ ciphertext: (line 12)

$$\mathsf{ct}_i^{(\ell+1)} \leftarrow \mathsf{Enc}(k^{(\ell+1)}, (s, \mathsf{msg}_i, \boxed{u \,\|\, \pi_x} \,\|\, s \,\|\, \mathsf{msg})).$$

During the aggregation phase (Figure 3), the server $\mathcal{S}$ decrypts $(u, \pi_x, s, \mathsf{msg}) \leftarrow \mathsf{Dec}(k^{(\ell+1)}, \mathsf{ct}^{(\ell+1)})$ (line 18), and checks s against the attached proof π_x as follows.

- Compute $x = H_s(s)$, and run $b = \mathsf{Verify}(\mathsf{pk}, u_s, x, \pi_x)$.
- If $b = 1$, then derive $f^{(\ell+1)}, \mathsf{tag}^{(\ell+1)} = H_p(u \,\|\, s)$.
- If the derived $\mathsf{tag}^{\ell+1}$ equals the tag for the current depth-$(\ell+1)$ group, then s is a correct measurement. Otherwise, discard s.

Preventing (1). Our goal is to prevent the server $\mathcal{S}$ from deriving a wrong key $k^{*(d)}$ for some depth-d group of $> t$ reports that contains wrong shares.

We first show a lightweight modification that allows the server $\mathcal{S}$ to efficiently recover the correct key, assuming the group contains much more than t honest shares, and much fewer than t wrong shares. When the assumption does not hold, the server $\mathcal{S}$ might time out trying to recover the correct key, and skips the group. We believe this suffices for many real world use cases, where the number of corrupted clients in the system is much smaller than the threshold t, and the majority of the heavy hitter measurements are reported much more than t times.

We modify how the server $\mathcal{S}$ derives a key for the group.

1. Interpolate a random subset R of $t+1$ shares to a polynomial $f_R^{(d)}$, and derive a *candidate* key $k_R^{(d)} = f^{(d)}(0)$.

2. Try decrypting the depth-d ciphertexts in R. If all decryption succeeds, then use $k_R^{(d)}$ for decrypting the rest of the group. Otherwise, repeat the above with a fresh random subset R'.

This procedure succeeds whenever the random subset R contains no malicious reports, which happens with a good probability when the above assumption holds. As an example, consider a threshold $t = 1000 - 1$, a group with $50,000$ reports, where 50 are malicious. The probability of sampling a subset R with no malicious reports is $\binom{49,950}{1000} / \binom{50,000}{1000} > 0.36$. Hence, in expectation it takes less than 3 tries to recover the correct secret key.

It's also possible to let the server $\mathcal{S}$ unconditionally recognize and discard all wrong shares during the aggregation process using a polynomial commitment scheme (PC). This allows us to fully prevent (1). We describe this heavier-weight method very briefly.

At high level, a PC scheme allows each client to compute a commitment C_f to a polynomial f, and a proof $\pi_{\mathsf{pt},f,y}$ that an evaluation y is computed correctly from the committed polynomial as $y = f(\mathsf{pt})$. We use a PC scheme, e.g. that of [25], where the commitment C_f is deterministically derived from f, so that C_f also functions as a unique tag for f.

In the reporting phase, each client replaces $\mathsf{tag}^{(d)}$ with a commitment $C_f^{(d)}$ to the polynomial $f^{(d)}$ and a proof $\pi_{\mathsf{pt}_i,f,y_i}^{(d)}$, for $d \in [\ell+1]$. During the aggregation phase, the server first proceeds optimistically without checking the commitments and proofs. (Our use of key-committing encryption ensures

successful decryption results are correct.) Only in case of a decryption failure, indicating a wrong key $k^{*(d)}$ is derived, does the server verify the shares used for interpolation against their commitments and proofs to discard the wrong ones.

Thanks to the optimistic server strategy, we do not expect significant changes in server loads, even though polynomial commitment checks could be expensive.

Implementing the interface VOPRF**.** We can implement the interface using any existing verifiable oblivious PRF (VOPRF) protocol, e.g. the one of [24] with an extra step.

At high level, a VOPRF protocol allows a client and the randomness server $\mathcal{O}$ securely evaluate a PRF based on the client's input x and the server's secret key sk. Additionally, the client can verify the evaluation result against a public key pk, using a proof π from the server.

This almost matches the desired interface, except the proof is only intended to be verified by the client. To output a proof that can be verified by anyone holding pk, we simply let the client attach its view during the protocol, including its internal randomness, to the proof.

7 Security Analysis

7.1 Ideal Functionality and Security Proofs

We formalize the security properties of POPSTAR into an ideal functionality $\mathcal{F}_{\mathsf{report}}$ (Figure 5, 6, 7) in the universal composability (UC) framework. (See the full version for an overview of UC.) The functionality has the following parameters.

- $M \in \mathbb{N}$ is an upper bound on the number of clients, and $t \in [M]$ is the threshold for heavy hitters.
- $\ell \in \mathbb{N}$ is the depth of the prefix tree T internally maintained by $\mathcal{F}_{\mathsf{report}}$. As we will explain, the leakage to a corrupted server $\mathcal{S}$ is captured by a set of leaked nodes on T. Asymptotically, setting $\ell = O(\lambda)$, where λ is the security parameter, bounds the number of leaked nodes to be $O(\lambda \cdot M/t)$ with overwhelming probability.

The honest interface. Figure 5 describes the interface with honest clients and the two servers $\mathcal{O}$ and $\mathcal{S}$, which captures the following correctness guarantee. *If all parties behave honestly, then* $\mathcal{F}_{\mathsf{report}}$ *reveals exactly the measurements (with associated messages) reported by* $> t$ *clients to the server* $\mathcal{S}$. We can verify every distinct measurement s is mapped to a distinct leaf node on the prefix tree T, and that in the end only the leaf nodes with count $> t$ are revealed to the server $\mathcal{S}$.

Functionality $\mathcal{F}_{\mathsf{report}}^{M,t,\ell}$

The functionality runs with up to M clients $P_1, P_2, \ldots$, a randomness server $\mathcal{O}$ and an report server $\mathcal{S}$.

Honest Interface:

Ignore all messages associated with sid before receiving $(\mathsf{init}, \mathsf{sid})$ from the server $\mathcal{O}$ and after receiving $(\mathsf{collect}, \mathsf{sid})$ from the server $\mathcal{S}$.

1. Upon receiving $(\mathsf{init}, \mathsf{sid})$ from the server $\mathcal{O}$, initialize two data structures (associated with sid):
   - tb: a random table mapping received measurements to ℓ-bit strings.
   - T: an ℓ-level binary tree where each node stores a count (initially 0) and a state (initially hidden).

   We call the initial nodes of T *inner nodes*. The functionality will add a *leaf node* for each distinct received measurement.
2. Upon receiving $(i, s, \mathsf{msg}, \mathsf{sid})$ from a client P_i, interpret $\mathsf{path}_s = \mathsf{tb}[s] \in \{0,1\}^\ell$ as a path on the tree T.
   - Add a leaf node labelled by s at the end of path_s if there is not one already, and store msg on it. (Let $\overline{\mathsf{path}_s}$ denote the path including the leaf node.)
   - Increase the count of each node on $\overline{\mathsf{path}_s}$.
   - If a node has count $> t$, set its state to $\mathsf{revealed}$.
3. Upon receiving $(\mathsf{collect}, \mathsf{sid})$ from the server $\mathcal{S}$, collect the measurements and messages stored on each revealed *leaf* node, and send them to the server $\mathcal{S}$.

Figure 5: The interface with honest parties. It captures the correctness of POPSTAR.

The leakage to a corrupted server $\mathcal{S}$**.** Figure 6 describes the interface with an adversary who statically corrupts the server $\mathcal{S}$ and a subset of the clients. It captures two ways the adversary learns additional information (i.e., the leakage) about the honest reports besides the legitimate aggregation results.

First, without any colluding clients, the server $\mathcal{S}$ learns the count of every $\mathsf{revealed}$ node and its children on the tree T. (See Figure 8 for an illustration.) This leakage does not reveal the clients' reports directly, but only how they are partially grouped together on the tree T.

To understand this leakage, we focus on the deepest leaked nodes, which we call *end* nodes. (The counts on the remaining leaked nodes can be inferred from those on the end nodes.) In the extreme case where all nodes on T are leaked, the end nodes are all the leaves. The counts on them essentially leaks an anonymized histogram of all received measurements.

Functionality $\mathcal{F}_{\mathsf{report}}^{M,t,\ell}$ Continued

Corrupted report server $\mathcal{S}$ and colluding clients:
For each corrupted client P_i, the adversary may send $(i,s,\mathsf{inner},\mathsf{sid})$ and $(i,s',\mathsf{leaf},\mathsf{sid})$ in any order.

- Upon receiving $(i,s,\mathsf{inner},\mathsf{sid})$, set all nodes on path_s to revealed, and leak path_s to the adversary;
- Upon receiving $(i,s',\mathsf{leaf},\mathsf{sid})$, set the leaf for s' to revealed, and leak its location on T to the adversary.

In the end, leak all revealed nodes and their children (i.e., their locations on T and stored counts) to the adversary.

Figure 6: The interface with the adversary corrupting the report server $\mathcal{S}$ and a subset of clients. It captures the potential leakages to a corrupted report server $\mathcal{S}$.

We argue the leakage in POPSTAR is much smaller than the extreme case by showing the number of end nodes on T is much less than the number of all leaves.

- If a revealed path has length $l < \ell$, then it creates $\leq l+1$ end nodes: two children by the last node on the path, and 1 child by each of the rest.
- The case of $l = \ell$ is similar, except the last node on the path causes all its leaves to be end nodes. When $\ell = O(\lambda)$, there are $O(1)$ leaves with overwhelming probability. Hence, $\ell + O(1)$ end nodes are created.

There are at most $M/(t+1)$ revealed paths, which creates at most $O(\ell \cdot M/(t+1))$ end nodes. If the threshold t is a constant fraction of M, there are $O(\ell) = O(\lambda)$ end nodes.

Second, with each corrupted client P_i, the adversary may cause $\mathcal{F}_{\mathsf{report}}$ to reveal a length-ℓ path and a leaf node, through the messages $(i,s,\mathsf{inner},\mathsf{sid})$ and $(i,s',\mathsf{leaf},\mathsf{sid})$. A revealed path adds at most $\ell + O(1)$ leaked *end* nodes in the leakage above. A revealed leaf (for s') lets the adversary learn the count of reports for s' and their associated messages.

The effect of malicious reports. Figure 7 describes the interfaces with an adversary who statically corrupts a subset of clients, and with one who additionally corrupts the server $\mathcal{O}$. It captures the effects of malicious reports.

When only clients are corrupted, for each corrupted client P_i, the adversary may first send (i,s,sid) to submit a measurement, but then instruct $\mathcal{F}_{\mathsf{report}}$ to update the prefix tree T based on an arbitrary path^* of length $\ell^* \leq \ell+1$.

In more detail, we assume every node in T is labelled with some tag τ, and path^* contains ℓ^* tags $\tau_1,\ldots,\tau_{\ell^*}$. The first tag τ_1 indicates the child of the root labelled with τ_1. Add such a child if it does not exist in T. Inductively, the d-th tag τ_d indicates the child of τ_{d-1} labelled with τ_d.

Functionality $\mathcal{F}_{\mathsf{report}}^{M,t,\ell}$ Continued

Corrupted clients only:
For each corrupted client P_i, the adversary sends $(i,s,\mathsf{inner},\mathsf{sid})$ to $\mathcal{F}_{\mathsf{report}}$, who replies with path_s. The adversary then sends one of the following, where path^* is an arbitrary path of length $\ell^* \leq \ell+1$.

- $(\mathsf{path}^*,\mathsf{msg},\mathsf{sid})$: update the count and state for each node on path^* as in the honest interface. If path^* includes a leaf node, then store msg on it.
- $(\mathsf{path}^*,\mathsf{damage},\mathsf{sid})$: after updating the counts and states for nodes on path^*, set the *sub-tree* rooted at its last node to damaged, which can no longer be revealed.

Corrupted randomness server $\mathcal{O}$ and colluding clients:
Denote the set of corrupted clients C, and the rest H. Notify the adversary upon receiving an honest input message. Upon receiving $(\mathsf{collect},\mathsf{sid})$ from the server $\mathcal{S}$, notify the adversary, who replies $(\{i,s_i^*,\mathsf{msg}_i^*\}_C,\mathsf{Discard}^*,\mathsf{sid})$, where $\mathsf{Discard}^*$ is a circuit that takes $\{s_i\}_{i\in H}$ as inputs, and outputs a subset $D \subseteq [H]$.
Run $D = \mathsf{Discard}^*(\{s_i\}_H)$, and discard the inputs indicated by D. Output the aggregation results over the remaining inputs to the server $\mathcal{S}$.

Figure 7: The interface with the adversary corrupting a subset of clients and possibly also the randomness server $\mathcal{O}$. It captures the potential damages caused by malicious reports.

In addition to updating the tree T according to path^*, the adversary specifies one of the two further actions for $\mathcal{F}_{\mathsf{report}}$. (1) $(\mathsf{path}^*,\mathsf{msg},\mathsf{sid})$ instructs $\mathcal{F}_{\mathsf{report}}$ to store msg on the leaf node, if any, specified by path^*. (2) $(\mathsf{path}^*,\mathsf{damage},\mathsf{sid})$ instructs $\mathcal{F}_{\mathsf{report}}$ to mark the sub-tree rooted at the last node on path^* as damaged and never revealed.

When the server $\mathcal{O}$ plus a subset of clients are corrupted, the adversary is allowed to specify an arbitrary function $\mathsf{Discard}^*$ that decides a subset $D \subseteq [H]$ of client inputs to discard. More specifically, the adversary first commits a measurement and message (s_i^*,msg_i^*) for every corrupted client, and specifies the function $\mathsf{Discard}^*$. Then $\mathcal{F}_{\mathsf{report}}$ runs it over received honest measurements $D = \mathsf{Discard}^*(\{s_i\}_{i\in H})$, and computes the aggregation results over the remaining inputs.

The robust variant. A weakness of $\mathcal{F}_{\mathsf{report}}$, is that even when only one client is corrupted, its malicious report could cause many valid measurements to become un-recoverable. This is modeled as the $(\mathsf{path}^*,\mathsf{damage},\mathsf{sid})$ command in Figure 7, which damages the entire sub-tree rooted at the last node of path^*. We describe a robust variant of POPSTAR in Section 6 that prevents this attack. Formally, the robust

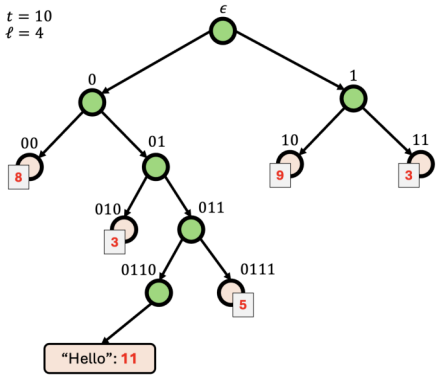

Figure 8: Example of a prefix-tree visible to the report server for a threshold $t = 4$ and depth $\ell = 4$. The numbers in the boxes correspond to the number of reports associated with the end nodes. Here, only a single measurement "Hello" exceeds the threshold.

functionality is identical to $\mathcal{F}_{\text{report}}$, except it does not allow the $(\mathsf{path}^*, \mathsf{damage}, \mathsf{sid})$ command.

Theorem statement. We state the security of POPSTAR below. See the full version for the formally stated theorem, the analogous theorem for the robust variant, and the proofs.

Theorem 1 (Informal)**.** *The protocol described in Section 5 UC-realizes the functionality $\mathcal{F}_{\text{report}}$ in the random oracle model, against a malicious adversary that statically corrupts at most one of the servers $\mathcal{S}, \mathcal{O}$ and any number of colluding clients.*

7.2 Leakage Comparisons with Prior Work

This section compares our leakage profile, formally captured by our ideal functionality, to that of prior works, and offers a heuristic evaluation of the profile. It is helpful to refer to Figure 8, which illustrates an example of the prefix tree visible to the server.

Leakage comparison with [18] (STAR). We first consider the case where only the report server $\mathcal{S}$ is corrupted, without any colluding clients. Every report in STAR contains a tag deterministically computed from the measurement s. The server learns an unlabeled histogram of the reported measurements by grouping them according to their tags.

While POPSTAR's leakage profile is complex, and could lead to more refined leakage abuse attacks, here we discuss the simplest type of inference attack which exploits the report counts for the end nodes in the prefix tree, and attempts to reconstruct the frequency histogram leaked by STAR. In general, because measurements are assigned to uniformly random paths, the deeper an end node in the tree, the more likely its count is attributed to reports for a single measurement. However, we argue that in POPSTAR many end nodes represent counts coming from reports for different measurements, and this therefore strictly reduces leakage.

To verify this experimentally, we sample $1,000,000$ reports from a Zipf power-law distribution with a support $N = 10,000$ and parameter $s := 1.03$, matching the evaluation settings in Section 8 and in [18]. In Table 1, we report the number of end nodes in the prefix tree of POPSTAR, (excluding the leaf nodes for actual heavy hitters), compared against the number of non-heavy hitter report groups formed in STAR. We also report the number of end nodes whose count is attributed to a single measurement (denoted "exact counts") in Table 1.

	$t = 10,000$	$t = 1000$	$t = 100$
Groups (STAR)	9990	9899	9059
End nodes (POPSTAR)	175	1071	4568
Exact counts (POPSTAR)	19	167	2120

Table 1: Leakage comparison between STAR and POPSTAR (with $\ell = 16$). A group in STAR leaks the exact count of a non-heavy hitter. An end node in POPSTAR leaks the combined count of ≥ 1 non-heavy hitters. The end nodes leaking 1 non-heavy hitter are called exact counts.

In the above experiment setting, increasing ℓ from 1 to 16 leads to a decrease in the number of end nodes. Increasing ℓ beyond 16 does not change the numbers anymore.

From Table 1, we observe that POPSTAR is most effective at leakage reduction at high thresholds. At a 0.1% threshold ($t = 1000$), which is the main setting considered by STAR and Poplar, STAR leaks the exact counts of 9899 non-heavy hitters, while POPSTAR leaks only 1071 combined counts. Among them, only 167 are exact counts.

Finally, we briefly note that in POPSTAR, a corrupted server $\mathcal{S}$, with each colluding client, may actively cause a path on the prefix tree to leak. In the worst case, i.e., when the leaked path corresponds to a non-heavy hitter reported by honest clients, this causes $\leq \ell$ leaked end nodes. Otherwise, the leaked path is likely to only overlap with the prefix tree at top levels, causing few leaked end nodes. In practice, the attack can be further mitigated by other means, such as rate limiting measures in the server $\mathcal{O}$.

Leakage comparison with [13] (Poplar). We compare with Poplar in the setting where one of its report servers is corrupted. Similar to POPSTAR, the leakage in Poplar can be captured by the report counts for the end nodes in a prefix tree. The difference, however, lies in how each measurement s maps to a path of the prefix tree.

In the main variant of Poplar, s maps to a path corresponding to itself in the clear. (In contrast, in POPSTAR, s maps to a path corresponding to $\mathsf{ODPRF}(H(s))$.) The leakage to the corrupted server reveals the counts of heavy hitter pre-

fixes of reported measurements, which can sometimes be dangerous. Consider an example borrowed from [18], where the measurements are country names, and a heavy hitter is `'united states'` with count 4. A leaked prefix `'united'` with a count 5 indicates the existence of a non-heavy hitter among only a few possibilities (e.g., `'united kingdom'`).

In the (slower) hashing variant ([13], Appendix B) of Poplar, s maps to a path corresponding to a public hash $H(s)$. The leakage only reveals the counts of heavy hitter prefixes of *hashes* of the measurements, which is much safer. Still, a possible attack from the corrupted server is to locally evaluate $H(\cdot)$ and try matching possible measurements to the leaked prefixes. Such an attack is impossible in POPSTAR because the corrupted server $\mathcal{S}$ cannot evaluate ODPRF locally.

Finally, we briefly note that in Poplar, a corrupted report server may actively, and adaptively, cause nodes on the prefix tree to leak. This is because the prefix tree is interactively reconstructed from the root by the two servers. For each node with count $> t$, the servers continue to reconstruct its two children. A corrupted server may arbitrarily inflate the count of any node, causing its two children to be leaked. The only restriction is that the total (inflated) counts of each level cannot exceed M.

7.3 Adding Differential Privacy Heuristically

In the setting where each client reports only its measurement without any associated messages, we propose a heuristic mechanism that we conjecture satisfies a meaningful notion of differential privacy [5] for sufficiently large M and when the threshold $t = O(M)$ is a constant fraction of M. We leave it as an important open question to analyze this method, and/or to provide attacks.

The idea is to let each client, in addition to the report of its actual measurement, send up to two fake reports:

1. with probability $p = O(1/M)$, send a fake report of its measurement (i.e., reporting the same measurement twice);
2. send a fake report of a random λ-bit measurement.

For a measurement with an actual count c, the fake reports may inflate the count to $c' = c \cdot (1+p) + O(\lambda)$. To counteract the inflation, we increase the original threshold t to $t' = t \cdot (1+p) + O(\lambda)$.

We provide some intuitions for the conjectured privacy. First consider a report of some measurement s with an (inflated) count $c' > t'$. The leakage with respect to this report is exactly the count c', which contains at least a noise of $\mathsf{Bin}(t,p) = \mathsf{Bin}(O(M), O(1/M))$ contributed by the type-(1) fake reports, where $\mathsf{Bin}(t,p)$ denotes the binomial distribution with t trials and probability p.

[5] The mechanism may still reduce the leakage to a corrupted server $\mathcal{S}$ even if we can not prove it provides differential privacy.

Next consider a report of some s with a count $c' \le t'$. The leakage with respect to this report is the count on a leaked inner node at some depth d. If c' is still relatively large, $c' > t'/2$, then the leakage still contains at least a noise of $\mathsf{Bin}(t/2, p) = \mathsf{Bin}(O(M), O(1/M))$.

If the count c' of s is small, $c' < t'/2$, we will argue that with $1 - O(\lambda/M)$ probability, the leaked inner node is at a low depth $d < \log(4M)$. In this case, each type-(2) fake report of a random measurement has a chance $2^{-d} > 1/(4M)$ of being mapped also to this leaked node. They contribute to at least a noise of $\mathsf{Bin}(M, 1/(4M)) = \mathsf{Bin}(O(M), O(1/M))$ to the leaked count of the inner node.

It remains to analyze the probability that the leaked inner node for s has depth $d > \log(4M)$. Recall that such a leaked inner node is a child of a revealed parent node at depth $d - 1 > \log(2M)$. Multiple measurements, including s, with a total count $> t'$ are mapped to this parent node. That is, s is mapped onto the same length-$(d-1)$ path together with other measurements with a total count of $> t'/2$. We further distinguish two cases, at least one of which must happen.

1. More than λ other measurements are mapped to the length-$(d-1)$ path together with s. Let this number be $k > \lambda$. Then this case happens with probability $\binom{M}{k}/2^{(d-1)\cdot k} < (M/2^{(d-1)})^k < 2^{-k} < 2^{-\lambda}$.
2. At least 1 other measurement with count $> t'/(2\lambda)$ is mapped to the length-$(d-1)$ path together with s. As there are at most $M/(t'/2\lambda) = O(\lambda)$ such measurements, this case happens with probability $O(\lambda)/2^{d-1} = O(\lambda/M)$.

In summary, for a report of some measurement s, the relevant leakage in our system is the number of actual report of s plus at least a binomial noise of parameter $\mathsf{Bin}(O(M), O(1/M))$ contributed by the fake reports. We conjecture that such noises are enough to hide the contribution of any single report.

8 Evaluation

We implement (in C++) the clients and the report server $\mathcal{S}$ following the (non-robust) protocol in Figure 2 and 3.

Below we report performances of the components in POPSTAR and compare them with prior threshold reporting systems STAR [18] and Poplar [13].

8.1 Implementation Details

Concretely, we choose $\mathbb{F} = \mathrm{GF}(2^{128})$, and use the NTL [6] library for polynomial evaluation and interpolation over $\mathbb{F}$.

We use SHA-256 to implement the two hash functions H_s, H_p in the protocol, and use AES-GCM with

[6] https://libntl.org/

128-bit keys to implement the symmetric key encryption scheme $(\mathsf{Enc}, \mathsf{Dec})$. To ensure the encryption scheme is key-committing [2], we always append a 96-bit vector $\mathbf{0}$ to the encrypted messages. We use the CryptoPP [7] library for the above cryptographic primitives.

We use the half-gate GC scheme of [34] and the actively secure OT scheme of [15] to implement our ODPRF and OPRF protocols. We use existing implementations from the emp-toolkit library. [8]

All benchmarks are run using a desktop machine with 32 Gigabyte of memory and a Ryzen 7 3800x CPU. Our prototype implementations run only on a single thread. For computation time measurements, we report the average over 10 experiment runs.

Client measurement sampling. We follow the same sampling process as in [18] (STAR) to sample measurements from a Zipf power-law distribution with a support of $N = 10,000$ and parameter $s = 1.03$. Each client's report contains a sampled 256-bit measurement and a 256-byte message.

Choosing the leakage parameter ℓ. Concretely, we benchmark three choices. As discussed in Section 7.2, choosing $\ell = 16$ is optimal for the setting of $1,000,000$ reports sampled from a Zipf power-law distribution with a support of $N = 10,000$ and parameter $s = 1.03$. We also benchmark a more aggressive choice $\ell = 8$, and a more conservative choice $\ell = 32$, which will be suitable when the reports are sampled from much smaller and larger supports respectively.

8.2 Communication Costs

Each client's communication with the server $\mathcal{O}$ consists of two parts: (1) receiving garbled circuits (GC) for double-PRF and PRF evaluations $v^{(1)}, \ldots, v^{(d)}$, and u; (2) running λ 1-out-of-2 OT with λ-bit strings as the receiver to obtain input keys K_x for evaluating the GCs.

Part (1) has size $1638 \cdot (\ell + 2) \cdot 2 \cdot \lambda$ bits using LowMC [3] as our choice of PRF, and [34], our choice of GC. Part (2) is much smaller compared to the former. We report concrete GC sizes in Table 2.

Each client's communication with the server $\mathcal{S}$ consists only of its report, which contains two field elements in the clear, ℓ encryptions of field element and tag pairs, and a final encryption of the client's measurement and message. We report concrete report sizes in Table 2.

8.3 Computational Costs

Client computation time. Client computation has two parts (Figure 2, and 4): (1) evaluating the GCs received from the server $\mathcal{O}$; (2) computing its report using the evaluations.

[7] https://www.cryptopp.com/

[8] https://github.com/emp-toolkit

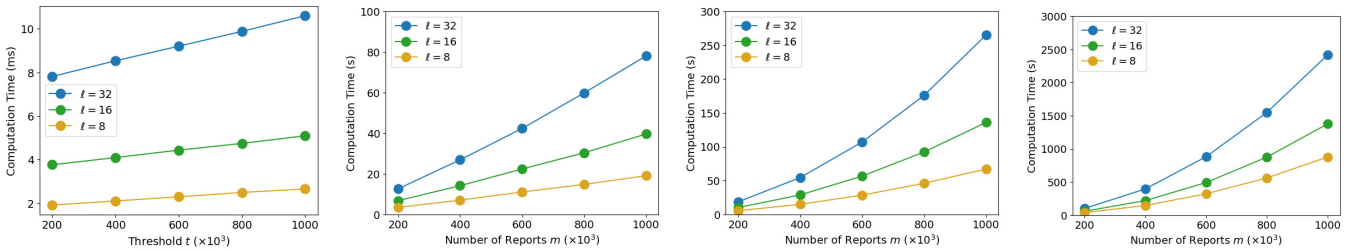
	$\ell = 8$	$\ell = 16$	$\ell = 32$
GC size (MB)	0.50	0.90	1.70
Report Size (KB)	0.93	1.49	2.62

Table 2: Communication sizes of a client with the randomness server $\mathcal{O}$ (first row), and with the report server $\mathcal{S}$ (second row).

	Client interaction w/ $\mathcal{O}$	Client com. w/ $\mathcal{S}$	Client local comp.	Server $\mathcal{S}$ comp.
STAR	1 round	0.45 (KB)	0.33* (ms)	20 (s)
POPSTAR	2 rounds	1.49 (KB)	4.82 (ms)	136.1 (s)

Table 3: Comparison between STAR (with 129-bit field) and POPSTAR (with $\ell = 16$) for 1 million reports and a threshold $t = 1,000$ (0.1%). The client computation time (*) for STAR excludes the VOPRF verification time.

The cost of (1) are $1.7/3.4/7.1$ ms when $\ell = 8/16/32$ respectively. We benchmark the cost of (2) for thresholds $t = 200$ to $t = 1,000$, i.e. 0.1% of $200,000$ to $1,000,000$ reports, and plot the combined computation cost of both steps in Figure 9a. We observe the computation cost of (2) increases linearly with t, which comes from expanding the double PRF and PRF evaluations $v^{(1)}, \ldots, v^{(\ell)}, u$ into degree $t+1$ polynomials, and computing their evaluations at a random point.



Server computation times. The computation cost of the server $\mathcal{O}$ consists mainly of preparing garbled circuits for each client. The costs per client are $1.9/4.1/8.4$ ms when $\ell = 8/16/32$ respectively, and don't depend on the total number of reports or the threshold. We benchmark the computation cost of the server $\mathcal{S}$ for aggregating $m = 200,000$ to $m = 1,000,000$ reports, and with thresholds at 0.01%, 0.1%, and 1% respectively. The results are plotted in Figure 9.

Computation costs of OT. The above computation times for each client and the server $\mathcal{O}$ exclude the costs of running $\lambda = 128$ OTs where the client is the receiver and the server $\mathcal{O}$ is the sender. Assuming the state-of-art protocol of [15], the main computation costs are 2λ and $2 + \lambda$ group exponentiations for the receiver and the sender respectively.

While the computation costs of group exponentiations are significant (6.5 ms for the client and 5.8 ms for the server $\mathcal{O}$), we argue that they are categorically different from the rest of the costs that we benchmark. The OT protocol consists of two round trips, [9] and the group exponentiations happen in between. In the end-to-end running time of λ parallel OT protocols, the computation times are insignificant compared to the network latency (e.g., $\sim 50ms$ between AWS datacenters). [10] In contrast, the rest of the computations we

[9] The first sender OT message in the protocol of [15] can be reused across different OT instances. Assuming a PKI setup where every client learns this message from the server $\mathcal{O}$, we only need 1 round trip for each OT protocol.

[10] According to https://www.cloudping.co/grid.

(a) Client report generation time. (b) Server comp. time, $t = 100$. (c) Server comp. time, $t = 1000$. (d) Server comp. time, $t = 10000$.

Figure 9: The computation times for each client and the report server $\mathcal{S}$.

benchmark above happen entirely locally. Finally, we note that the group exponentiations during λ OT protocols can be completely parallelized via multi-threading to increase throughput.

Computation costs of GC. We also note the cost of GC can be further reduced as our ODPRF protocol repeatedly garbles a fixed circuit, and some of the costs in managing the XOR gates are due to the generic nature of emp-toolkit. Instead of reading from a data structure in memory to determine the next gate to garble, a more optimized implementation can hard-code the circuit to avoid memory access costs.

Heavier server $\mathcal{O}$ than server $\mathcal{S}$. Throughout an aggregation session, the computation of the randomness server $\mathcal{O}$ is significantly ($\sim 70\times$) heavier than the aggregation server $\mathcal{S}$: under our main setting with 1 million reports at a 0.1% threshold and $\ell = 16$, the computation per client of the server $\mathcal{O}$ is 10 ms (4.1 ms for GC generation and 5.8 ms for OT), while that of the server $\mathcal{S}$ is 0.14 ms. (In fact, this is also true for STAR: as reported, its server $\mathcal{O}$ is $\sim 40\times$ heavier than its server $\mathcal{S}$.)

However, we believe the heavier server $\mathcal{O}$ does *not* create a bottleneck because its computation are distributed throughout an entire session as the clients asynchronously decide to make reports.

8.4 Comparing with STAR

In Table 3 we show the comparison in the setting of 1 million reports with a threshold $t = 1,000$ (0.1%) and $\ell = 16$. Overall, POPSTAR significantly reduces the leakage of STAR, at the cost of moderately increasing the computation times of each client ($\sim 15\times$) and the report server $\mathcal{S}$ ($\sim 7\times$). Each report in POPSTAR is roughly $3\times$ larger than in STAR.

Admittedly, each client's interaction with the randomness server $\mathcal{O}$ is significantly heavier in POPSTAR, both communication wise and computation wise due to our oblivious double PRF protocol based on GC and OT. However, we argue that the end-to-end running time of this interaction is bottlenecked by network latency rather than communication size or computation time. In POPSTAR, the oblivious double PRF protocol requires *two* round trips, assuming the OT protocol of [15], while in STAR the oblivious PRF protocol requires only *one* round trip. Therefore, we estimate each client's interaction with the server $\mathcal{O}$ to be $2\times$ to $3\times$ slower than in STAR. Finding a more efficient oblivious double PRF protocol is an intriguing direction for future work.

We note that in [18], the authors implemented STAR using the *partially* oblivious verifiable PRF protocol of [33]. The added verifiability in STAR lets a client detect whenever the randomness server deviates from the protocol and abort early, while the partially oblivious feature is not used. Our non-robust system uses an oblivious PRF without verifiability, hence giving up clients' ability to detect a malicious randomness server. To make the comparison fair, we exclude the verification time (0.301 ms) from the reported client computation time of STAR.

8.5 Comparing with Poplar

POPSTAR achieves a similar leakage profile to the hashing variant of Poplar ([13], Appendix B), while reducing the aggregation time dramatically. Note that the authors of [13] only benchmarked the more efficient variant without hashing. We use those reported numbers as an optimistic estimate for their hashing variant to compare with our system.

According to the benchmarking results in [13], the throughput for aggregating 1 million reports with a 0.1% threshold is $\sim 120/s$. Our randomness server $\mathcal{O}$ achieves a throughput of $100/s$, while our aggregation server $\mathcal{S}$ achieves more than $\sim 7300/s$. Comparing only the end-to-end aggregation time after all reports are collected, POPSTAR takes roughly 2 minutes while Poplar roughly 2 hours, i.e., a $\sim 60\times$ reduction. Communication wise, each client in POPSTAR needs to communicate ~ 0.9 MB while in Poplar, only 70 KB, i.e. a $\sim 13\times$ increase.

Again, we stress that we view the stateless nature of the server $\mathcal{O}$ and the decoupling between the two servers a much bigger benefit of POPSTAR.

9 Related Work

We briefly discuss alternative approaches (that do not rely on generic MPC) to privately compute heavy hitters.

Single server aggregation. Single server aggregation systems [8, 9, 12, 26, 27] allow the server to securely compute the sum of the clients' inputs. Melis et al. [28] shows that these systems can compute approximate heavy hitters using the count-min sketch data structure [16]. A drawback of these systems is that aggregation requires multiple rounds of interaction, hence need to tolerate client dropouts.

Out-sourced MPC. A common paradigm is to let each client secret share its input to multiple (≥ 2) servers, who then run a secure protocol to compute the heavy hitters. A subclass of such systems [1, 13, 17] (with two non-colluding servers) is formulated in [19] as verifiable distributed aggregation functions (VDAF). Their server protocols involve (1) a parallelizable phase where the shares are verified, and (2) a final phase where heavy hitters are computed. Other systems that do not fit the VDAF model include [7, 31, 32] (with two servers), and [11, 20, 23, 29] (with three servers). A challenge in deploying these systems is enlisting external entity(s) trusted not to be colluding, and willing to interact during the aggregation protocols.

Two non-communicating servers. STAR [18], as well as POPSTAR, involve two non-colluding servers that do not communicate with each other. One server, upon requests, provides randomness for clients to compute their reports. The other receives reports from the clients and computes the heavy hitters locally. To break the link between reports and clients, an abstract mixing server may be implemented as a buffer between the clients and the report server.

Randomized response. The systems for private analytics based on randomized response [5,6,14,30,35,36] involve each client just sending a message to a single server. A downside of these systems is that the clients' messages leak a non-negligible amount of information about their private inputs.

10 Conclusions

In this work, we have introduced POPSTAR, a threshold reporting system in the two server model, following the same architecture as STAR [18], and reducing its leakage at a moderate cost. Our prototype implementation is able to aggregate 1 million reports in ~ 2 minutes (roughly $7\times$ longer than STAR, but still within feasible range).

We provide an ideal functionality definition that captures the leakage in POPSTAR precisely, and a heuristic evaluation of this leakage profile. However, we believe further leakage analysis (both for POPSTAR and for STAR/Poplar) is needed to better understand leakage-abuse attacks. We pose this as an important open direction for future work which goes beyond the scope of this work.

Abstract

We consider the problem of publicly verifiable privacy-preserving data aggregation in the presence of a malicious aggregator colluding with malicious users. State-of-the-art solutions either split the aggregator into two parties under the assumption that they do not collude, or require many rounds of interactivity and have non-constant verification time.

In this work, we propose mPVAS, the first publicly verifiable privacy-preserving data aggregation protocol that allows arbitrary collusion, without relying on trusted third parties during execution, where verification runs in constant time. We also show three extensions to mPVAS: mPVAS+, for improved communication complexity, mPVAS-IV, for the identification of malicious users, and mPVAS-UD, for graceful handling of reduced user availability without the need to redo the setup. We show that our schemes achieve the desired confidentiality, integrity, and authenticity. Finally, through both theoretical and experimental evaluations, we show that our schemes are feasible for real-world applications.

1 Introduction

Data aggregation refers to the collection of data from one or more sources and its processing by a central *aggregator* for statistical analysis. These protocols find applications in many situations concerning sensitive data, such as automated power delivery and balancing mechanisms in smart grids [15, 11], patient monitoring [44], and mobile computing [23, 41]. While the benefits brought by data aggregation are evident, without proper countermeasures, they may represent a threat to the privacy of users [17, 33, 24]. Malicious actors could exploit the collected data to profile or track users' activities, social status, religious beliefs, and medical conditions [17, 33, 24]. Therefore, data aggregation protocols should guarantee users' privacy in the presence of malicious actors.

Drawbacks of current solutions. "Classical" privacy-preserving data summation protocols [13, 40, 28] assume that participants are honest-but-curious: They follow the protocol but may try to infer others' sensitive information. When users may also attempt to influence the correctness of the output, zero-knowledge proofs can be used to prove that users' inputs are well-formed [14, 26]. When aggregators may influence correctness, the problem is more difficult. The aforementioned protocols typically assume that the legal and reputational consequences of malicious behavior deter the aggregator from publishing a forged aggregate. However, without efficient methods to actually detect such tampering, these protocols may fail to prevent malicious behaviour.

A simple technique to detect tampering by the aggregator is to have each user sign their submitted value. However, this incurs high verification costs as possibly thousands of signatures need to be verified in applications with many users. A more common technique adopted in the literature is to make only the result of the aggregation verifiable using using privacy-preserving verifiable summation protocols [30, 35, 3, 21, 45, 22]. Unfortunately, both solutions fail to guarantee unforgeability when the malicious aggregator may collude with malicious users.

To the best of our knowledge, only three works have considered privacy-preserving verifiable summation against a malicious aggregator colluding with malicious users [34, 29, 37]. Leontiadis and Li [29] and Mouris and Tsoutsos [34] both assume a two-aggregator model in which at most one aggregator may collude with malicious users. Unfortunately, as we describe in Section 3.3, the work by Leontiadis and Li [29] contains a mistake that breaks unforgeability. Finally, Ren et al. [37] propose a single-server protocol in which the aggregate is hidden from the aggregator. Unfortunately, their protocol fails to provide confidentiality for small plaintext spaces, and verification time is linear in the number of users.

Contributions. We present mPVAS, the first privacy-preserving publicly verifiable summation protocol that allows for arbitrary collusions between a malicious aggregator and malicious users, requiring only a single server and constant-time verification. Note that data poisoning attacks from the users are outside the scope of this paper.

Our contributions can be summarized as follows.

- We propose a publicly verifiable aggregate signature scheme considering malicious users and aggregators (mPVAS), a novel signature scheme that allows users to sign their reports and compute a signature over the sum of the private values.
- We present three extensions to mPVAS. mPVAS+ reduces communication overhead in a slightly weaker adversarial model, mPVAS-IV allows the detection and removal of malicious users, and mPVAS-UD allows users to exit the protocol without necessitating a new setup phase for the other users.
- We provide theoretical evaluations of the security and performance of our protocols, as well as a practical analysis of their performance using a proof-of-concept implementation. Our results show that mPVAS and its extensions are practical for real-world scenarios.

Outline. In Section 2, we present the system model and our assumptions. In Section 3, we discuss related works. In Section 4, we introduce the building blocks of our schemes. In Section 5, we introduce mPVAS. In Section 6, we introduce mPVAS+, which reduces communication complexity. In Section 7, we introduce mPVAS-IV, which adds input validation to combat malicious users. In Section 8, we introduce mPVAS-UD, which adds support for user dropouts. In Section 9, we evaluate all four protocols. Finally, in Section 10, we present our conclusions.

2 System Model and Assumptions

The goal of our protocol is to publish the (authenticated) sum of all users' private values in round t, subject to two properties: individual users' values remain unknown to other parties *(confidentiality)*, and the published sum is guaranteed to match the true sum *(unforgeability)*. Note that unforgeability implies both integrity and authenticity [42].

We assume all adversaries are probabilistic and polynomially time-bounded. Furthermore, similar to related work [3, 29], we assume availability: Parties do not intentionally try to make the protocol fail (denial of service), and do not unexpectedly drop out. We loosen this assumption in Section 7 and Section 8, where we provide extensions for availability.

The following parties participate in the protocol.

Aggregator. The aggregator collects users' inputs and signatures, and publishes the input sum and an aggregate signature of the sum. The aggregator is malicious and may collude with other malicious parties. That is, the aggregator may deviate from the protocol in arbitrary ways, for example to learn users' private values, tamper with signatures, or publish an incorrect aggregate.

Users. We consider a set of n users $\mathbb{U} = \{1, 2, \ldots, n\}$. In any round t, each user $i \in \mathbb{U}$ holds some private integer $x_{i,t}$. We assume at most $k \leq n-2$ users are malicious and may collude with the aggregator. The remaining $n-k \geq 2$ users are honest-but-curious; these users follow the protocol, but may still try to obtain private data without colluding. Finally, all users have access to a synchronized clock indicating the current round t.

Verifier. Verifiers check that the aggregator's published output is correct. Any party may be a verifier; this includes external auditors, the aggregator, users, the dealer, and system administrators. We assume there is at least one verifier.

Dealer. We require a trusted dealer to set up the system, similar to nearly all related works [30, 35, 3, 21, 45, 22, 29, 37]. Though a fully trusted party is a strong assumption, we argue that it is feasible in relevant applications such as smart grids and medical data sharing, where the role can be fulfilled by a trusted institution or hardware manufacturer. The dealer is tasked with generating and distributing the public and private parameters to the other parties. After the setup, the dealer exits the protocol.

Communication. The dealer and aggregator both have direct communication channels with all users and verifiers, and with each other. These channels provide secrecy, authenticity, and integrity. Users cannot interact with each other directly but can ask the aggregator to forward messages for them.

3 Related Work

There is a large body of work on privacy-preserving computation. In this section, we discuss why these works cannot be trivially adapted to the adversarial model presented in Section 2. In Section 3.1, we briefly discuss protocols for general verifiable computation. Then, in Section 3.2, we discuss protocols for non-verifiable summation. Finally, in Section 3.3, we discuss protocols for verifiable summation, which we also summarise in Table 1.

3.1 General verifiable computation

In general verifiable computation [18], the aggregator computes an arbitrary function over users' data, while learning neither the function nor its inputs. Users can verify that the output is correct, without learning others' values.

Gordon et al. [19] prove that general verifiable computation is impossible if the aggregator colludes with users, even when only a single user colludes, this user is honest-but-curious, and the protocol uses a trusted setup. Therefore, general verifiable computation is not a suitable solution for our adversarial model. Note that since the above impossibility result requires that the function remains private, this does not preclude verifiable privacy-preserving summation in this adversarial model.

3.2 Non-verifiable summation

Privacy-preserving summation [28, 40, 7, 5] ensures confidentiality and availability in a variety of adversarial models.

Table 1: Overview of privacy-preserving verifiable summation works and their properties. The symbols ○, ◑, and ● respectively denote that a property is not, is partially, or is fully achieved by a particular work. The symbol – denotes that a property is not applicable. We abbreviate "aggregator" to "agg."

[1] Also includes public-key infrastructure and common reference string. [2] Requires trusted party in all phases of protocol. [3] Exactly one (trusted) verifier. [4] May collude with at most one aggregator. [5] Requires public ledger in all phases of protocol.

However, these works are not verifiable. That is, if a malicious aggregator publishes an arbitrary value as the sum, this cannot be detected by other parties. Therefore, these protocols are insufficient when the aggregator has an incentive to lie.

3.3 Verifiable summation

With privacy-preserving verifiable summation, the aggregator's output can be proven to be the sum of users' inputs.

We first discuss protocols for honest-but-curious users and then discuss protocols for malicious users. The aggregator is necessarily assumed malicious. We restrict our discussion to the verification techniques, ignoring the protocols' summation mechanisms. We summarise our results in Table 1.

Honest-but-curious users. Given honest-but-curious users and a malicious aggregator, the aggregator must prove that the published sum indeed corresponds to the users' inputs.

Early works [30, 35, 3] rely on a shared secret between the users and the verifier to ensure only authenticated parties can sign, and rely on a signature key that is secret-shared between the users to ensure a signature is valid only if all users are included. These protocols cannot ensure unforgeability when the aggregator colludes with honest-but-curious users, because if a user sends the aggregator the shared secret used for authentication, the aggregator can homomorphically modify valid signatures.

Recent works [21, 45, 22] use the same high-level ideas, but combine this with the non-verifiable summation protocol of Bonawitz et al. [7] to achieve reliability when users unexpectedly drop out. Each of these works similarly cannot ensure unforgeability when the aggregator colludes with users. We point out to interested readers that two of the above works have received security fixes [20, 32]. There are more works that achieve privacy-preserving verifiable summation with honest-but-curious users, but none that do not fit the above general descriptions.

Malicious aggregator and malicious users. To the best of our knowledge, only a few works tackle the problem of privacy-preserving verifiable summation with a malicious aggregator *and* malicious users.

Leontiadis and Li [29] propose the addition of a new honest-but-curious party, the converter. Users work with the converter to create homomorphic commitments of their data based on shares of the verifier's secret key. The aggregator then aggregates users' private data and their commitments (respectively), and sends both to the verifier. Finally, the verifier checks that the aggregation was done correctly. Unfortunately, this protocol is not truly publicly verifiable, since the verification key cannot be shared with users of the protocol. Furthermore, if a user, aggregator, and converter collude, unforgeability no longer holds. Finally, it appears that the protocol is flawed: If a malicious user sends the converter a commitment to 0 and the user then forwards the converter's response to the aggregator, the aggregator can create arbitrary valid signatures.

Mouris and Tsoutsos [34] propose splitting the aggregator into two parties: a curator and an analyst. Both may be

malicious, but they do not collude, and only the analyst has the decryption key for the aggregate. Users homomorphically encrypt their data and send it to the curator, and publish a homomorphic commitment to the ciphertext on a public ledger. The curator verifies that the received ciphertexts correspond to the commitments on the public ledger, and then publishes an aggregate ciphertext and an aggregate commitment on the public ledger. Finally, the analyst verifies the aggregate commitment, decrypts the aggregate ciphertext, and publishes the aggregate data together with a proof of correct decryption on the public ledger. The protocol requires that the curator and analyst do not collude; otherwise, the protocol cannot guarantee confidentiality and unforgeability. Furthermore, users colluding with the curator may affect correctness.

Ren et al. [37] propose a summation protocol that provides confidentiality, unforgeability, and availability against a malicious aggregator colluding with a malicious subset of clients. The protocol has four major drawbacks. First, only the users learn the obtained sum, whereas the aggregator learns nothing. Second, only participating users can verify the obtained sum, and there is no trivial extension to allow external parties to learn and verify the sum. Third, if the plaintext space is small (as in verifiable summation for smart meters [40, 30]), confidentiality can be broken by brute-forcing commitments. Finally, verification time is linear in the number of users.

4 Preliminaries

Before we present mPVAS in Section 5, we introduce its basic building blocks. We follow the definitions in [27].

Bilinear pairings. Given cyclic groups $\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T$, each of the same prime order p, a bilinear pairing is a function $e\colon \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_T$ such that, for any $g_1 \in \mathbb{G}_1$, $g_2 \in \mathbb{G}_2$ and $a, b \in \mathbb{Z}_p$,

$$e(g_1^a, g_2^b) = e(g_1, g_2)^{ab}. \tag{1}$$

Furthermore, $e(g_1, g_2)$ should be a generator of $\mathbb{G}_T$, and e should be efficiently computable. This excludes so-called degenerate bilinear pairings, in which $e(g_1, g_2) = 1$ for all $g_1 \in \mathbb{G}_1$ and $g_2 \in \mathbb{G}_2$. Finally, we assume that the SXDH assumption [2] holds, i.e. that the decisional Diffie-Hellman assumption holds in both $\mathbb{G}_1$ and $\mathbb{G}_2$, and that there exist no efficiently computable homomorphisms between the two.

Zero-knowledge proof of equality between commitments. We describe ZKPEq, a zero-knowledge proof that two different Pedersen commitments share the same committed value. Formally, given commitments $\mathcal{C}(x, r_1)$ and $\mathcal{C}(x, r_2)$, ZKPEq proves the relation

$$\{(x, y, z)\colon S = g_1^x h_1^{r_1} \wedge T = g_2^x h_2^{r_2}\}. \tag{2}$$

This proof can be implemented as an EQ-composition on the common witness x of two Okamoto protocols [36] running in parallel [39]. ZKPEq can be made non-interactive using the Fiat-Shamir heuristic [16].

5 mPVAS: Publicly Verifiable Aggregate Signatures with Malicious Users and a Malicious Aggregator

We present mPVAS, a novel aggregate signature scheme for summations. mPVAS can be used to verify that the output of a separate summation protocol was not tampered with by the aggregator. The core idea behind mPVAS is to create commitment-like signatures of the inputs and wrap each signature under a common secret exponent s, similar to other verifiable schemes [3, 30, 31]. Unlike other schemes, however, we allow users to collude with the aggregator by revealing their private parameters. mPVAS guarantees unforgeability of the aggregate signature given at most k malicious users. To achieve this, we use Shamir secret sharing over s with a threshold of $k+1$.

mPVAS runs in *four phases*: setup, signing, aggregation, and verification. During setup, the participants interactively determine the scheme's public and private parameters. During signing, users cooperatively calculate signatures of their inputs to a separate summation protocol. During aggregation, the aggregator combines users' signatures into a single signature. Finally, during verification, verifiers compare the aggregate signature with the summation protocol's output.

mPVAS provides only an aggregate signature and, for large plaintext spaces, must operate adjacent to a separate privacy-preserving summation scheme. The order of operations is that mPVAS runs up to (but excluding) verification, then the summation protocol reveals the sum and, finally, mPVAS verifies correctness. Alternatively, if the plaintext space is small enough, the sum can be extracted in polynomial time from the aggregate signature itself by repeated verification on all possible values.

Data poisoning attacks are outside the scope of this paper. However, range proofs can be used during the signing phase of the protocol to partially mitigate these types of attacks.

5.1 Setup

During the setup, the trusted dealer chooses and publishes the public parameters $pp = (H, H_1, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2, e, p, n, k)$, generated according to a strong security parameter λ. Each $\mathbb{G}_i$ is a cyclic group of order p, where p is a large prime number. g_1 and g_2 are random generators of $\mathbb{G}_1$ and $\mathbb{G}_2$, respectively. $e\colon \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_T$ is a type-3 bilinear pairing in which the Symmetric External Diffie-Hellman (SXDH) [2] assumption holds. Furthermore, $H\colon \{0,1\}^* \to \mathbb{G}_1$ and $H_1\colon \{0,1\}^* \to \mathbb{G}_1$ are two distinct and cryptographically-secure hash functions. Finally, n is the number of users, and $k \leq n-2$ is the maximum number of malicious users.

The dealer assigns each user a unique identifier $i \in \{1 \ldots n\}$, chooses a secret $s \leftarrow\!\!\$\, \mathbb{Z}_p$, and creates n secret shares $[s]_i$ using $(k+1)$-out-of-n Shamir secret sharing. Recall that each Shamir secret share consists of a coordinate (x_i, y_i) on the 2D

plane. The dealer ensures that the x-coordinates correspond exactly to the user identifiers, and defines $[s]_i = y_i$. Next, for each $i \in \{1 \dots n\}$ and each $j \in \{1 \dots k+1\}$, the dealer chooses encryption key $ek_{i,j} \leftarrow\$ \mathbb{Z}_p$, but sets the last encryption key to

$$ek_{n,k+1} = -\sum_{i=1}^{n}\sum_{j=1}^{k} ek_{i,j}. \tag{3}$$

It follows that the sum of all encryption keys is 0. The dealer then sends $(pp, i, [s]_i, \{ek_{i,j} \mid 1 \le j \le k+1\})$ to the corresponding user i.

Each user i generates a signature key $sk_i \leftarrow\$ \mathbb{Z}_p$ and sends it to the dealer.

Once all n signature keys have been received, the dealer calculates the verification key tuple

$$vk = \left((g_2^s)^{\Sigma_{i=1}^n sk_i}, g_2^s\right), \tag{4}$$

sends (pp, vk) to each verifier, and then leaves the protocol.

5.2 Signing

User i creates a signature of their private input $x_{i,t}$ in round t of the summation protocol using the following interactive four-step procedure.

1) Create initial signature. User i computes their initial signature for round t as

$$\sigma_{i,t}^1 = H(t)^{sk_i} g_1^{x_{i,t}} \in \mathbb{G}_1. \tag{5}$$

and sends it to the aggregator.

2) Create partial signatures. The aggregator forwards the initial signature tuple of each user i to an arbitrary[1] set $\mathcal{U}_i$ of k users other than user i. We call $\mathcal{U}_i$ the signing set of user i. The aggregator also sends the list of identifiers $\mathcal{U}_i$ to user i. After receiving the initial signature of user i, each user $j \in \mathcal{U}_i$ computes

$$\sigma_{i,t}^{2,j} = H_1(t)^{ek_{j,i}} (\sigma_{i,t}^1)^{[s]_j^*} \tag{6}$$

$$= H_1(t)^{ek_{j,i}} (H(t)^{sk_i} g_1^{x_{i,t}})^{[s]_j^*} \in \mathbb{G}_1, \tag{7}$$

where (in a minor abuse of notation) $ek_{j,i}$ denotes the encryption key that user j chooses to uniquely associate with user i, and $[s]_j^*$ denotes the partial reconstruction of user j's Shamir secret share of s, computed via interpolation by multiplying $[s]_j$ with the Lagrange basis polynomial corresponding to user j. User j then sends $\sigma_{i,t}^{2,j}$ to the aggregator.

3) Sum secret shares. Once the aggregator has received k partial signatures $\sigma_{i,t}^{2,j}$ for user i, the aggregator combines the shares in the exponent by computing

$$\sigma_{i,t}^3 = \prod_{j \in \mathcal{U}_i} (\sigma_{i,t}^{2,j}) = H_1(t)^{\Sigma_{j \in \mathcal{U}_i} ek_{j,i}} (\sigma_{i,t}^1)^{\Sigma_{j \in \mathcal{U}_i} [s]_j^*} \tag{8}$$

$$= H_1(t)^{\Sigma_{j \in \mathcal{U}_i} ek_{j,i}} (H(t)^{sk_i} g_1^{x_{i,t}})^{\Sigma_{j \in \mathcal{U}_i} [s]_j^*} \in \mathbb{G}_1. \tag{9}$$

[1] In our evaluation, we assume that the signing set consists of the next k users after user i when ordered by their numerical identifier.

The aggregator then sends $\sigma_{i,t}^3$ back to user i.

4) Compute final user signature. At this point, k secret shares of s have been added to the exponent. Adding one more secret share therefore reconstructs s in the exponent. User i computes the final user signature as

$$\sigma_{i,t} = H_1(t)^{ek_{i,i}} \cdot \sigma_{i,t}^3 \cdot (H(t)^{sk_i} g_1^{x_{i,t}})^{[s]_i^*} \tag{10}$$

$$= H_1(t)^{ek_{i,i} + \Sigma_{j \in \mathcal{U}_i} ek_{j,i}} (H(t)^{sk_i} g_1^{x_{i,t}})^s \in \mathbb{G}_1, \tag{11}$$

where $ek_{i,i}$ is the single remaining unused encryption key. User i submits their final user signature $\sigma_{i,t}$ to the aggregator.

Note that this signature cannot be verified using the verification key, because this key only works for aggregated signatures. This is intentional, as verifying individual user signatures would trivially allow an adversary to learn the private input of a user by brute force.

5.3 Signature Aggregation

After having received the final user signatures of all users for round t, the aggregator computes the aggregate signature

$$\sigma_t = \prod_{i=1}^{n} \sigma_{i,t} \tag{12}$$

$$= H_1(t)^{\Sigma_{i=1}^n \Sigma_{j=1}^{k+1} ek_{i,j}} (H(t)^s)^{\Sigma_{i=1}^n sk_i} (g_1^s)^{\Sigma_{i=1}^n x_{i,t}} \tag{13}$$

$$= (H(t)^s)^{\Sigma_{i=1}^n sk_i} (g_1^s)^{\Sigma_{i=1}^n x_{i,t}} \in \mathbb{G}_1. \tag{14}$$

The aggregator sends σ_t to each verifier.

Only at this point should the adjacent summation protocol reveal the sum of users' inputs.

5.4 Verification

Once the aggregator has published the sum of all $x_{i,t}$ and the aggregate signature σ_t, each verifier checks the equation

$$e(H(t), vk_1)\, e\left(g_1^{\Sigma_{i=1}^n x_{i,t}}, vk_2\right) \tag{15}$$

$$= e\left(H(t), (g_2^s)^{\Sigma_{i=1}^n sk_i}\right) e\left(g_1^{\Sigma_{i=1}^n x_{i,t}}, g_2^s\right) \tag{16}$$

$$\stackrel{?}{=} e(\sigma_t, g_2). \tag{17}$$

5.5 Security Analysis of mPVAS

We show that the verification procedure is correct, does not leak private data, and cannot be fooled into accepting an incorrect signature.

To see that verification succeeds for a correct signature, observe that

$$e(\sigma_t, g_2) = e\left((H(t)^s)^{\Sigma sk_i} (g_1^s)^{\Sigma x_{i,t}}, g_2\right) \tag{18}$$

$$= e\left((H(t)^s)^{\Sigma sk_i}, g_2\right) e\left((g_1^s)^{\Sigma x_{i,t}}, g_2\right) \tag{19}$$

$$= e\left(H(t), (g_2^s)^{\Sigma sk_i}\right) e\left(g_1^{\Sigma x_{i,t}}, g_2^s\right) \in \mathbb{G}_T. \tag{20}$$

Theorem 1. *mPVAS is Aggregator Oblivious.*

Proof. See Appendix A. ☺

Theorem 2. *mPVAS is Aggregate Unforgeable against Type-I and Type-II forgeries.*

Proof. Intuitively, because the aggregator does not know s, they cannot create a correct signature for a sum other than the published one. For the full proof, see Appendix B. ☺

6 mPVAS+: mPVAS with Lower Communication Overhead

In mPVAS (see Section 5), communication complexity is linear in the number of malicious users k. Though we assume malicious users to be in the minority, this level of interactivity may be too high for some applications. We present mPVAS+, an extension of mPVAS to significantly reduce communication complexity. Recall that we provide a runtime analysis of mPVAS and all extensions in Section 9.

We show that we can significantly decrease the communication complexity using a divide-and-conquer strategy. Intuitively, our solution works by dividing users into random groups of size $c \leq k$ and providing each group with an independent set of secret shares of s. Since each group can now individually reconstruct s in the exponent, we can eliminate cross-group communication. As long as at least one user in each group is non-malicious, adversaries cannot reconstruct s. We provide a statistical analysis that this holds in Section 6.3.

6.1 Modifications in mPVAS+

We describe how mPVAS+ differs from mPVAS.

Setup. The key difference with the setup of mPVAS (see Section 5.1) is that in mPVAS+, instead of creating a single sharing over all users, the dealer randomly assigns users to groups of size $c \leq k$ and, for each group, generates c-out-of-c Shamir secret shares of s. If c does not divide n, then n mod c arbitrary groups should have one additional user, and the secret sharing threshold of this group is adjusted accordingly. After having chosen the random secret $s \leftarrow\$ \mathbb{Z}_p$ (as in mPVAS), the dealer creates separate c-out-of-c Shamir secret shares of s for each group. Because a separate set of shares is created for each group, shares from different groups cannot be combined together. As in mPVAS, each share $[s]_i$ is sent to the corresponding user i. Furthermore, the dealer creates only nc encryption keys instead of $n(k+1)$. In mPVAS+, the list of other users in the group is additionally sent to user i.

Signing. In this phase, the only difference with mPVAS (see Section 5.2) is that the aggregator sends the initial signature $\sigma^1_{i,t}$ of each user i to the $c-1$ other users in user i's group, rather than sending them to k arbitrary other users.

Aggregation. The aggregation phase remains unchanged (see Section 5.3).

Verification. The verification phase remains unchanged (see Section 5.4).

6.2 Security Analysis of mPVAS+

Theorem 3. *mPVAS+ is Aggregator Oblivious.*

Proof. The mPVAS+ extension changes the behavior of the base mPVAS scheme. When c malicious users end up in the same group, they can collectively reconstruct s and share it with the aggregator, thus allowing it to tamper with the signatures of honest users. However, note that even with knowledge of s, the aggregator still cannot learn the private values of individual users because they are also blinded by the secret factor $H(t)^{sk_i}$. When s is known by the aggregator, the mPVAS scheme directly reduces to the PPATS scheme of [40], which is Aggregator Oblivious. ☺

Theorem 4. *mPVAS+ is Aggregate Unforgeable against Type-I and Type-II forgeries.*

Proof. The mPVAS+ scheme can be seen as multiple instances of the regular mPVAS scheme running on multiple groups of users, but with different instances of Shamir secret sharing used to generate the secret shares of s. Thus, Aggregate Unforgeability still holds following the same logic presented in Section 5.5 for the mPVAS scheme, as long as each group contains at least one honest user. We provide a statistical analysis that this requirement holds in Section 6.3. ☺

We emphasise that mPVAS+ provides Aggregate Unforgeability with k malicious users only if we assume non-adaptive corruptions. Otherwise, the security of mPVAS+ is downgraded to that of an mPVAS instance with $k = c-1$.

6.3 Statistical Analysis of mPVAS+

The communication complexity of mPVAS+ is better than that of mPVAS only if $c \leq k$. However, unlike mPVAS, in mPVAS+ it is possible that at least one group consists of adversaries only. These adversaries may then collude to retrieve private key material. We give an exact formula for this probability, and show that it can be made negligibly small.

Let n be the number of users, k the number of malicious users, c the group size, and $d = floor(n/c)$ the number of groups. We assume that c divides n exactly. Otherwise, $n-cd$ groups should be given one user more, and the following calculations give an upper bound rather than an exact value.

We calculate the probability using a combinatorial counting argument. We model the process of dividing users into groups as first dividing all n users into groups, and then randomly (non-adaptively) corrupting k users. We count the number of instances in which at least one group is fully corrupted, and

divide this by the total number of instances.[2] The total number of instances (the denominator) is simply $\binom{n}{k}$ (i.e. the binomial coefficient "n choose k"), but the number of problematic instances (the numerator) is harder to compute.

Intuitively, the numerator is the number of combinations in which *exactly* one group is fully compromised (which is d, since there are d groups), multiplied by the number of ways in which the remaining $n-c$ users can contain $k-c$ corruptions (which is $\binom{n-c}{k-c}$), *seemingly* giving the probability

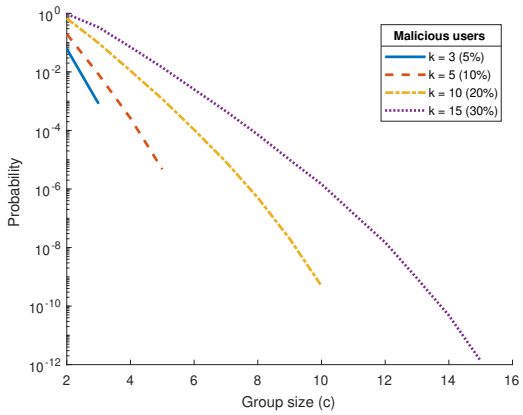
$$\frac{d\binom{n-c}{k-c}}{\binom{n}{k}}. \tag{21}$$

However, this is inaccurate, because if the remaining users also fully corrupt a group, that case is counted twice. In fact, duplicates are counted twice, triplicates are counted thrice, and, in general, r-replicates are counted r times. Luckily, by the inclusion-exclusion principle, it suffices to separately count and subtract these cases.

Let $R = floor\left(\frac{k}{c}\right)$ denote the "replicity", which is the highest order of replication. To determine the number of r-replicates, we first define a helper function that counts the number of r-replicates *after fixing which r groups are fully corrupted*:

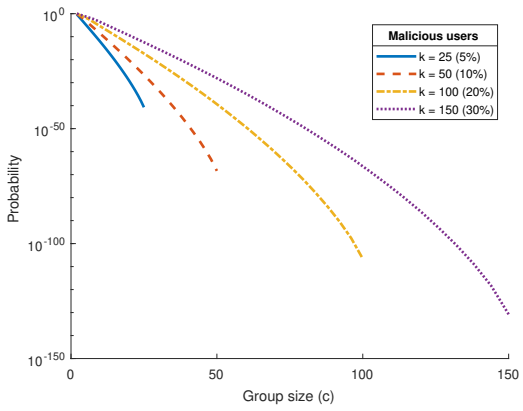
$$rep(r) = \binom{n-rc}{k-rc} - \sum_{i=r+1}^{R} \left(\binom{d-r}{i-r} \cdot rep(i) \right). \tag{22}$$

This function counts the number of ways to corrupt remaining users and then recursively subtracts higher-order replicates. The number of recursive i-replicates is found by first fixing $r-i$ additional groups and then multiplying by $rep(i)$.



We conclude that the probability that at least one group is fully corrupted is exactly

$$\frac{d \cdot \binom{n-c}{k-c} - \sum_{r=2}^{R}((r-1) \cdot \binom{d}{r} \cdot rep(r))}{\binom{n}{k}} \tag{23}$$



if c divides n, and is a strict upper bound otherwise. As in (22), for each order of replication, we multiply by the number of ways to choose r groups, and additionally multiply by $r-1$ to actually the multiply-counted items.

We visualize (23) for various values of n, k, and c in Figure 1. The figure shows that, given sufficient users, the probability of accidentally assigning only malicious users to a group can be made negligible with an appropriate choice of c. For example, with 50 users, of which 20% malicious, choosing $c = 7$ gives a probability of approximately 0.000841%, and can be made even smaller.

[2] We calculate the probability as a combinatorial problem. Modeling this as a permutation instead would require counting all possible ways to assign identity to users after fixing a specific combination. This can be done by multiplying both the numerator and denominator by $(n-k)!\,k!$. Therefore, both methods give the same result.

(a) $n = 50$

(b) $n = 500$

Figure 1: Probability that at least one group is fully corrupted in mPVAS+. Due to the logarithmic y-axis, lines end when they reach zero.

7 mPVAS-IV: mPVAS with Input Validation

We have thus far assumed that parties do not try to make the protocol fail. In this section, we present mPVAS-IV, an extension to mPVAS (see Section 5) to allow the aggregator to identify and remove users that attempt to cause an invalid aggregate signature. mPVAS-IV is fully compatible with both mPVAS+ (see Section 6) and mPVAS-UD (see Section 8).

In terms of our adversarial model (see Section 2), we loosen our assumptions on users, who may now send ill-formed messages with the intent of causing verification to fail. We model the aggregator as a service provider, who may attempt to obtain users' private data or output a falsified signature, but is expected to ensure well-formed outputs so as to not disrupt users reliant on their services. As such, the malicious aggregator may still collude with malicious users against confidentiality and unforgeability, but the aggregator acts honestly with regard to availability. Furthermore, we assume that the adjacent summation protocol ensures availability in this model, including *verified* commitments to users' summation inputs.

mPVAS-IV validates that users' inputs are well-formed, and pinpoints which user caused the invalid input. That user is then barred from participating in future instances of the protocol, and the protocol is restarted from scratch with the remaining users. In the worst case, malicious users are removed one at a time, requiring k restarts. After that, all malicious users have been removed, and users can continue additional rounds indefinitely. Therefore, whereas in mPVAS adversaries could prevent all output without end, mPVAS-IV reduces this adversarial capability to a linearly bounded overhead.

At its core, mPVAS-IV adds a mechanism to validate individual final user signatures when verification fails. However, since users may tamper with others' signatures, we must also add a detection mechanism there. Note that we do not need to validate the initial signature, since either the subsequent final user signature is valid and there is no problem to begin with, or the final user signature is invalid and is detected as such.

7.1 Modifications in mPVAS-IV

We describe how mPVAS-IV differs from mPVAS.

Setup. The setup phase of mPVAS-IV starts by running the setup phase of mPVAS (see Section 5.1). The dealer then generates additional information to perform input validation.

First, the dealer chooses g_T and h_T as random generators of $\mathbb{G}_T$, and, for each user i, generates $r_i \leftarrow\$ \mathbb{Z}_p$, and the set of values $EK_{j,i} = g_2^{ek_{j,i}}$. The dealer sends r_i, $EK_{j,i} = g_2^{ek_{j,i}}$, and g_2^s to each user i.

Next, for each user i, the dealer generates $SK_i = g_T^{sk_i} h_T^{r_i}$, $SS_i = g_2^{[s]_i}$, $EK_{j,i} = g_2^{ek_{j,i}}$, for $j \in \{1 \dots k\}$, $EKS_{j,i} = g_2^{\frac{ek_{j,i}}{s}}$, for $j \in \{1 \dots k+1\}$, and sends these values to the aggregator, along with $\nu = g_2^{\frac{1}{s}}$.

Finally, the dealer sends the additional public parameters (g_T, h_T) to all participants.

Signing. We require additional operations before and after the regular signing phase of mPVAS (see Section 5.2).

Before the regular signing phase, we require that the adjacent summation scheme outputs Pedersen commitments of the users' inputs to that summation scheme. This is to ensure consistency of the inputs between the two schemes. If mPVAS-IV is used without a separate summation scheme, the committed values should be validated using range proofs instead. Either way, let $C(x_{i,t})$ for each user i denote these commitments.

After the regular signing phase is complete, each user checks their final user signature for tampering. If tampering is detected, the user informs the aggregator, who then validates the corresponding partial signatures. If the aggregator also detects tampering, the aggregator marks the user(s) who sent that partial signature as malicious. Otherwise, if the aggregator does not detect tampering, the reporting user is instead marked as malicious. After that, the protocol restarts without the detected malicious users.

User i checks their final user signature $\sigma_{i,t}$, calculated in (10), for tampering by checking that

$$e(H_1(t), g_2^{\varepsilon_i})\, e(H(t), (g_2^s)^{sk_i})\, e(g_1^{x_{i,t}}, g_2^s) \stackrel{?}{=} e(\sigma_{i,t}, g_2) \quad (24)$$

holds, where $\varepsilon_i = \sum_{j=1}^{k+1} ek_{j,i}$. In a nutshell, the left-hand side re-calculates user i's expected final user signature under a bilinear mapping (compare with (10)), while the right-hand side bilinearly maps the actual final user signature. If (24) does not hold, the user reports this to the aggregator.

Since the aggregator forwards all partial signatures, the aggregator possesses the initial signature $\sigma_{i,t}^1$ as well as the partial signature $\sigma_{i,t}^{2,j}$ of each user $j \in \mathcal{U}_i$. Upon receiving user i's claim that their signature was tampered with, the aggregator computes for each user $j \in \mathcal{U}_i$ the value

$$\sigma_{i,t}^{2,j^*} = e\left(H_1(t), g_2^{ek_{j,i}}\right) e\left(\sigma_{i,t}^1, g_2^{[s]_j^*}\right), \quad (25)$$

where $[s]_j^*$ is as in (6), i.e. the partial reconstruction of user j's Shamir secret share of s, here calculated in the exponent of g_2 using the set SS. Finally, the aggregator validates the partial signature $\sigma_{i,t}^{2,j}$ by checking

$$\begin{aligned}
\sigma_{i,t}^{2,j^*} &\stackrel{?}{=} e\left(\sigma_{i,t}^{2,j}, g_2\right) && (26)\\
&= e\left(H_1(t)^{ek_{j,i}} \left(H(t)^{sk_i} g_1^{x_{i,t}}\right)^{[s]_j^*}, g_2\right) && (27)\\
&= e\left(H_1(t)^{ek_{j,i}}, g_2\right) e\left((H(t)^{sk_i} g_1^{x_{i,t}})^{[s]_j^*}, g_2\right) && (28)\\
&= e\left(H_1(t), g_2^{ek_{j,i}}\right) e\left(\sigma_{i,t}^1, g_2^{[s]_j^*}\right) && (29)
\end{aligned}$$

If this holds, then user j did not act maliciously; otherwise, user j is marked as malicious and expelled from the protocol. The aggregator repeats this process for all users in $\mathcal{U}_i$, as there can be more than one user behaving maliciously in a single signing set.

Aggregation. The aggregation phase remains unchanged (see Section 5.3).

We assume that the adjacent summation scheme aborts no later than this point if the Pedersen commitment $C(x_{i,t})$ of any user i does not correspond to that user's real input to the summation scheme.

Verification. The verification phase of mPVAS-IV starts by running the verification phase of mPVAS (see Section 5.4). If verification fails, the aggregator tries to find the culprit by verifying that the final user signature $\sigma_{i,t}$ of each user i matches (10). This verification entails removing the term containing the encryption keys ek and then asking user i for a zero-knowledge proof of equality between the expected and the actual value of the remaining term.

To remove the term with the encryption keys, the aggregator first computes

$$g_2^{\frac{\varepsilon_i}{s}} = \prod_{j=1}^{k+1} EK_{j,i} = \prod_{j=1}^{k+1} g_2^{\frac{ek_{j,i}}{s}} \in \mathbb{G}_2, \quad (30)$$

and then removes the term by computing

$$\sigma'_{i,t} = \frac{e\left(\sigma_{i,t}, g_2^{\frac{1}{s}}\right)}{e\left(H_1(t), g_2^{\frac{\varepsilon_i}{s}}\right)} \tag{31}$$

$$= \frac{e\left(H_1(t)^{\varepsilon_i}(H(t)^{sk'_i} g_1^{x'_{i,t}})^s, g_2^{\frac{1}{s}}\right)}{e(H_1(t), g_2)^{\frac{\varepsilon_i}{s}}} \tag{32}$$

$$= \frac{e\left(H_1(t)^{\varepsilon_i}, g_2^{\frac{1}{s}}\right) e\left(H(t)^{sk'_i} g_1^{x'_{i,t}}, g_2\right)}{e(H_1(t), g_2)^{\frac{\varepsilon_i}{s}}} \tag{33}$$

$$= e(H(t), g_2)^{sk'_i} e(g_1, g_2)^{x'_{i,t}} \in \mathbb{G}_T, \tag{34}$$

where the values of sk'_i and $x'_{i,t}$ are implied. Finally, the aggregator asks user i to prove that $sk'_i = sk_i$ and $x'_{i,t} = x_{i,t}$. User i does so by interpreting (34) as a Pedersen commitment and providing two ZKPEq proofs (see Section 4): one for proving the equality $sk'_i = sk_i$ between $\sigma'_{i,t}$ and SK_i, and another for proving equality of $x'_{i,t} = x_{i,t}$ between $\sigma'_{i,t}$ and $C(x_{i,t})$.

If mPVAS-IV is used without an adjacent summation protocol, user i must also provide a range proof (such as a Bulletproof [9]) of $x_{i,t}$ to show that their input lies in a restricted range, and that extraction of the sum from σ_t is tractable. Users that fail to send valid proofs are removed from the protocol and subsequent executions.

7.2 Security Analysis

Theorem 5. *mPVAS-IV is Aggregator Oblivious.*

Proof. The additional information received by the aggregator does not yield any advantage to breaking Aggregator Obliviousness. In fact, the secret shares the aggregator receives in the set SS cannot be efficiently extracted due to the hardness of the DLP in $\mathbb{G}_2$. The commitments contained in the set SK are hiding, thus the aggregator cannot extract the signing keys either. Furthermore, as with mPVAS, all initial and final user signatures $\sigma^1_{i,t}, \sigma^{2,j}_{i,t}, \sigma^3_{i,t}, \sigma_{i,t}$ contain the secret factor $H(t)^{sk_i}$, which perfectly hides $x_{i,t}$ in $\mathbb{G}_1$ and prevents the aggregator from exploiting the verification algorithm in (24) to find $x_{i,t}$.

The intermediate value $e(H(t), g_2)^{sk'_i} e(g_1, g_2)^{x'_{i,t}}$ from (34) is also hiding under the random oracle model. Finally, the proof ZKPEq does not leak any information about the private witness due to its zero-knowledge property. We conclude that the aggregator cannot learn the private value of honest users, and thus mPVAS-IV is Aggregator Oblivious. ☺

Theorem 6. *mPVAS-IV is Aggregate Unforgeable against Type-I and Type-II forgeries.*

Proof. See Appendix C. ☺

8 mPVAS-UD: mPVAS with User Dropouts

Requiring that all users are always online is not feasible for some applications. In this section, we present mPVAS-UD, an extension to mPVAS (see Section 5) to allow users to choose a set of rounds in which they will not participate by sending one or more recovery keys containing the necessary material that would otherwise be missing from those rounds. As with the base mPVAS protocol, mPVAS-UD works as long as at least $k+2$ users do not drop out of the protocol. mPVAS-UD is fully compatible with both mPVAS+ (see Section 6) and mPVAS-IV (see Section 7).

8.1 Modifications in mPVAS-UD

We describe how mPVAS-UD differs from mPVAS.

Setup. In addition to the regular setup of mPVAS (see Section 5.1), the dealer also sends $EK_j = g_2^{\sum_{i=1}^{k} ek_{j,i}}$, for each $j \in \{1 \dots n\}$, to all verifiers.

If mPVAS-UD is combined with mPVAS+, then the setup should be adjusted to use c-out-of-c' secret sharing instead of c-out-of-c secret sharing, where $c' \geq c$. This ensures that at most $c' - c$ users in each group can drop out without resulting in incomplete signatures. The statistical analysis in Section 6.3 still applies to c.

Signing. In any round t, before running the regular signing phase (see Section 5.2), each user i has the option of dropping out for a set of rounds $\mathcal{T}$, possibly including the remainder of the current round t. For each round $\tau \in \mathcal{T}$ from which user i would like to drop out, user i calculates a recovery key

$$rk_{i,\tau} = e\left(H(\tau)^{-sk_i}, g_2^s\right) \in \mathbb{G}_T. \tag{35}$$

User i then sends $m_i = (i \parallel \tau \parallel rk_{i,\tau})$ to the aggregator, who forwards both to the verifiers. Note that the aggregator can aggregate all recovery keys $rk_{i,t}$ together before sending them to the verifiers to save space and reduce the communication overhead.

If mPVAS-UD is used in the adversarial model of mPVAS-IV (see Section 7), we must additionally ensure that user i cannot invalidate signatures of rounds $\mathcal{T}$. Therefore, user i must prove that the recovery key is well-formed using a zero-knowledge proof that sk_i in $rk_{i,\tau}$ is the same as in the commitment $g_T^{sk_i} h_T^{r_i}$ from the setup of mPVAS-IV. Concretely, user i proves the relation

$$\{(x,y) : S = g_1^x h_1^y \wedge T = g_2^x\}, \tag{36}$$

which can be implemented and made non-interactive similar to ZKPEq (see Section 4).

The signing phase then proceeds as normal, but without the users who have opted to drop out of round t.

Aggregation. The aggregation phase remains unchanged (see Section 5.3).

Verification. The verification phase of mPVAS-UD replaces that of regular mPVAS (see Section 5.4). In round t, let $\mathcal{D}_t$ be the set of users that dropped out, and let $\mathcal{R}_t$ be the set of the remaining users. Since users $\mathcal{D}_t$ do not participate in the adjacent summation protocol of round t, the published sum should be $x_t = \sum_{i\in\mathcal{R}_t} x_{i,t}$, and the aggregate signature should similarly be over that sum. To verify that the signature σ_t is correct, the verifier uses the dropped-out users' recovery keys and checks

$$e(g_1^{x_t}, vk_2)\, e(H(t), vk_1) \prod_{i\in\mathcal{D}_t} rk_{i,t} \stackrel{?}{=} \frac{e(\sigma_t, g_2)}{e\big(H_1(t), \prod_{i\in\mathcal{R}_t} EK_i\big)}. \tag{37}$$

This is essentially a modification of (15) wherein the verifier assumes that dropped-out users input $x_{i,t} = 0$, while compensating for missing information using the recovery material. To see that correctness holds, let $\sigma'_t = (H(t)^{\sum_{i\in\mathcal{R}_t} sk_i} g_1^{x_t})^s$ be the desired signature (see (14)), recall the definition of vk from (4), and observe that on the left-hand side of (37) we find

$$e(g_1^{x_t}, vk_2)\, e(H(t), vk_1) \prod_{i\in\mathcal{D}_t} rk_{i,t} \tag{38}$$

$$= e(g_1^{x_t}, g_2^s)\, e(H(t), vk_1)\, e(H(t), g_2^s)^{-\sum_{i\in\mathcal{D}_t} sk_i} \tag{39}$$

$$= e(g_1^{x_t}, g_2^s)\, e(H(t), g_2^s)^{\sum_{i\in\mathcal{R}_t} sk_i} \tag{40}$$

$$= e\Big((H(t)^{\sum_{i\in\mathcal{R}_t} sk_i} g_1^{x_t})^s, g_2\Big) = e(\sigma'_t, g_2). \tag{41}$$

Similarly, on the right-hand side of (37), we find

$$\frac{e(\sigma_t, g_2)}{e\big(H_1(t), \prod_{i\in\mathcal{R}_t} EK_i\big)} \tag{42}$$

$$= \frac{e\Big(H_1(t)^{\sum_{i\in\mathcal{R}_t} \sum_{j=1}^{k+1} ek_{j,i}} \big(H(t)^{\sum_{i\in\mathcal{R}_t} sk_i} g_1^{x_t}\big)^s, g_2\Big)}{e\big(H_1(t), \prod_{i\in\mathcal{R}_t} EK_i\big)} \tag{43}$$

$$= \frac{e(H_1(t), g_2)^{\sum_{i\in\mathcal{R}_t} \sum_{j=1}^{k+1} ek_{j,i}}\, e(\sigma'_t, g_2)}{e(H_1(t), g_2)^{\sum_{i\in\mathcal{R}_t} \sum_{j=1}^{k+1} ek_{j,i}}} \tag{44}$$

$$= e\big(\sigma'_t, g_2\big). \tag{45}$$

9 Complexity Analysis of mPVAS, mPVAS+, mPVAS-IV, and mPVAS-UD

We evaluate the complexity of mPVAS and each of its extensions. In Section 9.1, we present the asymptotic communication complexity of our schemes, and compare this with a selection of related works. In Section 9.2, we describe our experimental setup for empirically determining runtime complexity. After that, we present the results of this analysis for mPVAS in Section 9.3, for mPVAS+ in Section 9.4, for mPVAS-IV in Section 9.5, and for mPVAS-UD in Section 9.6.

9.1 Asymptotic Communication Complexity

In Table 2, we summarize the asymptotic communication complexity of all proposed schemes and compare them with state-of-the-art protocols that consider malicious users. The dealer has to share information with every user, which leads to a complexity of $O(n)$ for all signature schemes. Users only communicate within their own signing set, for a complexity of $O(k)$, or $O(c)$ in the mPVAS+ scheme. The aggregator needs to relay messages between each user and their signing set, which leads to a complexity of $O(kn)$ for the mPVAS and mPVAS-IV schemes, and $O(cn)$ for the mPVAS+ scheme. Verifiers do not actively participate in the protocol.

Table 2: Asymptotic communication complexity per party in related works and in the mPVAS family.

Protocol	Dealer	Agg.	User	Verifier	Ledger
[29]	$O(n)$	$O(1)$	$O(1)$	-	no
[34]	$O(1)$	$O(1)$	$O(1)$	-	$O(n)$
[37]	$O(n)$	$O(n^2)$	$O(n)$	-	no
mPVAS	$O(n)$	$O(kn)$	$O(k)$	-	no
mPVAS+	$O(n)$	$O(cn)$	$O(c)$	-	no
mPVAS-IV	$O(n)$	$O(kn)$	$O(k)$	-	no
mPVAS-UD	$O(n)$	$O(kn)$	$O(k)$	-	no

The mPVAS family of protocols enjoys reduced communication complexity compared to [37], but increased communication complexity compared to [29, 34]. We note that similar schemes such as [3, 30, 29, 34], work in a different system and adversarial model where there is little to no interaction between the participants except for the initial setup. As such, the communication complexities for these schemes is $O(1)$ for both the aggregator and the users. (Similarly, the computation complexity is $O(1)$ for the users and $O(n)$ for the aggregator.) While this is better than any of the mPVAS variants, the adversarial model in these related works is also weaker than those used in our work. As discussed in Section 3, the compared schemes either assume honest behavior from the users [30, 3], no collusions between the aggregator and the users [34], or they rely on a semi-trusted party during protocol execution [34, 29]. That said, mPVAS can trivially be generalized to these alternative scenarios. For example, honest users can be simulated by choosing $k = 0$, which leads to a non-interactive scheme with $O(1)$ communication complexity and a computation complexity nearly identical to that of the

PUDA scheme [30]. Similarly, choosing $k = 1$ for mPVAS corresponds to the scheme presented in [29], which entrusts a semi-trusted third party with the secret signing key, and similarly leads to constant communication complexity.

9.2 Experimental Setup

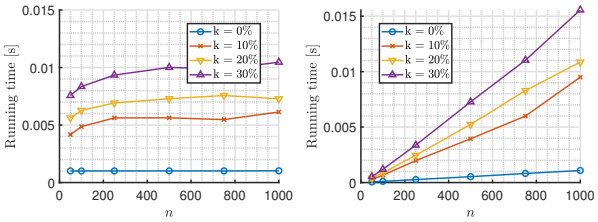
We describe the experimental setup with which we empirically determine the runtime complexity of our protocols.

We use the Charm framework [6] to develop a proof-of-concept implementation of mPVAS and its extensions. This framework is widely used for the prototyping and benchmarking of cryptographic schemes, e.g. [1, 38].

The experiments are performed over the MNT224 elliptic curve, which is pairing friendly, provides 112 bits of security [10], and allows for type-3 pairings, which are necessary for the SXDH assumption [3]. This is the most secure curve provided by the Charm framework that is compatible with our schemes. While the current recommendation is to use curves that provide 128 bits of security as a conservative choice, 112 bits is the minimum security level required by NIST for the US Federal Government [4]. In this curve, elements in $\mathbb{G}_1$ are 56 bytes, in $\mathbb{G}_2$ are 168 bytes, in $\mathbb{G}_T$ are 168 bytes, and in $\mathbb{Z}_p$ are 28 bytes [25], which we verified experimentally. The size of the elements influences the performance of the various algebraic operations performed in each group.

The experiments were run on a Threadripper 7970X CPU with 256GB of RAM. The protocol was executed sequentially on a single core without special optimizations. Messages are assumed to be delivered instantaneously, so that the measured runtime represents only the computational complexity.

9.3 mPVAS Runtime



We show the runtime of mPVAS (see Section 5) in Figure 2.

Figure 2(a) shows that, even when there are 1000 users and $k = 30\%$ of all users are malicious, the runtime is only around 0.36 seconds for a single user. As expected from an asymptotic complexity $O(k)$, the runtime decreases with the number of malicious users k.

Figure 2(b) shows a similar trend for the aggregator. Moreover, when $k = 0$, the aggregator does not have to combine partial secret sharing for every user, and the runtime dips below even that of a single user.

Finally, Figure 2(c) shows the runtime for verifiers. As expected, since a verifier only needs to compute three pairings, regardless of the number of users, runtime is constant.

9.4 mPVAS+ Runtime

(a) Single user (b) Aggregator

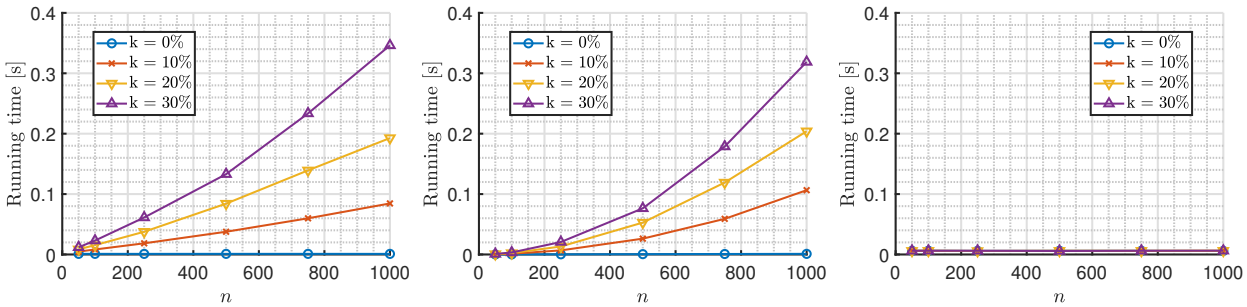


Figure 3: Experimental runtime of mPVAS+.

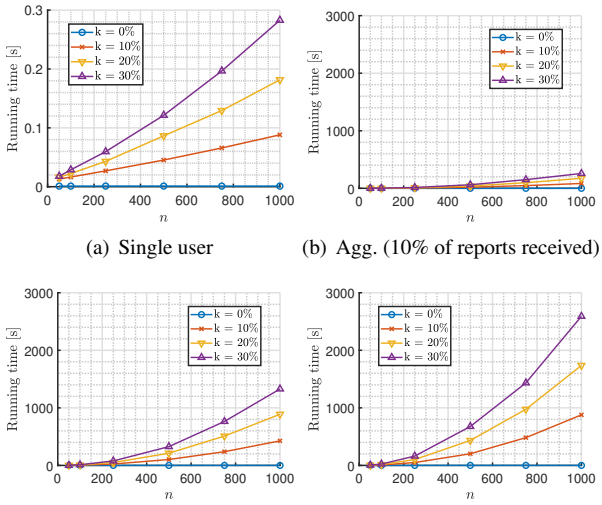
mPVAS+ (see Section 6) reduces computational complexity under well-defined probabilistic assumptions, assuming non-adaptive corruptions. We present its runtime in Figure 3.

We note that, at $k = 0\%$, mPVAS+ reduces directly to mPVAS, and complexity is independent of the number of users. For experiments with $k > 0\%$, we choose the smallest group size c such that the probability that at least on group is fully compromised is at most 10^{-5}, using our combinatorial formula in (23), giving us group sizes ranging from 5 up to 14.

We see in Figure 3(a) that, compared to mPVAS, user runtime is reduced by an order of magnitude for our choice of parameters. Since the runtime depends only on the constant c, this leads to an upper bound on the runtime. As n continues to grow, the runtime becomes apparently constant.

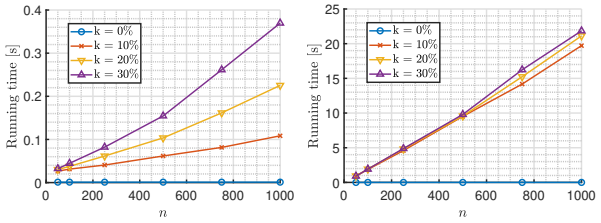
We see in Figure 3(b) that the speedup for the aggregator is similar. As in regular mPVAS, the main bottleneck for the aggregator is combining the partial user signatures as



(a) Single user (b) Aggregator (c) Verifier

Figure 2: Experimental runtime of mPVAS.

in Equation 8. (Combining the final user signatures requires negligible runtime.) Reducing the group size c affects this bottleneck directly. For example, with 1000 users, of which 30% is malicious, setting $c = 14$ means the aggregator must only aggregate $c - 1 = 13$ values per user instead of $k = 300$, reducing complexity in this part by a factor of 23.



9.5 mPVAS-IV Runtime

(a) Single user (b) Agg. (10% of reports received)

(c) Agg. (50% of reports received) (d) Agg. (100% of reports received)

Figure 4: Experimental runtime of mPVAS-IV with final user signature tampering.

(a) Single user (with proof generation) (b) Agg. checks final user signatures

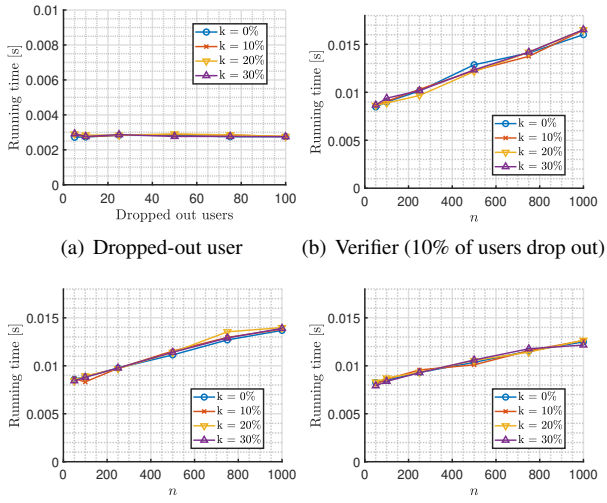
Figure 5: Experimental runtime of mPVAS-IV with aggregate signature tampering.

mPVAS-IV (see Section 6) deals with malicious users who submit malformed signatures to the aggregator. The aggregator identifies these users through several additional checks.

Since the aggregator does not know the number of malicious users beforehand, they will check all signatures in order to find every user that acted maliciously during each round.

First, we consider the case in which users obtain invalid final user signatures during the signing phase and report these to the aggregator. Figure 4(a) shows the runtime for a single user. We see that the total runtime for a single user is comparable to that of the mPVAS scheme, as there are no additional steps required from users at this stage. For the aggregator, instead, the runtime is dependent on the number of reports received and the size k of each signing set. This dependence is clearly shown in Figure 4(b), Figure 4(c), and Figure 4(d), in which we consider three cases where 10%, 50%, and 100% of users submit a report to the aggregator. In all cases, the runtime is noticeably higher than in the base mPVAS protocol. The reason for this steep increase is the additional exponentiations and pairings required to check whether each signature $\sigma^2_{j,i}$ is well formed. Moreover, these checks must be repeated for every user in a signing set in order to find every possible instance of tampering or whether the report was actually false. We remark that our implementation does not include any specific optimizations, such as parallelization. Since verification is embarrassingly parallel for the aggregator, we expect this can be sped up linearly in the number of cores.

Next, we consider the case in which malicious users submit malformed final user signatures to the aggregator. When this happens, verification of the aggregate signature fails, and the aggregator starts a procedure to identify the malicious users. The checks in this procedure must be performed on all n users, thus giving a linear complexity for the aggregator. Figure 5(a) and Figure 5(b) show the runtime for a single user and for the aggregator, respectively. We see that the runtime for the aggregator can reach up to 22 seconds on our machine. Despite the increased runtime for the aggregator, recall from Section 7 that this identification procedure is necessary only after malicious behavior has occurred. Our experiments represent the cumulative worst-case "denial of service" that malicious users can inflict on the aggregator and other users.



9.6 mPVAS-UD Runtime

In mPVAS-UD (see Section 8) there are changes in the signing phase for users that drop out and in the verification phase for the verifiers. We, therefore, focus on the runtime of those specific parties in Figure 6. In our experiments, we fixed the number of user dropouts to be 10%, 30%, and 50% of the total number of users.

Figure 6(a) shows the runtime for each dropped-out user. We find that the runtime is independent of the number of malicious users and the number of dropped-out users, which is expected since the protocol is non-interactive for these users and the recovery material can be computed in constant time.

From Figure 6(b), Figure 6(c), and Figure 6(d) we see that the runtime for the verifier is not constant anymore, unlike all other variants of mPVAS. In mPVAS-UD, the verifier's runtime is linear in the number of remaining users because it must compute the product of the masking factors EK_j for every remaining user j, as described in (37). Note that the product of the recovery keys $rk_{i,t}$ is precomputed by the aggregator before being sent to the verifiers to save bandwidth. Still,

these multiplications not particularly expensive and, even in the worst case we consider, with 1000 users and only 10% dropouts, the total running time is below 0.0165 seconds.

(a) Dropped-out user (b) Verifier (10% of users drop out)

(c) Verifier (30% of users drop out) (d) Verifier (50% of users drop out)

Figure 6: Experimental runtime of mPVAS-UD.

10 Conclusions

mPVAS and its extensions ensure the confidentiality of the input values and the integrity and authenticity of the aggregate even in the presence of a malicious aggregator and a subset of malicious users that collaborate to tamper with the result of the aggregation. Ensuring not only confidentiality but also integrity and authenticity even in the presence of malicious adversaries helps to develop more trust in the results of privacy-preserving schemes and make such schemes appealing to a wider range of scenarios.

A Aggregator Obliviousness of mPVAS

We provide the proof of Theorem 1. We first provide some preliminaries, and then restate the theorem as Theorem 9.

We show that if a probabilistic polynomial-time adversary has a non-negligible advantage of breaking Aggregator Obliviousness of mPVAS, then it also has a non-negligible advantage of breaking Aggregator Obliviousness of the Shi et al. [40] scheme, which is proven under the Decisional Diffie-Hellman assumption. The proof of this property follows an indistinguishability-based game and it provides an adversary with access to the following oracles.

- $O_{\text{Setup}}(1^\lambda)$: Performs the setup of the mPVAS scheme using the given security parameter λ and replies with the public parameters pp and the verification key vk. The secret values of each user $([s]_i, sk_i)$ are kept secret.
- $O_{\text{Compromise}^1}(i \in \mathbb{U})$: When queried on user i, the oracle replies with the secret of user i, namely $([s]_i, sk_i)$.
- $O_{\text{Sign}}(i \in \mathbb{U}, t, x_{i,t})$: Given an input $x_{i,t}$ of user i in round t, the oracle replies with $\left(\sigma^1_{i,t}, \{\sigma^{2,j}_{i,t}\}_{j\in\mathcal{U}_i}, \sigma^3_{i,t}, \sigma_{i,t}\right)$, where each $\sigma^\ell_{i,t}, 1 \le \ell \le 3$ is a final user signature, and $\sigma_{i,t}$ is the final user signature.
- $O_{\text{Challenge}}(\mathcal{X}^0_{t^*}, \mathcal{X}^1_{t^*})$: Given two sets of input values $\mathcal{X}^0_{t^*}, \mathcal{X}^1_{t^*}$ of size $|\mathcal{X}^i_{t^*}| = n$, such that $\sum_{i\in U^*} x^0_{i,t^*} = \sum_{i\in U^*} x^1_{i,t^*}$, the oracle randomly flips a coin $b \leftarrow\$ \{0,1\}$ and, for set $\mathcal{X}^b_{t^*}$, it returns all the corresponding partial and final user signatures of its inputs.

Aggregator Obliviousness security game. The Aggregator Obliviousness security game is based on the game introduced by Shi et al. [40].

We can now define Aggregator Oblivious. We follow the definitions seen in [30, 29].

Definition 1 (Aggregator Oblivious)**.** *Let* $\Pr[\mathcal{A}^{AO}]$ *denote the probability that aggregator* $\mathcal{A}$ *outputs* $b^* = b$ *in the AO game. A data aggregation protocol is said to be Aggregator Oblivious if, any polynomially bounded* $\mathcal{A}$ *has negligible advantage* $\Pr[\mathcal{A}^{AO}] \le \frac{1}{2} + \text{negl}(\lambda)$ *of winning the AO game.*

Theorem 9. *The mPVAS scheme is Aggregator Oblivious in the random oracle model under SXDH in* $\mathbb{G}_1$ *and* $\mathbb{G}_2$.

Proof. Let us assume an adversary $\mathcal{A}$ that can win the AO game with a non-negligible advantage. We show how a polynomial time algorithm $\mathcal{B}$ can break the AO scheme of [40], henceforth referred to as PPATS, which is provably secure under the DDH assumption, by using $\mathcal{A}$ as a subroutine. We refer to the following oracles provided by the PPATS scheme. $O^{\text{PPATS}}_{\text{Setup}}$ returns the public parameters. $O^{\text{PPATS}}_{\text{Encrypt}}$ returns the ciphertext $c_{i,t}$ of a given input $x_{i,t}$ in round t using the PPATS scheme. $O^{\text{PPATS}}_{\text{Compromise}}$ returns the secret encryption key sk'_i of a specified user $i \in \mathbb{U}$. Finally, $O^{\text{PPATS}}_{\text{Challenge}}$, only called once during the game, randomly flips a coin $b \leftarrow\$ \{0,1\}$ and, similarly to the challenge phase described above, encrypts one of the two plaintext sets chosen by the adversary $\mathcal{X}^b_{t^*} = \{x_{i,t^*}\}_{i\in\mathbb{U}^*}$.

We follow the AO security game and show how $\mathcal{B}$ reacts to the queries of $\mathcal{A}$.

1. **Setup.** When $\mathcal{A}$ queries the $O_{\text{Setup}}(1^\lambda)$ oracle, $\mathcal{B}$ queries $O^{\text{PPATS}}_{\text{Setup}}(1^\lambda)$. The latter returns the public parameters $pp_{\text{PPATS}} = (H, \mathbb{G}_1, g_1, p)$. $\mathcal{B}$ also queries the $O^{\text{PPATS}}_{\text{Compromise}}(0)$, which returns the secret key of the aggregator $sk_A = -\sum_{i=1}^n sk'_i$. $\mathcal{B}$ will additionally choose the remaining public parameters of the mPVAS scheme $pp = (H, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2, e, k)$. Finally, $\mathcal{B}$ also chooses the secret keys $(s, \{sk_i\}_{i\in\mathbb{U}}, \{\{ek_{i,j}\}_{1\le j\le k}\}_{i\in\mathbb{U}})$, creates n secret shares $[s]_i$ using $(k+1, n)-$Shamir Secret Sharing, and creates the verification key as $vk = \left((g^s_2)^{-sk_A}, g^s_2\right) = \left((g^s_2)^{\sum_{i=1}^n sk'_i}, g^s_2\right)$. Finally, $\mathcal{B}$ returns pp and vk to $\mathcal{A}$.
2. **Learning. Compromise.** When $\mathcal{A}$ queries the $O_{\text{Compromise}^1}(i \in \mathbb{U})$ oracle, $\mathcal{B}$ will, in turn, query $O^{\text{PPATS}}_{\text{Compromise}}(i \in \mathbb{U})$ and return the corresponding secret key sk'_i of user i. Additionally, the secret share $[s]_i$ is also sent to $\mathcal{A}$.

   Sign. When $\mathcal{A}$ calls $O_{\text{Sign}}(i \in \mathbb{U}, t, x_{i,t})$, $\mathcal{B}$ queries $O^{\text{PPATS}}_{\text{Encrypt}}(i \in \mathbb{U}, t, x_{i,t})$ to obtain $c^{\text{PPATS}}_{i,t} = H(t)^{sk'_i} g_1^{x_{i,t}}$. $\mathcal{B}$ then computes:

   $\sigma^1_{i,t} = c^{\text{PPATS}}_{i,t} = H(t)^{sk'_i} g_1^{x_{i,t}}$;

   $\sigma^{2,j}_{i,t} = H_1(t)^{ek_{j,i}} \left(\sigma^1_{i,t}\right)^{[s]^*_j}$;

   $\sigma^3_{i,t} = \prod_{j\in\mathcal{U}_i} \sigma^{2,j}_{i,t}$;

   $\sigma_{i,t} = H_1(t)^{ek_{i,i}} \cdot \left(\prod_{j\in\mathcal{U}_i} \sigma^{2,j}_{i,t}\right) \cdot \left(\sigma^0_{i,t}\right)^{[s]^*_i} = H_1(t)^{ek_{i,i} + \sum_{j\in\mathcal{U}_i} ek_{j,i}} \cdot \left(H(t)^{sk'_i} g_1^{x_{i,t}}\right)^s$.

Notice how each partial signature and the final user signature $\sigma_{i,t}$ are constructed from the ciphertext output by the encryption algorithm of PPATS but perfectly simulates a partial or final user signature mPVAS scheme. Finally, $\mathcal{B}$ returns $\left(\sigma^1_{i,t}, \{\sigma^{2,j}_{i,t}\}_{j\in\mathcal{U}_i}, \sigma_{i,t}\right)$ to $\mathcal{A}$.

Verify. $\mathcal{A}$ can test the correctness of an aggregate sum using the verification key vk obtained during the setup according to (15).

3. **Challenge.** $\mathcal{A}$ chooses a set of uncompromised users $U^* \subseteq \mathbb{U}$, with $|U^*| \geq 2$ and an aggregation round t^* for which no sign queries were made in the learning phase. Then, $\mathcal{A}$ also chooses two sets of ciphertexts $X^0_{t^*} = \{x^0_{i,t}\}_{i\in U^*}$ and $X^1_{t^*} = \{x^1_{i,t}\}_{i\in U^*}$ such that $\sum_{i\in U^*} x^0_{i,t^*} = \sum_{i\in U^*} x^1_{i,t^*}$. When $\mathcal{A}$ calls the $\mathcal{O}_{\text{Challenge}}(\mathcal{X}^0_{t^*}, \mathcal{X}^1_{t^*})$ oracle, $\mathcal{B}$ queries $\mathcal{O}^{\text{PPATS}}_{\text{Challenge}}(\mathcal{X}^0_{t^*}, \mathcal{X}^1_{t^*})$. The oracle flips a coin $b \leftarrow\$ \{0,1\}$ and returns the encrypted ciphertexts of the b^{th} set $\{c^{\text{PPATS}^b}_{i,t}\}_{i\in U^*}$. $\mathcal{B}$ computes the partial and final user signatures using the $\mathcal{O}_{\text{Sign}}$ oracle, returning $\Big(\{\sigma^{1^b}_{i,t^*}\}_{i\in U^*}, \{\{\sigma^{2^b,j}_{i,t^*}\}_{j\in\mathcal{U}_i}\}_{i\in U^*}, \{\sigma^{3^b}_{i,t^*}\}_{i\in U^*}, \{\sigma^b_{i,t^*}\}_{i\in U^*}\Big)$ to $\mathcal{A}$. In particular, the final user signature is $\sigma^b_{i,t^*} = H_1(t^*)^{ek_{i,i}+\sum_{j\in\mathcal{U}_i} ek_{j,i}} \cdot \left(H(t^*)^{sk'_i} g_1^{x^b_{i,t^*}}\right)^s$, for $i \in U^*$. Notice how σ^b_{i,t^*}, and all partial signatures are computed from the ciphertexts output by the encryption algorithm of the PPATS scheme and perfectly simulate the ciphertexts, partial and final user signatures of the mPVAS scheme. The aggregation of all such final user signatures is also valid and correctly verified using the verification key vk as $\sigma^b_{t^*} = \prod_{i\in U^*} \sigma^b_{i,t^*} = (H(t^*)^s)^{\sum_{i\in U^*} sk'_i} (g_1^s)^{\sum_{i\in U^*} x^b_{i,t^*}}$.

If $\mathcal{A}$ has a non-negligible advantage ε of guessing the correct bit b^* in the AO game of the mPVAS scheme, then $\mathcal{B}$ can also win the AO game of the PPATS scheme with the same non-negligible advantage ε by guessing the same bit b^*. This would contradict the DDH assumption in $\mathbb{G}_1$, because the security of the PPATS scheme relies on this assumption. Additionally, if the DDH does not hold in $\mathbb{G}_1$, then the SXDH assumption does not hold either since it requires that the DDH problem be hard in $\mathbb{G}_1$. Therefore, the mPVAS scheme is Aggregator Oblivious in the random oracle model under the SXDH assumption. ☺

B Aggregate Unforgeability of mPVAS

We provide the proof of Theorem 2.

Proof. **Type-I Unforgeability.** A Type-I forgery [3, 30, 29, 12, 43] occurs when the aggregator outputs a valid aggregate signature σ_t in a round t without receiving any users' signatures. Thus, the aggregator can only use knowledge from previous rounds or by colluding with users. First, we note how signatures from different rounds are incompatible with each other. Assuming a cryptographically-secure hash function $H\colon \{0,1\}^* \to \mathbb{G}_1$ under the random oracle model its output can be considered random. As such, in each round t, each signature has a different random factor $H(t)$. Even assuming the aggregator chooses the round identifier t, because of the collision resistance property of H, it has a negligible probability of finding two different round identifiers t, t' such that $H(t) = H(t')$. Similarly, because of the second pre-image resistance property of H, given t, the aggregator has negligible probability of finding another t' such that $H(t) = H(t')$. The same arguments hold for the other hash function $H_1\colon \{0,1\}^* \to \mathbb{G}_1$ used in the protocol. It follows that the aggregator cannot reuse signatures from previous rounds. The only other option left for the aggregator is to construct new signatures itself. However, in order to do so, all secret signing keys sk_i are required but, assuming colluding users, the aggregator has only access to at most k of them. The aggregator also needs the secret exponent s to compute a valid signature, but it has only access to at most k secret shares of s, which are not enough to reconstruct s.

Type-II Unforgeability. [3, 30, 29, 12, 43] There are two pieces of information that can allow the aggregator to successfully forge an aggregate signature in a round in which it received all signatures from the users: the secret exponent s or the factor g_1^s. The exponent s is secret-shared by all users using $(k+1,n)$-Shamir Secret Sharing. Since we assume at most k malicious users who collude with each other and k shares leak no information about the underlying secret s, then no dishonest party can directly learn s from exchanging their shares. Additionally, if $g^s \in \mathbb{G}_1$ is known, for any $g \in \mathbb{G}_1$, recovering s is considered computationally infeasible because DLP is assumed to be hard in $\mathbb{G}_1$. The same argument applies to the value $g_2^s \in \mathbb{G}_2$, which is part of the verification key and known by every verifier. Note that, while a malicious actor may know g_2^s, since the Co-Computational Diffie-Hellman (Co-CDH) [8] problem is assumed to be hard in $\mathbb{G}_1$ and $\mathbb{G}_2$, obtaining g_1^s is still considered hard.

In a malicious setting where users can behave arbitrarily, sending malformed signatures may allow them to gain additional information that will allow them to break the Aggregate Unforgeability property.

Each signature starts with the form $\sigma^1_{i,t} = H(t)^{sk_i} g_1^{x_{i,t}}$. Clearly, any malicious party can immediately tamper with this signature since g_1 is public. However, the aggregator is required to send a *Compute final user signature* request to every user in order for the aggregate signature to be successfully verified. From (10), any $\sigma^3_{i,t}$ that was not computed using user i's original $\sigma^1_{i,t}$ will lead to an invalid $\sigma_{i,t}$, because the bases of the two factors will not match. This, in turn, will lead to an invalid aggregate signature σ_t.

In order to prevent malicious actors from manipulating any of the partial signatures to obtain g_1^s, each user j is required to further mask any response to a *Create partial signature* or *Compute final user signature* request with a fresh masking factor $H_1(t)^{ek_{j,i}}$. Assuming at most k malicious users, any signing request from each user i will result in a $\sigma_{i,t}$ containing at least one such factor, since either user i itself or a user in its signing set must be honest by assumption. Therefore, all that malicious actors can learn by deviating from the protocol is of the form $H_1(t)^{\varepsilon} g^{s}$ or $H_1(t)^{\varepsilon} g^{[s]_j^*}$, where $g \in \mathbb{G}_1$ and ε indicates the sum of any non-empty subset of masking exponents $ek_{j,i}$. None of these values can be used to successfully forge a valid aggregate signature, as they would introduce extra masking exponents that would not sum up to 0 anymore. As a result, the verification algorithm will fail. ☺

C Aggregate Unforgeability of mPVAS-IV

We provide the proof of Theorem 6.

Proof. In the mPVAS-IV extension, the aggregator is trusted to detect users who may attempt disrupt the normal execution of the protocol and not to disrupt the protocol itself. However, the aggregator is still considered malicious with respect to the unforgeability property of the mPVAS-IV extension. This extension provides the aggregator with additional knowledge that is not available in the main scheme. As such, in this section, we provide additional arguments to show why Aggregate Unforgeability is still maintained in the mPVAS-IV extension.

Type-I Forgeries. The new pieces of information that the aggregator is handed in the mPVAS-IV extension are the sets $SS_i = g_2^{[s]_i}, SK_i = g_T^{sk_i} h_T^{r_i}$, $EK_{j,i} = g_2^{ek_{j,i}}$, $EKS_{j,i} = g_2^{\frac{ek_{j,i}}{s}}$, and the value $\nu = g_2^{\frac{1}{s}}$. Since DLP is assumed to be intractable in $\mathbb{G}_2$, the aggregator has a negligible probability of obtaining the secret share $[s]_i$ or the masks $ek_{j,i}$ of a user i from $g_2^{[s]_i}$ and $g_2^{ek_{j,i}}$, respectively. Similarly, finding $\frac{1}{s}$ from ν is also hard. Additionally, because of the perfect hiding property of Pedersen commitments, the aggregator cannot learn any information about the signing key sk_i from its corresponding commitment in SK_i. Hence, the additional information that is handed to the aggregator in the mPVAS-IV extension gives the aggregator no advantage of learning the necessary information to create Type-I forgeries.

Type-II Forgeries. There is no additional piece of information handed to the aggregator in the mPVAS-IV extension that could allow it to create Type-II forgeries. Intuitively, this is because all of the additional values are members of either $\mathbb{G}_2$ or $\mathbb{G}_T$, but the signatures are elements of $\mathbb{G}_1$. As such, there is no additional information that could be used by the aggregator to tamper with the signatures in $\mathbb{G}_1$, assuming the SXDH assumption holds in the chosen pairing group. ☺

D Aggregator Obliviousness of mPVAS-UD

We provide the proof of Theorem 7.

Proof. In the mPVAS-UD protocol, the signing phase is identical to that of the main mPVAS protocol for all remaining users. As such, the signature of each remaining user perfectly hides the input value, as proven in Theorem 1.

The signing phase is, however, different for dropped-out users. Each user is required to send a recovery key $rk_{i,t}$ for every round t it wish to drop out of. This value could, in turn, be plugged in (24), using $EK_{j,i}$, to find user i's secret input value by brute force. Fortunately, the signing key sk_i is bound to the generator $H(t)$ and, thus, can only be successfully used in round t, during which dropped-out users do not submit any data. Additionally, if malicious users collaborate to create k additional recovery factors $rk_{i,t}$, then, as long as at least 2 honest users do not drop out during round t, only the sum of their input data can be computed, but not the individual values.

As a result, the input data of both remaining and dropped-out users remain private during every step of the protocol. ☺

E Aggregate Unforgeability of mPVAS-UD

We provide the proof of Theorem 8.

Proof. The main addition introduced by the mPVAS-UD extension is the recovery key $rk_{i,t}$ that users that wish to exit the protocol during some round t submit to the aggregator. The recovery key is computed over $\mathbb{G}_T$, so it cannot be used to directly affect the signatures, which are elements of $\mathbb{G}_1$.

The aggregator cannot lie about the set of users that drop out during any given round t and cannot publish more than one valid aggregate signature. Forcing a subset of users out of the protocol would lead to a failed verification, since the aggregator cannot provide the verifiers with valid recovery keys for the missing users on its own. Similarly, the aggregator cannot force a dropped-out user i in the protocol as it does not possess its signing key sk_i. Assuming a subset of users colludes with the aggregator and provides it with valid recovery keys, we identify two cases.

If any of these users actually engage in the protocol, then their recovery key alone would not suffice anymore, because their final user signature would contain at least one masking factor $H_1(t)^{ek_{j,i}}$, with $ek_{j,i}$ belonging to an honest user j, which has not been redistributed among the remaining users. As such, the check in (37) would fail.

If they do not submit anything, then the aggregator is forced to forward their recovery keys, indicating they have indeed dropped out, otherwise, the verification would fail.

As for Type-I forgeries, the same arguments presented in Theorem 2 apply to mPVAS-UD. ☺

PINE: Efficient Verification of a Euclidean Norm Bound of a Secret-Shared Vector*

Kunal Talwar
Apple

Abstract

Secure aggregation of high-dimensional vectors is a fundamental primitive in federated statistics and learning. A two-server system such as PRIO allows for scalable aggregation of secret-shared vectors. Adversarial clients might try to manipulate the aggregate, so it is important to ensure that each (secret-shared) contribution is well-formed. In this work, we focus on the important and well-studied goal of ensuring that each contribution vector has bounded Euclidean norm. Existing protocols for ensuring bounded-norm contributions either incur a large communication overhead, or only allow for approximate verification of the norm bound. We propose **P**rivate **I**nexpensive **N**orm **E**nforcement (PINE): a new protocol that allows exact norm verification with little communication overhead. For high-dimensional vectors, our approach has a communication overhead of a few percent, compared to the 16-32x overhead of previous approaches.

1 Introduction

Data analyses and machine learning on user data have the potential to improve various applications, but might raise concerns about users' privacy. Fortunately, these analyses can be performed in a federated setting [Kai+21; LSTS20] while ensuring strong formal privacy guarantees. This has sparked significant interest in developing techniques and infrastructures to support private federated data analyses. In this work, we focus on a fundamental primitive: estimating the mean (or equivalently, the sum) of a set of high-dimensional vectors. This primitive is natural and important in its own right, and is also a basic building block for several tasks (e.g. [RNFH19; RZHP20]). Most notably, it is fundamental for federated optimization of machine learning models. Furthermore, several other ML tasks such as PCA, k-means and EM can be reduced to (multiple applications of) aggregation.

Secure Aggregation techniques enable strong privacy guarantees without requiring trust in a single server. Various approaches have been studied for designing such systems. One approach is to have client devices run a secure multiparty computation to compute the aggregate, which has been explored in [DKMMN06; BIKMMPRSS17; SGA20; SGA21; BBGLR20]. Another approach relies on two or more servers to perform the aggregation, using protocols that ensure that no single server can learn anything beyond the final aggregate (security holds so long as the two servers do not collaborate). A common approach is for each client to secret-share its contribution between the two servers, and for the servers to use a secure protocol that allows them to learn the aggregate, but nothing more about any individual client's contribution. We refer to this approach as *distributed aggregation*. The PRIO system [CB17] proposed a protocol for computing arbitrary functions over secret-shared data in the presence of two or more servers. This approach has been further developed in subsequent research [BBCGI19; BBCGI21; BGGKMRS22; CP22; BBCGI23; Tal+23], applied in practice [HMR18; AG21] and forms the basis of an IETF [GPRW23] draft standard for aggregation. In this work, we focus on distributed aggregation of high-dimensional integer[1] vectors.

Real-world implementations of secure aggregation must deal with adversarial clients attempting to manipulate the results. An important advantage of the PRIO approach is that it allows the servers to validate certain properties of the client contributions, while preserving a zero-knowledge (ZK) property, meaning that the servers learn nothing beyond the aggregate and the fact that the client shares were valid. A rich line of research has focused on developing efficient methods to verify various properties of client contributions. In the context of summing up vectors in $\mathbb{R}^d$, a natural objective is verifying that each client contribution has bounded Euclidean norm. The Euclidean norm constraint arises naturally in many machine

*Extended abstract. See [ROCT23] for the full version.

†Part of this work was performed while EO was at Apple.

[1] While one is often interested in vectors of floating point values, standard techniques can translate the problem to fixed-precision vectors. Scaling then turns those into integer vectors from a bounded range. See the discussion in Sections 1.1 and 5.

learning settings [Dos+21; Deh+23; ZLLBRZGS23]. Many model poisoning attacks (e.g. [BBG19; FCJG20; SH21]) rely on clients submitting vectors of large norm (so called "boosted gradients"). Recent works [SHKR22; SKSM19] have shown that ensuring a bounded ℓ_2 norm is effective against a large family of realistic poisoning attacks in the federated learning setting.[2]

In this work, we focus on zero-knowledge protocols for verifying the bounded Euclidean norm property. Such protocols require the client and the servers to perform additional computations and communication, where different works obtain different overheads. One important measure is the communication cost, especially in settings where the vectors involved can be of high dimensions (e.g. [RMRB19; Pau+21; Xu+23; XZACKMRZ23; PAFSTL23]). We review the works most related to our contributions.

One approach taken by prior work [CB17; BBCGI19] and in proposed implementations in the IETF standard [ISR23; RU23] has the client secret-share each bit of each coordinate of its vector as an element in a finite field. For d-dimensional vectors with b bits of precision, this requires the client to send at least *bd field elements* to each server. The field size itself must be rather large to keep the soundness error small. In high-dimensional settings, this translates to a substantial communication overhead. For example, in the implementation in [RU23], the communication overhead is at least 16x (compared to secret sharing without validity proofs). We note that the servers also need to verify that the secret shares are indeed of bits, but the communication needed for this latter task can be smaller [BBCGI19].

In PRIO+ [AGJOP22], the communication from the client to each server is only *bd bits* (rather than field elements), but this requires an offline setup phase that involves expensive cryptographic operations (it also gives a weaker norm bound guarantee). In ELSA [RSWP22], the setup avoids expensive cryptographic operations, but requires more communication from the clients. We elaborate on the comparison with these works below, but the main distinction is that our work focuses on a setting where there is no expensive setup, and we aim to minimize the communication from the clients to the servers.

With the goal of minimizing the client-to-server communication, the work of [Tal22] relaxed the zero-knowledge guarantee to differential ZK and showed a more communication-efficient protocol. However, that protocol only ensured approximate norm verification, limiting its usefulness in some settings. The protocol allows for a trade-off between the soundness and completeness errors and the approximation guarantee, but even for relatively permissive error thresholds (say, 0.01 soundness and completeness errors), the protocol might accept vectors of norm 50x the target bound. This reduces its effectiveness in dealing with malicious clients.

[2]No method can completely prevent model poisoning [SHKR22] (for a theoretical perspective, see e.g. [MM17]); bounding the ℓ_2 norm limits the impact of adversarial clients.

1.1 Our Work

Our main contribution is PINE (for **P**rivate **I**nexpensive **N**orm **E**nforcement): a communication-efficient protocol for Euclidean norm verification that can verify the exact norm bound with a strong (statistical) zero knowledge guarantee and with no offline setup. Zero knowledge holds even against malicious behavior by a server (we always assume the servers do not collaborate, i.e. at least one of them is honest). Theoretically, our verification protocol requires the client to communicate only $\tilde{O}(\sqrt{d})$ additional field elements. In practice, for typical parameter settings, this overhead is a small fraction of the communication needed to secret share d field elements.

Theorem 1.1 (Informal version of Theorem 3.15)**.** *Let $X \in \mathbb{Z}^d$ be a secret-shared vector and $B \geq 0$. Fix $\rho > 0$, and set $r = \lceil 32 \ln \frac{1}{\rho} \rceil$. For any field of size $q \geq \Omega(\max\{B, 3r\})$ there is a distributed verification protocol with the following properties:*

1. ***Completeness:*** *If $\sum_i X_i^2 \leq B$, the verifiers accept with probability at least $1 - \rho$.*
2. ***Soundness:*** *If $\sum X_i^2 > B$ (over the integers), the probability that the verifiers accept is at most $\rho + O(\sqrt{d}/q)$.*
3. ***Zero-Knowledge****: The protocol satisfies distributed statistical zero-knowledge: the view of each verifier can be simulated up to statistical distance ρ. This guarantee holds even for a single malicious verifier (so long as the other verifier follows the protocol).*

The proof system is in the common reference string model, and consists of a single message of length $O\left(\sqrt{d}\log q + r\log^2 q\right)$ sent by the prover to each verifier.

The protocol is derived from the interactive 4-message protocol of Theorem 3.15 by using a variant of the Fiat-Shamir heuristic suited for the distributed verification setting (see the full version [ROCT23]).[3] While we state our results for the case of two verifiers, our approach is modular and can be used with multiple verifiers. Concrete performance evaluation is below and in Section 5.

Statistical PINE: Overview. A central difficulty in efficient verification of Euclidean norms is that PRIO relies on arithmetic over a finite field, whereas our property of interest deals with arithmetic over integers/reals. One can use known techniques [BBCGI19] to efficiently verify that the sum of of squared entries *modulo the field size* satisfies a certain bound. If the coordinates are all small enough, then the squared norm modulo the field sizes equals the squared norm over the integers, so the preceding check suffices. However, it is challenging to validate smallness of coordinates in their natural representation as field elements. Existing approaches achieve

[3]The soundness error is proved for the interactive protocol, and should be set to be sufficiently small to account for the Fiat-Shamir transform.

this by encoding the coordinates in their binary representation, which can enforce the requisite smallness.

We take a different approach. Instead of encoding the coordinates of a vector in their binary representation, we devise a randomized test that can detect whether there is a "wraparound" when computing the sum of squares over a finite field. We first verify that the sum of squared entries modulo the field size q is in the range $[0,B]$. For large enough q, this gives us a promise problem: either the sum of squared entries (over integers) is at most B, or is at least q. We test for this *wraparound* by taking a random dot product with a $-1,0,1$ vector, and we demonstrate that if there is wraparound, the dot product is likely to be large. On the other hand, if the sum of the squared entries was small to begin with, then the dot product will be small with high probability. These bounds on the dot product, which are our main technical contribution, are proved using a delicate case analysis on the vector's infinity norm. The challenging case (small infinity norm) is analyzed using the Berry-Esseen theorem.

Thus, we reduce the problem of proving a bound on the squared norm to proving boundedness of a few scalars (the outcomes of independent dot products), which can be done at a small overhead. Our communication overhead is dominated by the communication needed to verify the sum of squared entries over the finite field; the $\sqrt{d}$ term can be further reduced to $d^{1/c}$ by using an $c+O(1)$-round protocol (the additional interaction can be eliminated using the Fiat-Shamir transform).

Differential ZK. We also show a simpler scheme that relaxes ZK to Differential ZK: intuitively, the secrecy of the client's contribution is protected via a *differential privacy* [DMNS06] guarantee (rather than the perfect or statistical guarantees that are more common in the literature). Beyond its simplicity, the protocol also achieves smaller communication in some parameter regimes (especially when the number of dimensions is not too large). We note that the relaxation to differential ZK can be quite reasonable, since differential privacy is often all that is guaranteed given that the (approximate) results of the entire aggregation are to be made public to the servers.

Theorem 1.2 (Informal Version of Theorem 4.3)**.** *Let $X \in \mathbb{Z}^d$ be a secret-shared vector. Let $\varepsilon,\delta \in (0,1)$ and $B \geq 1$. For a field of size $q > 4\left(\sqrt{B}+\sqrt{d}+\sqrt{dB\frac{2\ln 2.5/\delta}{\varepsilon}\cdot(1+\frac{2\sqrt{\log 8e/\delta}}{\sqrt{d}}+\frac{2\log 8e/\delta}{d})}\right)^2$, there is a distributed verification protocol with:*

1. ***Completeness:** If $\sum_{i=1}^d X_i^2 \leq B$, then the verifiers accept with probability* 1.
2. ***Soundness:** If $\sum X_i^2 > B$ (over the integers), the probability that the verifiers accept is at most $O(\sqrt{d}/q)$.*
3. ***Zero-Knowledge**: The protocol satisfies (ε,δ)-differential zero knowledge: the view of each verifier can be efficiently simulated up to (ε,δ)-closeness. This guarantee holds even for a single malicious verifier (so long as the other verifier follows the protocol).*

In addition to the secret shares of x, the client sends a proof of length $(O(\sqrt{d})+O(\log_2 q))\cdot\lceil\log_2 q\rceil$.

This protocol is derived from an interactive 3-message protocol a distributed-verification variant of the Fiat-Shamir heuristic, see the full version [ROCT23].

Performance analysis. We analyze the performance of our protocols in terms of the communication overhead, beyond the communication that is needed to simply send secret shares for distributed aggregation (without any robustness to poisoning attacks). In Section 5, we provide analyses for several choices of parameters. Here, in Table 1, we highlight the performance for a typical choice of parameters, where we aggregate d-dimensional integer vectors of ℓ_2 norm at most 2^{15} with $d \in \{10^4,10^5,10^6,10^7\}$. We work over a field of size $\approx 2^{64}$ and use soundness and zero-knowledge error 2^{-50}.

As seen in Table 1, our statistical zero-knowledge protocol achieves small overhead even when the number of dimensions is as small as 10^4, and the communication overhead becomes negligible as the number of dimensions grows. Comparing with prior work [BBCGI19; ISR23], the overhead is reduced by a multiplicative factor of between 70x (when the number of dimensions is only 10,000) to 10^4x (when the number of dimensions is as high as 10^7).

Our differential ZK protocol achieves even smaller overheads so long as the number of dimensions is not huge (albeit, the secrecy guarantee is more relaxed). Once the number of dimensions grows to 10^7, PINE with Differential ZK requires a larger field size (9 bytes instead of 8 bytes), this incurs an initial overhead of $\frac{1}{8}$ for secret-sharing the data over a larger field. Previous work with differential ZK [Tal22], would have similar increased field size requirements for these parameters. While their protocol would not have any additional overhead, it only gives a weaker robustness guarantee that vectors that are 50x the norm bound are rejected with probability 0.99.

We briefly elaborate on our choice of the norm bound: a typical setting when aggregating gradients is that we aggregate floating point vectors of Euclidean norm at most 1. We can convert these floating point vectors to integer vectors by multiplying by 2^b and rounding. With $b=15$ bits of precision per co-ordinate, this translates the problem to verifying ℓ_2 norm bound $\sqrt{B}=2^{15}$. This is typically sufficient for high dimensional vectors. Working over a field of size about $\approx 2^{64}$ suffices to allow aggregating millions of such vectors (whereas field size $\approx 2^{32}$ would not be sufficient for 100K vectors). We refer the reader to Section 5 for further elaboration and for performance evaluation in other parameter regimes.

Further comparison to PRIO+ and ELSA. In Table 2, we provide a qualitative comparison to the most closely related

	$d = 10^4$	$d = 10^5$	$d = 10^6$	$d = 10^7$
no robustness, # bits sent	$64 \cdot 10^4$	$64 \cdot 10^5$	$64 \cdot 10^6$	$64 \cdot 10^7$
prior work, overhead [BBCGI19; ISR23]	$> 1500\%$	$> 1500\%$	$> 1500\%$	$> 1500\%$
PINE, Statistical ZK, overhead	22%	3.18%	0.49%	0.13%
PINE, Differential ZK, overhead	4.77%	1.46%	0.32%	12.63%

Table 1: Communication analysis: our protocols and prior work. Parameters: field size $q \approx 2^{64}$ for aggregation, d-dimensional data, soundness error 2^{-50}, zero-knowledge error $\delta = 2^{-50}$. For differential ZK $\varepsilon = 0.1$.

Protocol	Linear online	Linear offline	Expensive crypto
Prio3 [BBCGI19; ISR23]	N	Y	N
Prio+ [AGJOP22]	Y	N	Y
ELSA [RSWP22]	Y	N	N
PINE (our work)	Y	Y	N

Table 2: Qualitative comparison to representative prior works. All works are in the distributed two-server trust model. *Linear offline and online* mean that the communication is dominated by the cost of communicating at most d field elements for the field where aggregation should occur, either in an offline stage (before the client's contribution is specified), or in the online stage (respectively). *Expensive crypto* means that the protocol uses operations such as oblivious transfer.

works to ours. In particular, we consider works in the distributed aggregation setting, with two non-colluding servers and privacy against (one out of two) malicious servers. The PRIO+ system [AGJOP22] reduces the communication cost of sharing the client's vector to bd bits (where 2^b bounds the magnitude of each entry). This is significantly smaller than our protocol, which requires sending d field elements (e.g. in Table 1 each field element is 64 bits, whereas $b = 15$). However, PRIO+ requires an expensive offline setup between the servers, which perform cryptographic oblivious transfer operations and exchange more communication than d field elements per client. Moreover, verifying a bound on the Euclidean norm would also require a subsequent online cryptographic protocol (and there is further overhead for malicious-server security, see [RSWP22]). Other works, such as [HLXCZ21; HKJ20], also make use of more advanced cryptographic operations. PINE avoids an expensive setup and cryptographic operations of this type. The ELSA system [RSWP22] also avoids the use of expensive cryptographic operations, but replaces them with communication from the client, which sends more than d field elements to the servers. The expensive communication from the client to the servers can be performed offline, but it is a large communication compared to our work. Further, in many PRIO-like settings, anonymous clients engage in a one-shot interaction with the servers, so an offline setup is not appropriate.

Further related work. In a very recent work Boneh *et al.* [BBCGI23] show how *arithmetic sketching schemes* can be used to design efficient protocols for verifying properties of secret-shared data. They show, however, that the linear sketches at the heart of their technique cannot be used to verify L_2-norm constraints (or any L_p norm for $p > 1$).

2 Model, Definitions and Preliminaries

Definition 2.1. *The statistical distance between two finite random variables X and Y is*

$$\mathrm{SD}(X,Y) = \frac{1}{2}\sum_a |\Pr[X = a] - \Pr[Y = a]|\,.$$

Two ensembles $X = \{X_n\}_{n\in\mathbb{N}}$ and $Y = \{Y_n\}_{n\in\mathbb{N}}$ are said to be statistically close, denoted $X \overset{s}{\equiv} Y$, if there exists a negligible function $\mu(\cdot)$, such that for all $n \in \mathbb{N}$, it holds that $\mathrm{SD}(X_n, Y_n) \le \mu(n)$.

Runtimes and field operations over $\mathbb{GF}[q]$. We measure the prover's and the verifiers' runtimes by the number of field operations we perform: we usually count addition and multiplication as a single field operation, and also allow other basic atomic operations such as translating field elements to their natural representation as bit vectors and vice versa. In performance evaluations, we also measure the number of multiplications as a primary complexity measure (as done in prior work, since these are significantly more expensive than other field operations).

Secret sharing over $\mathbb{GF}[q]$. In the distributed verification setting we study, a client (or prover) secret-shares data between two or more servers (or verifiers). Each secret-shared value is an element $\alpha \in \mathbb{GF}[q]$ from a field, and the secret shares are random field elements whose sum is α ("arithmetic shares"). In particular, each server's share is, on its own, a uniformly random field element.

2.1 Distributed Verification Protocols

As discussed above, we study a distributed model, in which a single prover (or client) $\mathbf{P}$ interacts with two verifiers (or servers) $\mathbf{V}_0, \mathbf{V}_1$ over a complete network with secure point-to-point channels. We design several protocols in this setting,

and then compose these protocols to obtain the PINE proof systems. Our distributed verification protocols have inputs and outputs of the following type:

Common (Public) Inputs: All three parties hold the same common and publicly known parameter vector $\bar{\mathbf{T}}$. Such parameters may include, field size, scalars, protocol parameters.

Private Inputs: The prover holds some vector of input values $\bar{\mathbf{I}}$. Each such value I is secret-shared by the two verifiers such that $\mathbf{V}_j$ holds the share $[I^{(j)}]$.

Common (Public) Output: The common output of the two verifiers includes a single bit, indicating whether they accepted or rejected the proof. The verifiers can also output additional common outputs.

Private Outputs: At the end of the interaction, the prover outputs new private values. Each such value $\bar{\mathbf{O}}$ is secret-shared by the two verifiers, and these are called the shared outputs of the verifiers.

We define distributed interactive zero-knowledge proof protocols (dZKIPs) for this setting. These protocols guarantee completeness and soundness based on a condition on the common and private inputs (this "input condition" is formalized by requiring that the combined input is in a (pair) language). The zero knowledge property is also guaranteed for inputs that satisfy this input condition (are in the language). Some of the protocols also have an "output condition" on the common and private outputs (also formalized as membership in an output pair language, this condition can be empty). Completeness means that if the inputs satisfy the input condition and all parties follow the protocol, then w.h.p. the verifiers should accept and the common and private outputs (if any) should be in the output language. Soundness means that if the input condition is violated, then w.h.p. either the verifiers reject (in their common output), or the output condition is violated. Note that the verifiers might not "know" that the output condition is violated (since they only see secret shares of the private outputs): in our work this will be detected by a subsequent protocol. Allowing for private inputs and outputs, and for general input and output conditions is helpful for designing modular sub-protocols that can later be composed.

Our protocols also guarantee a strong zero-knowledge property: so long as the input is in the input language, and the verifiers are honest, both verifiers learn nothing from executing the protocol. Formally, each verifier's view in a protocol execution with the honest prover and a second verifier who follows the protocol can be simulated efficiently (the view includes the common inputs, its secret shares of the private inputs, random coins, messages received, and its secret shares of private outputs). We remark that in the classical setting for (non-distributed) interactive zero-knowledge proofs, a single prover $\mathbf{P}$ interacts with a single verifier $\mathbf{V}$ over a common input X. In such an interaction, the aim of the prover is to convince the verifier that $X \in L$ for some language L, where the verifier knows what X is, and zero-knowledge means that the verifier should not learn anything beyond X and the fact of its membership in L. In contrast, in our (distributed) setting, the statement X is not known to any single verifier (since it is secret-shared), and the zero-knowledge requirement means that any single verifier should learn nothing beyond X's membership in L.

Definition 2.2 (Distributed ZK Interactive Proof (dZKIP))**.** *We say that a 2-verifier interactive proof protocol* $\Pi = (\mathbf{P}; \mathbf{V}_0; \mathbf{V}_1)$ *is a distributed (strong) zero-knowledge proof for an input (pair) language* L_{inp} *and an output language* L_{out} *if* Π *satisfies the following:*

- α***-Completeness.*** *If the common and private inputs are in the input language, i.e.* $(\bar{\mathbf{T}}, \bar{\mathbf{I}}) \in \mathbf{L}_{\mathsf{inp}}$ *and the prover and the verifiers follow the protocol, then with all but* α *probability the verifiers accept and the private outputs satisfy the output condition, i.e.* $\bar{\mathbf{O}} \in \mathbf{L}_{\mathsf{out}}$ *(the probability is over all coins tossed by all parties in the protocol).*

- β***-Soundness.*** *If the common and private inputs are* not *in the language, i.e.* $(\bar{\mathbf{T}}, \bar{\mathbf{I}}) \notin \mathbf{L}_{\mathsf{inp}}$*, then for any adversarial cheating prover strategy, with all but* β *probability, either the verifiers reject, or the private outputs violate the output condition, i.e.* $\bar{\mathbf{O}} \notin \mathbf{L}_{\mathsf{out}}$ *(the probability is over the verifiers' coin tosses. The cheating prover is deterministic w.l.o.g).*

- γ***-Strong Distributed Honest-Verifier Zero-Knowledge (dZK)*** *(see [BBCGI19]). There exists an efficient simulator* S*, such that for every input pair* $(\bar{\mathbf{T}}, \bar{\mathbf{I}}) \in \mathbf{L}_{\mathsf{inp}}$*, for every* $j \in \{0,1\}$ *and every 2-out-of-2 sharing* $[\bar{\mathbf{I}}] = \left(\bar{\mathbf{I}}^{(\mathbf{0})}, \bar{\mathbf{I}}^{(\mathbf{1})}\right)$*, the view of* $\mathbf{V}_j$ *in an execution with the honest prover and* $\mathbf{V}_{1-j}$ *is* γ*-statistically close to the output of the simulator* S *on input* $\left(j, \bar{\mathbf{T}}, \bar{\mathbf{I}}^{(\mathbf{j})}\right)$*.*

By default we take $\alpha = 0$ *(perfect completeness) unless we explicitly note otherwise. Similarly, by default* $\gamma = 0$ *(perfect distributed zero-knowledge). We say the protocol is* public-coins *if all the messages sent from the verifiers to the prover are random coin tosses. We also require that in a public-coins protocol, the communication between the two verifiers consists solely of a single simultaneous message exchange: after the interaction with the prover is complete,* $\mathbf{V}_0$ *sends a single message to* $\mathbf{V}_1$*, and (at the same time)* $\mathbf{V}_1$ *sends a single message to* $\mathbf{V}_0$*. These messages should not depend on each other (this property is important for zero-knowledge of the Fiat-Shamir transform, see [ROCT23]).*

We sometimes consider dZKIPs for *promise problems*, where the completeness condition and the soundness condition apply to disjoint sets (rather than to the language L_{inp}

and its complement). See, for example, the "wraparound protocol" of Section 3.2.

Remark 2.3 (indistinguishability under varying private inputs)**.** *The dZK property implies that, for a fixed public input $\bar{\mathbf{T}}$, we can consider different private inputs that are in the pair language, and each verifier's views will be β-statistically close under these varying inputs, so long as its share remains unchanged. For example, fixing $\mathbf{V}_0$'s share to be $\bar{\mathbf{I}}^{(\mathbf{0})}$, we can consider an execution where V_1's share is $\bar{\mathbf{I}}^{(\mathbf{1})}$ and another execution where V_1's share is $\bar{\mathbf{I}}'^{(1)}$, and $\mathbf{V}_0$'s views in these executions will be statistically close, so long as the underlying private inputs $\bar{\mathbf{I}},\bar{\mathbf{I}}'$ are both in the pair language (w.r.t. the fixed public input $\bar{\mathbf{T}}$).*

Remark 2.4 (Non-interactive and malicious ZK via Fiat-Shamir)**.** *We construct and analyze our protocols as interactive proof systems with honest-verifier zero-knowledge guarantees, as formalized in Definition 2.2. These protocols can be transformed to non-interactive protocols that guarantee zero-knowledge against (one out of two) malicious verifiers using the Fiat-Shamir transform for the distributed setting.*

2.2 Composition of dZKIPs

Distributed ZKIP protocols maintain their zero-knowledge properties under (sequential) composition, so long as the protocols have the property that for every common input, for every input share there exists a completion of the share to an input on which the verifiers accept.

Lemma 2.5 (ZK composition)**.** *Let Π,Π' be dZKIP protocols (see Definition 2.2) that are run sequentially,where the secret shares of the private input to Π' can be efficiently computed from the shares of the private inputs and private outputs of Π (each verifier can compute its share of the private input to Π' on its own), and where the public inputs to Π' can be efficiently computed from the public inputs and outputs of Π. Suppose that:*

1. *Π is γ-dZK and α-complete. Π' is γ'-dZK.*
2. *If Π's inputs and outputs are in that protocol's input and output languages (L_{inp} and L_{out}), respectively, then they specify inputs for Π' that are in Π's input language L'_{inp}.*

Consider the composed protocol $(\Pi\circ\Pi')$, which runs Π, and then uses the resulting private output to specify inputs to an execution of Π'. Then the composed protocol $(\Pi\circ\Pi')$ satisfies $(\alpha+\gamma+\gamma')$-dZK.

2.3 An Example: Verifying Linear Equalities

We next provide an example for a distributed zero-knowledge protocol, which allows a prover to prove to two verifiers that some linear equality holds with respect to the shared inputs that the verifiers hold. The protocol is very simple and requires no interaction with the prover. Nevertheless, this protocol will be useful as a sub-protocol in our construction.

Example 1 (A protocol for linear equality)**.** ***Common inputs:*** *Field size $q\in\mathbb{N}$, Dimension $d\in\mathbb{N}$, coefficients $\alpha_1,\ldots,\alpha_d,\in\mathbb{GF}[q]$, a field element $z\in\mathbb{GF}[q]$.*

Secret-shared inputs: *A vector $X\in\mathbb{GF}[q]^d$, where each X_i is secret-shared as $[X_i]=(X_i^{(0)},X_i^{(1)})$. The prover knows the secret-shared values X and the shares $[X]$. The verifiers each know their own shares (respectively $X^{(0)}$ and $X^{(1)}$).*

Claim (to be verified): *$\sum_{i=1}^d\alpha_i\cdot X_i=z$. I.e. the input language is $L_{\mathsf{inp}}=\{((q,d,\{\alpha_i\},z),X):\sum_i\alpha_i\cdot X_i=z\}$, there are no private outputs (or output language).*

The Protocol: *For $j\in\{0,1\}$, verifier $\mathbf{V}_j$ (locally) computes $z_j=\sum_{i=1}^d\alpha_i\cdot X_i^{(j)}$ and sends z_j to $\mathbf{V}_{1-j}$. Both verifiers accept if $z=z_0+z_1 \pmod q$ and reject otherwise.*

Properties of the protocol: *This protocol offers perfect completeness and perfect soundness in the sense that the verifiers accept if and only if*

$$z=\sum_{i=1}^d\alpha_i\cdot(X_i^{(0)}+X_i^{(1)}) \pmod q.$$

To see that the protocol is perfect zero-knowledge, observe that for every input share $X^{(j)}$ for verifier $\mathbf{V}_j$, the simulator can compute $z_j=\sum_{i=1}^d\alpha_i\cdot X_i^{(j)} \pmod q$, and send to $\mathbf{V}_j$ the value $z-z_j \pmod q$ as its only message from $\mathbf{V}_{1-j}$.

3 Norm Verification

We build our protocol in multiple steps. Some of our sub-protocols output secret shares of values that are then checked in subsequent sub-protocols, e.g. checking that the secret-shared values are bits (i.e. 0 or 1).

In Section 3.1 we show a protocol that reduces checking that a secret-shared value is in some range to: (i) checking a linear equality over secret-shared values, and (ii) checking that shares generated in the protocol are secret shares of bits. In Section 3.2, we build on this to construct our main contribution: a protocol for verifying that the sum of secret-shared values is not larger than the field size (the sum is taken over the integers, not over the field). In particular, this protocol lets us reduce certifying a norm bound of secret-shared values to certifying quadratic constraints. We recall the appropriate form for quadratic constraint validation in Section 3.3 and combine these ingredients to derive our main result in Section 3.4.

3.1 Range-Check Subprotocol

We present a simple 1-message protocol that is helpful in verifying inequalities of the form $\sum_i \alpha_i Q_i \in [\beta_1, \beta_2] \pmod q$, where the coefficients $\alpha_i \in \mathbb{GF}[q]$ and the lower and upper bounds $\beta_1, \beta_2 \in \mathbb{GF}[q]$ are known and public (we view elements of $\mathbb{GF}[q]$ as integers in the set $\{-\lfloor q/2 \rfloor, \ldots, \lfloor q/2 \rfloor\}$), but the Q_i's are known only to the prover, not to the verifiers. In particular, the Q_i's are either secret-shared between the verifiers, or they are functions of secret-shared values (e.g. when we are verifying the inequality $\sum_i X_i^2 \leq B \pmod q$ over the secret-shared values X_i). The protocol reduces this verification task to: (i) the verification of an *equality* modulo q, an easier claim to deal with, and (ii) verifying that new secret-shared values (generated in the course of the protocol) are secret shares of bits.

Protocol overview. The prover computes $V = ((\sum_i \alpha_i Q_i) - \beta_1)$, and secret-shares the bits $\{v_j\}$ of V's binary representation. It also computes $U = (\beta_2 - (\sum_i \alpha_i Q_i))$ and secret-shares the bits $\{u_j\}$ of U's binary representation. Observe that $U, V \in [0, (\beta_2 - \beta_1)]$, and thus U and V can be represented using $b = \lceil \log(\beta_2 - \beta_1 + 1) \rceil$ bits. The verifiers get secret shares of these bits and verify that the sum of the values they represent is correct, i.e. that $(\sum_j v_j \cdot 2^j) + (\sum_j u_j \cdot 2^j) = (\beta_2 - \beta_1) \pmod q$ (recall that linear equalities over secret-shared values are easy for the verifiers to check). If this holds, and also: (i) the v_j's and the u_j's are all secret shares of bits, (ii) $\sum_j v_j \cdot 2^j = (\sum_i \alpha_i Q_i) - \beta_1$, and (iii) $q > 3(\beta_2 - \beta_1) + 2$, then indeed it must be the case that $\sum_i \alpha_i Q_i \in [\beta_1, \beta_2]$. Note that if Q_i's are themselves secret-shared values, then the verifiers can verify that condition (ii) holds, and all that remains is to verify that the secret-shared values are indeed of bits (but we will also use this protocol in situations where the verifiers do not have secret shares of the Q_i values). The protocol is in Figure 1, its complexity and guarantee are in Lemma 3.1.

Lemma 3.1. *The protocol of Figure 1 satisfies:*

1. ***Completeness:*** *If $\sum \alpha_i Q_i \in [\beta_1, \beta_2] \pmod q$ (this is the input condition), then the verifiers accept and it holds that: (i) $(\sum_{i=1}^n \alpha_i Q_i) - \beta_1 = \sum_{j=0}^{b-1} v_j \cdot 2^j \pmod q$, and (ii) the secret-shared values are bits: $\forall j : v_j, u_j \in \{0,1\}$ ((i) and (ii) are the output conditions).*

2. ***Soundness:*** *If $\sum_{i=1} \alpha_i Q_i \notin [\beta_1, \beta_2] \pmod q$, if the verifiers do not reject, then either: (i) $(\sum_{i=1}^n \alpha_i Q_i) - \beta_1 \neq \sum_{j=0}^{b-1} v_j \cdot 2^j \pmod q$, or (ii) for some j, either v_j or u_j is not in $\{0,1\}$.*

3. ***Zero-Knowledge****:The protocol is strong zero-knowledge as per Definition 2.2.*[4]

The proof consists of a single message of length $(2\lceil \log(\beta_2 - \beta_1 + 1) \rceil \cdot \log(q)$ from the prover to each verifier (this message contains the secret shares of the bits $\{v_j, u_j\}$). The prover performs $O(n + \log(\beta_2 - \beta_1 + 1))$ field operations. The verifiers each perform $O(\log(\beta_2 - \beta_1 + 1))$ field operations and communicate $\log(q)$ bits between themselves.

The proof of Lemma 3.1 is omitted: it follows from the construction. The simulator generates dummy shares of the bits v_j and u_j, and simulates receiving a message in the protocol that verifies the linear equality, as in Example 1.

Remark 3.2. *We note that if $(\beta_2 - \beta_1 + 1)$ is a power of two, we can simplify this protocol by skipping sending U and skipping the equality check. Indeed the fact that $V = (\sum_i \alpha_i Q_i) - \beta_1$ can be represented as $\sum_{j=0}^{b-1} v_j 2^j$, for bits v_j, is equivalent in this case to $V \in [0, 2^b - 1] = [0, \beta_2 - \beta_1]$.*

3.2 Detecting Wraparound

Our main technical contribution is a protocol that allows the servers to verify that the sum of the squares of the secret-shared values is not larger than the field size (where the sum is taken over the integers), i.e. that there is no "wraparound" when we take the sum of squares modulo the field size. The guarantees and complexity of the protocol are in Lemma 3.3. The protocol itself is in Figure 2.

In more detail: let q be the size of the field, constraints on which will be determined below. We view each X_i as an integer whose value is in the range $\{0, \ldots, q-1\}$. In what follows, all equalities and inequalities are over the integers unless we explicitly note otherwise (using and abusing the $\pmod q$ notation). The protocol considers a *promise problem*: in the YES case we have $\|X\|_2^2 \leq B$, whereas in the NO case we have $\|X\|_2^2 \geq q$ (i.e., there is wraparound). The verifiers accept or reject, and they also output secret shares $\{[w_j]\}$, which should be shares of bits (i.e. it should be true that $w_j \in \{0,1\}$, and this always holds in the YES case assuming the prover follows the protocol). Soundness guarantees that in the NO case, the probability that the verifiers accept *and* the output shares are all of bits is small. The verifiers will run a subsequent sub-protocol to verify that all w_j's are shares of bits.

Protocol overview. The verifiers pick a random vector $Z \in \{-1, 0, 1\}^d$, where each Z_i is -1 w.p. $1/4$, 1 w.p. $1/4$, and 0 w.p. $1/2$. The verifiers send Z to the prover, and verify that for a constant $\alpha > 0$ (set below, where we assume $q > 2\alpha\sqrt{B}$):

$$\sum_i Z_i X_i \in \left[-\alpha\sqrt{B}, \alpha\sqrt{B}\right] \pmod q. \tag{1}$$

This verification is performed using the protocol of Figure 1. We show that for an appropriate choice of α there is a small constant η s.t. in the YES case ($\|X\|_2^2 \leq B$) Equation (1) holds

[4] Technically, this protocol does not fall into our distributed verification model, as the verifiers do not hold secret shares of the Q_i's. Indeed, here the simulator can create its view without *any* access to shares of the Q_i's.

Protocol: Range Check $(\mathrm{mod}\ q)$

Common inputs: Field size $q \in \mathbb{N}$, number of variables $n \in \mathbb{N}$, coefficients $\alpha_1, \ldots, \alpha_n \in \mathbb{GF}[q]$ and claimed lower and upper bounds $\beta_1, \beta_2 \in \mathbb{GF}[q]$, viewed as integers in $\{-\lfloor q/2 \rfloor, \ldots, \lfloor q/2 \rfloor\}$, s.t. $\beta_1 \leq \beta_2$ and $q > 3(\beta_2 - \beta_1) + 2$.

Other inputs: The prover knows $Q_1, \ldots, Q_n \in \mathbb{GF}[q]$. We do not assume the verifiers have access to these Q_i's.

Secret-shared outputs: Shares $\{[v_j], [u_j]\}_{j=0}^{b-1}$, where $b = \lceil \log(\beta_2 - \beta_1 + 1) \rceil$ (for each j, each verifier outputs its respective shares, $(v_j^{(0)}, u_j^{(0)})$ or $(v_j^{(1)}, u_j^{(1)})$).

The Protocol:
The prover secret shares:

1. The b bits $(v_j)_{j \in [0,\ldots,b-1]}$ of $V = (\sum_i \alpha_i Q_i) - \beta_1 \pmod q$,
2. The b bits $(u_j)_{j \in [0,\ldots,b-1]}$ of $U = \beta_2 - (\sum_i \alpha_i Q_i) \pmod q$.

The verifiers verify the linear equality $(\sum_{j=0}^{b-1} v_j \cdot 2^j) + (\sum_{j=0}^{b-1} u_j \cdot 2^j) = \beta_2 - \beta_1 \pmod q$ (rejecting otherwise).

Figure 1: Range Check $(\mathrm{mod}\ q)$ Protocol

with probability at least $1 - \eta$ over the choice of Z. In the NO case, the probability is at most $1/2$. We can repeat the test in parallel to make the soundness error negligible. This effectively reduces our original problem to range-checks (and, via the protocol of Figure 1, to bit-checks). There is, however, a zero-knowledge issue: there's a non-negligible failure probability in the YES case, and the verifiers see whether the test failed or not (and the values Z that led to failure), which leaks information about X.

We could resolve this issue by increasing the field size to the point where the failure probability in the YES case becomes negligible, but this would entail a significant cost in the communication complexity required for sending field elements (we remark that increasing the field size doesn't reduce the soundness error). Instead, we take advantage of the fact that the protocol will be repeated many times (for soundness). The verifiers will not learn whether any of the individual repetitions succeeded, but only whether "many" of them succeeded. The threshold for "many" is set by a parameter τ indicating the fraction of repetitions that should succeed (by default we set $\tau = 3/4$, so the verifiers accept if and only if at least three quarters of the repetitions succeed). In the YES case this will happen with all but negligible probability (so we get statistical zero-knowledge). To accomplish this, we repeat the test r times, where in the k-th repetition the prover secret-shares a bit $g_k \in \{0,1\}$, indicating whether or not Equation (1) holds with respect to the k'th test. The verifiers multiply both sides of the equation by g_k, so that if $g_k = 0$ the test passes even though the equation doesn't hold. Later, the verifiers also verify that $\sum_k g_k \geq \tau \cdot r$ (the inequality can be verified in zero-knowledge using the protocol of Figure 1). Checking that Equation (1) holds after multiplying by g_k is done using the protocol of Section 3.3 for checking quadratic constraints over secret-shared values.

We make two minor modifications to improve the protocol's efficiency: First, the cost of the quadratic constraint protocol grows with the (square root of the) number of summands. Thus, for each iteration, each verifier computes (on its own) its secret share for the sum $\sum_i Z_i X_i$ (a linear function of the secret-shared X_i's). This gives the verifiers a single secret-shared field element that should be multiplied by g_k (instead of d). Indeed, in the full protocol, we fold further summands into this secret-shared sum. The second minor efficiency improvement we use is having the honest prover set *exactly* a $(1-\tau)$-fraction of the bits g_k to 0 (w.h.p. this means that some repetitions where Equation (1) holds will not be checked). This allows the verifiers to replace checking $\sum_k g_k \geq \tau \cdot r$ (an inequality) with a simpler equality check $\sum_k g_k = \tau \cdot r$.

Lemma 3.3. *Fix a bound B, a number of repetitions r, a desired completeness error for each repetition $\eta \in [0,1]$ and a threshold $\tau \in (1/2, 1]$ s.t. $\tau \cdot r$ is an integer. Let the field size q be at least $\max\{81B \cdot \ln(2/\eta), 100, 2r\}$.*

Let $\mathsf{Bin}(\ell; r, p)$ denote the probability that the Binomial distribution with parameters r and p has outcome (number of successes) at least ℓ. The protocol of Figure 2 has the following properties:

1. ***Completeness:*** *If $\sum X_i^2 \leq B$, then the probability that the prover aborts is at most:*

$$\rho_C = 1 - \mathsf{Bin}((\tau \cdot r); r, 1-\eta). \tag{2}$$

Thus, for $\tau \in (1/2, 1-\eta)$, we get that $\rho_C \leq \exp\left(-2(1-\eta-\tau)^2 \cdot r\right)$. For $\tau \in [1-\eta, 1]$, it is still the case that $\rho_C \leq r \cdot \eta$.

If the prover doesn't abort, then the verifiers accept and it holds that: (i) for every $k \in [r]$, $g_k \cdot S_k = 0$, and (ii) the output shares $\{[g_k], [v_{k,j}], [u_{k,j}]\}$ are shares of bits.

Wraparound Detection Protocol

Common inputs: Dimension $d \in \mathbb{N}$, claimed bound $B \in \mathbb{N}$, field size $q \in \mathbb{N}$, number of repetitions $r \in \mathbb{N}$, completeness error per repetition $\eta \in [0,1]$, threshold $\tau \in (1/2,1]$ for successful repetitions, s.t. $\tau \cdot r$ is an integer.

Secret-shared inputs: A vector $X \in \mathbb{GF}[q]^d$, where each X_i is secret-shared as $[X_i] = (X_i^{(0)}, X_i^{(1)})$.
The client (prover) knows the secret-shared values X and the shares $[X]$.
The servers (verifiers) each know their own shares (respectively $X^{(0)}$ and $X^{(1)}$).

Secret-shared outputs: $\{[g_k],[S_k],[v_{k,j}],[u_{k,j}]\}_{k\in[r],j\in[b]}$ where $b = \left(\lceil \log(2\alpha\sqrt{B}+1)\rceil\right)$.

The Protocol:
Fix $\alpha = \sqrt{\ln(2/\eta)}$. Let D_Z be the distribution that samples a d-dimensional vector where for each $i \in [1,\ldots,d]$, Z_i is drawn independently to be -1 w.p. $1/4$, 0 w.p. $1/2$ and 1 w.p. $1/4$

1. The following test is repeated in parallel r times, where in the k-th repetition:
   (a) The verifiers choose a random string $Z_k \sim D_Z$ and send it to the prover.
   The prover computes $Y_k = \sum_{i=1}^d Z_{k,i} X_i$.
   (b) If $Y_k \in [-\alpha\sqrt{B}, \alpha\sqrt{B}]$, the prover sets $g_k = 1$ and uses the protocol of Figure 1 to prove that $(\sum_i Z_{k,i} X_i) \in [-\alpha\sqrt{B}, \alpha\sqrt{B}]$. Let $\{v_{k,j}, u_{k,j}\}_{j\in[b]}$ be the secret-shared outputs of that protocol.
   Otherwise ($Y_k \notin [-\alpha\sqrt{B}, \alpha\sqrt{B}]$), the prover sets $g_k = 0$, sets the bits $\{v_{k,j}\}$ to be the bit representation of the value $2\alpha\sqrt{B}$, and sets the bits $\{u_{k,j}\}_{j\in[b]}$ to all be 0. Note that this setting ensures that the linear check in the protocol of Figure 1 (the last step of that protocol) succeeds.
2. If there are more than $(1-\tau)\cdot r$ repetitions in which $g_k = 0$ then the prover aborts (and the verifiers reject).
   Otherwise, the prover sets $g_k = 0$ for as many of the repetitions as needed to ensure there are *exactly* $(1-\tau)\cdot r$ such repetitions, and sends secret shares of $\{g_k\}_{k\in[r]}$.
3. For each $k \in [r]$, the verifiers will check that either $g_k = 0$ or the v_j's satisfy soundness condition (i) of the protocol of Figure 1 (see Lemma 3.1). Towards this, each verifier computes its a share of:
$$S_k = \left(\sum_{i=1}^d Z_{k,i} X_i\right) + \alpha\sqrt{B} - \left(\sum_{j\in[b]} 2^j \cdot v_{k,j}\right) \pmod q,$$
   Note that the sum S_k is a linear function of secret-shared values, so each verifier can indeed compute its share on its own. The protocol of Section 3.3 will later be used to check the quadratic equality $g_k \cdot S_k = 0 \pmod q$ (see the protocol of Figure 3).
4. The verifiers verify the linear equality $\sum_{k\in[r]} g_k = \tau \cdot r \pmod q$ (otherwise they reject).

Figure 2: Wraparound Detection Protocol

2. ***Soundness:*** *If $\sum X_i^2 \geq q$, the probability that the verifiers accept, and that (i) for every k it holds that $g_k \cdot S_k = 0$, and (ii) the shares $\{[g_k],[v_{k,j},[u_{k,j}]\}$ are all shares of bits, is at most*
$$\rho_S = \mathsf{Bin}((\tau\cdot r); r, \frac{1}{2}) \leq \exp\left(-2\left(\tau - \frac{1}{2}\right)^2 \cdot r\right). \quad (3)$$
3. ***Zero-Knowledge****: The protocol satisfies statistical zero-knowledge: the view of each verifier can be simulated up to statistical distance ρ_C (see Equation (2)).*

The protocol is public-coins, with 2 messages. The verifier's message is $(2\cdot d\cdot r)$ bits, the prover's response is of length $\left(\left(\left\lceil \log\left(\sqrt{2B\cdot\ln(2/\eta)}+1\right)\right\rceil + 2\right)\cdot r\cdot\log(q)\right)$. The prover performs $O\left((d+\log(B\cdot\ln(2/\eta)))\cdot r\right)$ field operations. The verifiers each perform $O\left((d+\log(B\cdot\ln(2/\eta)))\cdot r\right)$ field operations, and communicate $O(r\cdot\log(q))$ bits between themselves.

Proof. The protocol is in Figure 2, and the claimed complexity bounds follow by construction. We proceed to prove completeness for a single repetition (Proposition 3.4) and soundness for a single repetition (Proposition 3.5). For clarity, we omit the subscript k when we consider a single iteration. Let Y be the vector where $Y_i = Z_i X_i$. Recall that we set the parameter $\alpha = \sqrt{\ln(2/\eta)}$. The proof of the following completeness claim follows from standard subgaussian concentration, and deferred to the full version [ROCT23].

Proposition 3.4 (Completeness)**.** *Let $\sum_i X_i^2 \le B$. For every $\alpha > 0$ and every field size $q \ge 2\alpha\sqrt{B}$:*

$$\Pr_{Z_1,\ldots,Z_d}\left[Y \in [-\alpha\sqrt{B}, \alpha\sqrt{B}]\right] \ge 1 - 2e^{-\alpha^2}.$$

Proposition 3.5 (Soundness)**.** *For every B, every $\alpha \ge 1$ and every field size $q \ge \max\{81\alpha^2 B, 100\}$, if it is the case that $\sum_i X_i^2 > q$, then:*

$$\Pr_{Z_1,\ldots,Z_d}[Y \in [-\alpha\sqrt{B}, \alpha\sqrt{B}] \pmod q] \le \frac{1}{2}.$$

Proof. If any of the secret-shared w_j values are not bits, then the soundness condition is automatically satisfied. Thus, we only need to bound the probability that the verifiers accept conditioned on the event that all w_j's are bits. Under this conditioning, $(\sum_j w_j \cdot 2^j) \in [0, 2\alpha\sqrt{B}]$. The verifiers check that $(\sum_j w_j \cdot 2^j) = Y + \alpha\sqrt{B} \pmod q$, and thus they will reject unless $Y \in [-\alpha\sqrt{B}, \alpha\sqrt{B}] \pmod q$. We bound the probability that $Y \pmod q$ is in this range using a case analysis (soundness follows), where we view the value of each X_i modulo q as an integer between $-q/2$ and $q/2$.

Soundness, case *I* (large max). If:

$$\max_i |X_i| > 2\alpha\sqrt{B} \pmod q,$$

then let i^* be the argmax, where $|X_{i^*}| > 2\alpha\sqrt{B} \pmod q$ (note that this can only happen if $q > 4\alpha\sqrt{B}$). The probability, over the choice of Z, that $\sum_i Z_i X_i \pmod q$ lands in the interval $[-\alpha\sqrt{B}, \alpha\sqrt{B}]$ is at most $1/2$. To see this, fix all of Z's entries except the i^*-th entry. There are two cases:

- Let S be the sum of all Y_i's except the i^*-th $\pmod q$. If $S \in [-\alpha\sqrt{B}, \alpha\sqrt{B}]$, then when we add or subtract X_{i^*}, we end up outside the interval. This is because if $Z_{i^*} \neq 0$, then

  $$|Y_{i^*}| \in (2\alpha\sqrt{B}, q/2] \pmod q.$$

  Suppose w.l.o.g that Y_{i^*} is positive (modulo q), then:

  $$Y = S + Y_{i^*} \in (\alpha\sqrt{B}, q/2 + \alpha\sqrt{B}] \pmod q,$$

  and thus Y is outside the interval (recall that $q > 4\alpha\sqrt{B}$). A similar statement holds for the case that Y_{i^*} is negative (modulo q).

- If the sum of all Y_i's except the i^*-th is outside the interval, then w.p. $1/2$ we have that $Z_{i^*} = 0$ and the total sum is also outside the interval.

Soundness, case *II* (bounded max). Suppose it is the case that:

$$\max_i |X_i| \le 2\alpha\sqrt{B}.$$

In this case, we use the Berry-Esseen theorem to show that the distribution of Y is sufficiently close to a Normal distribution, and this allows us to bound the probability that its magnitude is small modulo q.

Theorem 3.6 (Berry-Esseen for our setting, see [Fel91; She10].)**.** *Suppose $\max_i |X_i| \le 2\alpha\sqrt{B}$, and take $\sigma^2 = \sum_i X_i^2/2$. Then for any $y \in \mathbb{R}$:*

$$\left|\Pr[Y \le y] - \Pr[\mathcal{N}(0,\sigma^2) \le y]\right| \le \frac{0.56 \cdot \alpha\sqrt{B}}{\sigma}.$$

A symmetric claim follows for bounding the probability that Y is above a value y'. For an interval $[y', y]$, the probability of Y lying in the interval can be bounded via a Union Bound on the probability that it is below y' and the probability that it is above y.

We use the Berry-Essen theorem, together with the concentration (and anti-concentration) properties of the Normal distribution, to bound the probability that Y's magnitude is small modulo q. In Claim 3.7 we bound the probability that Y lies in any single interval where its magnitude modulo q is small. In Claim 3.8 we bound the probability that Y is far from its expectation. To prove the soundness lemma, we combine these claims: bounding the probability that Y is not too far from its expectation and has small magnitude modulo q, and also that it is far from its expectation. We prove the following claims in the full version [ROCT23].

Claim 3.7. *Suppose that $\alpha \ge 1$, the field size is $q \ge 2\alpha\sqrt{B}$, and that $\max_i |X_i| \le 2\alpha\sqrt{B}$, and take $\sigma^2 = \sum_i X_i^2/2$. Then for every integer $u \ge 0$:*

$$\sum_{t=-u}^{u} \Pr\left[Y \in [-\alpha\sqrt{B} + t \cdot q, \alpha\sqrt{B} + t \cdot q]\right] \le (2u+1) \cdot \left(1.12 + \sqrt{\frac{2}{\pi}}\right) \cdot \frac{\alpha\sqrt{B}}{\sigma}$$

Claim 3.8. *Suppose that $\alpha \ge 1$, the field size is $q \ge 2\alpha\sqrt{B}$, and that $\max_i |X_i| \le 2\alpha\sqrt{B}$. Take $\sigma^2 = \sum_i X_i^2/2$. Then for every integer $t \ge 1$, it holds that:*

$$\Pr\left[|Y| \ge -\alpha\sqrt{B} + t \cdot q\right] \le \sqrt{\frac{2}{\pi}} \exp\left(-\frac{\left(-\alpha\sqrt{B} + t \cdot q\right)^2}{2\sigma^2}\right) + \frac{1.12\alpha\sqrt{B}}{\sigma}$$

As described above, putting these claims together, we can bound both the probability that $Y \pmod q$ has small magnitude but $|Y|$ isn't too large, and the remaining case, where $|Y|$ is large. Towards this, for a parameter $\delta > 0$ to be specified below, we set:

$$u = \left\lfloor \frac{(\sigma\sqrt{2\ln(1/\delta)}) + (\alpha\sqrt{B})}{q} \right\rfloor.$$

By a union bound over Claims 3.7 and 3.8, an easy computation (see the full verison [ROCT23]) establishes that

Claim 3.9. *Under the notation above,*

$$\Pr[Y \in [-\alpha\sqrt{B}, \alpha\sqrt{B}] \pmod q]$$
$$\leq \left(\alpha\sqrt{B} \cdot \left(1.12 + \sqrt{\frac{2}{\pi}}\right) \cdot \left(\frac{2\sqrt{2\ln(1/\delta)} + 0.04\sqrt{q}}{q}\right) + \delta\right).$$

Taking $\delta = e^{-3}$, and $q \geq 100$ s.t. $0.04\sqrt{q} + 2\sqrt{6} \leq 2.1\sqrt{q}$, we have that:

$$\Pr[Y \in [-\alpha\sqrt{B}, \alpha\sqrt{B}] \pmod q]$$
$$\leq \left(2.1 \cdot \left(1.12 + \sqrt{\frac{2}{\pi}}\right)\right) \frac{\alpha\sqrt{B}}{\sqrt{q}} + e^{-3}.$$

This probability can be bounded by $1/2$ for $q \geq \max\{81\alpha^2 B, 100\}$. □

In each repetition k, the prover can satisfy the conditions (i) $g_k \cdot S_k = 0$, and (ii) the secret-shared values $\{g_k, v_{k,j}, u_{k,j}\}$ are all shares of bits, if and only if either it holds that $Y_k \in [-\alpha\sqrt{B}, \alpha\sqrt{B}] \pmod q$, or the prover sets $g_k = 0$. Over all r repetitions, the prover can get the verifiers to accept while satisfying conditions (i) and (ii) above, if and only if in at least $\tau \cdot r$ of the repetitions, $Y_k \in [-\alpha\sqrt{B}, \alpha\sqrt{B}] \pmod q$.

Completeness and soundness over the r repetitions are thus bounded by claimed Binomial terms (see Equations (2) and (3)). The binomial tail terms can be further bounded by taking a Chernoff Bound. For completeness, in each repetition the probability of success is at least $1 - \eta$. The probability that in r repetitions we have fewer than $\tau \cdot r$ successes is bounded by:

$$\exp\left(-D_{\mathrm{KL}}\left(\tau \| 1-\eta\right) \cdot r\right) \leq \exp\left(-2\left(1-\eta-\tau\right)^2 \cdot r\right), \quad (4)$$

where $D_{\mathrm{KL}}(p\|q)$ is the KL divergence between the Bernoulli distribution with mean p and the distribution with mean q. For soundness, the probability of success in each repetition is at most $1/2$. The probability that in r repetitions we have at least $\tau \cdot r$ successes is bounded by:

$$\exp\left(-D_{\mathrm{KL}}\left(\tau \| 1/2\right) \cdot r\right) \leq \exp\left(-2\left(\tau - \frac{1}{2}\right)^2 \cdot r\right). \quad (5)$$

Remark 3.10. *We note that while the protocol is described as sending the vectors $Z_1, \ldots, Z_k$, standard techniques [SSS95; AS00] of using limited independence ($O(\log 1/\rho)$-wise independence suffices for the concentration bounds) can be used to reduce the communication to $O(r \log d \log 1/\rho)$ bits.*

Remark 3.11. *The analytic Chernoff bound expressions here can be rather loose for particular values of parameters (especially when η is close to zero). In practice, one can use better analytic estimates, or numerical estimates for concentration on binomial random variables We directly state the bounds in terms of the CDF of the Binomial distribution in Equations (2) and (3).*

Remark 3.12. *Suppose that for some L, H satisfying $-\alpha\sqrt{B} \leq L < 0 < H \leq \alpha\sqrt{B}$, we test for $Y \in [L, H]$ instead of $Y \in [-\alpha\sqrt{B}, \alpha\sqrt{B}]$. Then the soundness argument continues to hold as $Y \in [L, H] \Rightarrow Y \in [-\alpha\sqrt{B}, \alpha\sqrt{B}]$. Moreover, the completeness argument now holds with $\tau' = 2\exp(-\hat{\alpha}^2)$ where $\hat{\alpha} = \min(\frac{-L}{\sqrt{B}}, \frac{H}{\sqrt{B}})$. The protocol's practical efficiency can be improved by a careful choice of L, H, see Remark 3.2.*

Honest-verifier zero-knowledge. To prove zero-knowledge, we need to show that for a single verifier V_j, there exists a simulator S that does not know the private input X, but receives some share $X^{(j)}$ and generates a view that is statistically closely distributed to the view of the verifier V_j in a real interaction with the prover and the remaining verifier V_{1-j}. We sketch the construction of such a simulator. Let $\left\{X_1^{(j)}, \ldots X_d^{(j)}\right\}$ be the shares, given to V_j as input.

The Simulation: The simulator S starts by setting $\hat{X} = 0^d$ to be the (fake) input for the simulation and setting (fictitious) shares for V_{1-j} accordingly. Specifically, S sets the "shares" for the second verifier V_{1-j} to be $\hat{X}_i^{(1-j)} = -X_i^{(j)}$ and emulates an interaction between the two verifiers as follows.

1. The simulator S repeats the following r times in parallel, where in the k-th repetition:

   It simulates the verifier V_{1-j} in choosing a random string $Z_k \sim D_Z$ and receives from V_j its messages to the prover to determine Z_k.

   S simulates the prover, setting $Y_k = \sum_{i=1}^d Z_{k,i}\hat{X}_i$ to be 0. If $1 \leq k \leq \tau \cdot r$ the simulator sets $g_k = 1$, and otherwise sets $g_k = 0$.

   The simulator then sets the bits $\{v_{k,j}\}$ to be the Binary representation of the value $2\alpha\sqrt{B}$, and sets the bits $\{u_{k,j}\}_{j\in[b]}$ to all be 0. The simulator S simulates the view of $\mathbf{V}_j$ in the appropriate k executions of the protocol in Figure 1, with $\alpha_i = Z_{k,i}$.

2. The simulator selects shares for $\{g_k\}_{k\in[r]}$ and sends $\mathbf{V}_j$ its shares.

3. For each $k \in [r]$, the simulator computes $\mathbf{V}_j$'s share of S_k by taking the appropriate linear combination of existing shares:.

$$(s_k)^{(j)} = \left(\sum_{i=1}^{d} Z_{k,i}(X_i)^{(j)}\right) + \alpha\sqrt{B} - \left(\sum_{j\in[b]} 2^j \cdot (v_{k,j})^{(j)}\right) \pmod q$$

4. The simulator S emulates $\mathbf{V}_{1-j}$ in its interaction with $\mathbf{V}_j$ verifying the linear equality $\sum_{k\in[r]} g_k = \tau \cdot r \pmod q$ (see Example 1).

We first note that all choices of Z_k for all r repetitions are identically distributed in the simulation as in a real execution of the protocol. Condition on the event that for these choices, in the real execution of the protocol, it holds that there are at least τr values of k, for which $Y_k \in [-\alpha\sqrt{B}, \alpha\sqrt{B}]$. This means that the prover does not abort. Under the aforementioned conditioning, the view of $\mathbf{V}_j$ in the real execution is distributed identically to the view generated by the simulator. This is true since all that $\mathbf{V}_j$ ever sees are random shares and the views it sees in the simulation of the sub-protocol, which are perfectly simulated (since they are on accepting inputs). Finally, since in the real world, the probability that the prover aborts is at most ρ_C, we conclude that even without the conditioning, the two views are of statistical distance ρ_C. □

3.3 Verifying Quadratic Constraints

In this section we recall a protocol from the work of Boneh *et al.* [BBCGI19] for verifying a conjunction of low-degree constraints over secret-shared values. We focus on quadratic constraints. Let $\{X'_i\}_{i\in[n]}$ be a collection of secret-shared values. A quadratic constraint C_k is specified by public coefficients $\{c_{k,i,j} \in \mathbb{GF}[q]\}_{i,j\in\{0,\ldots,n\}}$ and a target value $a_k \in \mathbb{GF}[q]$, and the claim (to be verified) is that:

$$\sum_{i,j\in[0,n]} c_{k,i,j} \cdot X'_i \cdot X'_j = a_k,$$

where we use the convention that $X'_0 = 1$ (this allows us to include linear terms in the constraint).

Given a collection of m quadratic constraints as above, there is a 2-message protocol for verifying that all the constraints hold, where the communication complexity scales with the *square-root* of the number of variables. More generally, the communication complexity can be reduced to (roughly) $n^{1/r}$ by increasing the amount of interaction to $(2r-2)$ messages.

Verifying that a secret-shared value v is a bit can be expressed as the quadratic constraint $v^2 - v = 0$. Thus, we use this protocol to verify that (multiple) secret shares produced in other protocols are composed of bits.

Lemma 3.13 (Boneh *et al.* [BBCGI19, Corollary 4.7 and Remark 4.8])**.** *For a field of size q, an integer n that is a perfect square, a collection of secret-shared values $\{X'_i\}_{i=1}^n$, and quadratic constraints $C = \{c_{k,i,j}, a_k\}_{k\in\{1,\ldots,m\},i,j\in\{0,\ldots,n\}}$, there is a protocol for verifying the constraints as follows: all parties get as input the field size q and the constraints. The prover gets both shares of each value X'_i. Each verifier gets a single share of each secret-shared value, where:*

Completeness: *If all constraints hold, the verifiers accept.*

Soundness: *If at least one of the constraints is violated, then (no matter what strategy the prover follows) the probability that the verifiers accept is at most $\left(\frac{2\sqrt{n}}{q-\sqrt{n}} + \frac{m}{q}\right)$.*

Zero-Knowledge *: The protocol is perfect strong distributed honest-verifier zero-knowledge (see Definition 2.2).*

The protocol is public-coins, with 2 messages. The verifiers' message is $\log(q)$ bits and the prover's message is $((4\sqrt{n}+1)\cdot\log(q))$ bits. Let $\mathsf{nnz}(C)$ be the total number of non-zero coordinates in the constraints $\{c_{k,i,j}\}$. The prover performs $O(\mathsf{nnz}(C) + n\log(n) + m\log(m))$ field operations. In the course of verification, the verifiers each perform $O(\mathsf{nnz}(C) + n\log(n) + m\log(m))$ field operations, and they exchange $(2\sqrt{n}+2)\cdot\log(q)$ bits with each other.

Soundness amplification. The soundness error can be reduced by parallel repetition [BM88; Gol01]:

Corollary 3.14 (Parallel repetition of Lemma 3.13)**.** *For the same inputs considered in the protocol of lemma 3.13, repeating that protocol in parallel t times, where the verifiers accept iff all repetitions accept, gives a 2-message public-coins protocol with perfect completeness and zero-knowledge, where:*

1. *The soundness error is reduced to $\left(\frac{2\sqrt{n}}{q-\sqrt{n}} + \frac{m}{q}\right)^t$.*
2. *The communication and runtime complexities are t times larger than those in Lemma 3.13.*

3.4 Putting it Together: The Norm-Bound Protocol

Our final norm-bound protocol is described in Figure 3. We defer the proof to the full version [ROCT23].

Theorem 3.15. *Fix a bound B, parameters $r,t \in \mathbb{N}, \eta \in [0,1], \tau \in (1/2,1]$ s.t. $\tau \cdot r$ is an integer. Let the field size be $q \geq \max\{81B\cdot\ln(2/\eta), 1000, 3r\}$. The protocol of Figure 3 has the following properties:*

1. ***Completeness:*** *If the claim is true and the prover follows the protocol, the verifiers accept with prob. $\geq 1-\rho_C$, where*

$$\rho_C = 1 - \mathsf{Bin}((\tau\cdot r); r, 1-\eta),$$

L_2-Bound Protocol

Common inputs: Dimension $d \in \mathbb{N}$, claimed bound $B \in \mathbb{N}$, field size $q \in \mathbb{N}$, errors $\rho_C, \rho_S \in [0,1]$.

Secret-shared inputs: A vector $X \in \mathbb{GF}[q]^d$, where each X_i is secret-shared as $[X_i] = (X_i^{(0)}, X_i^{(1)})$.
The client (prover) knows the secret-shared values X and the shares $[X]$.
The servers (verifiers) each know their own shares (respectively $X^{(0)}$ and $X^{(1)}$).

Claim (to be verified): $\sum_{i=1}^{d} X_i^2 \leq B$ (where summation is over the integers).

The Protocol:

1. Run the wraparound protocol of Section 3.2, setting the parameters r, η, τ as in Theorem 3.15.
   The two messages in this subprotocol (the verifier sends the first message) are sent in messages 1 and 2 of the L_2-bound protocol. This results in secret shares of values $\{s_k\}_{k\in[r]}$ and alleged shares of bits $\{g_k, u_{k,j}, v_{k,j}\}$.
2. Run the protocol of Section 3.1 to verify that $\sum_i X_i^2 \in [0, B] \pmod q$.
   The prover's message in this sub-protocol is sent in message 2 of the L_2-bound protocol. Results in alleged shares of bits $\{v'_{j'}, u'_{j'}\}$.
3. Use the quadratic constraints protocol of Corollary 3.14, setting the number of repetitions t as in Theorem 3.15, to verify the following quadratic constraints:
   (a) $\sum_{i=1}^{d} X_i^2 = \sum_{j'} v'_{j'} \cdot 2^{j'} \pmod q$.
   (b) $\forall k \in [r], g_k \cdot s_k = 0$.
   (c) the secret-shared values $\{v'_{j'}, u'_{j'}\}$ and $\{g_k, u_{k,j}, v_{k,j}\}$ are all bits (i.e. in $\{0,1\}$).
   The two messages of this sub-protocol (the verifier sends the first message) are sent in messages 3 and 4 of the L_2-bound protocol.

If the verifiers in any of the sub-protocols executed above reject, then the verifiers in the L_2-bound protocol reject immediately. Otherwise, they accept.

Figure 3: L_2-Bound Protocol

where $\mathsf{Bin}(\ell; r, p)$ *denotes the probability that the Binomial distribution with parameters r and p has outcome (number of successes) at least* ℓ.

Thus, for $\tau \in (1/2, 1-\eta)$, $\rho_C \leq \exp\left(-2(1-\eta-\tau)^2 \cdot r\right)$. *For* $\tau \in [1-\eta, 1]$, $\rho_C \leq r \cdot \eta$.

2. ***Soundness:*** *If* $\sum X_i^2 > B$ *(over the integers), the probability that the verifiers accept is at most:*

$$\exp\left(-2\left(\tau - \frac{1}{2}\right)^2 \cdot r\right) + \left(\frac{2\sqrt{d + (\log(q)\cdot(r+2)/2)}}{q - 2\sqrt{d + (\log(q)\cdot(r+2)/2)}} + \frac{\log(q)\cdot(r+2)}{2q}\right)^t.$$

3. ***Zero-Knowledge****: The protocol satisfies statistical zero-knowledge: the view of each verifier can be simulated up to statistical distance* ρ_C *(see above).*

The protocol is public-coins, with 4 messages. The message lengths (in bits) are:

1. *the first messsage, sent by the verifier, is of length* $2dr$.
2. *the second message, sent by the prover, is of length at most* $(\frac{r}{2}+2)\cdot\log^2(q)$.
3. *The third message, sent by the verifier, is of length* $t \log q$.
4. *The fourth message, sent by the prover, is of length* $\left(t \cdot \left(4\sqrt{d + (\log(q)\cdot(r+2)/2)} + 1\right) \cdot \log(q)\right)$.

4 Differentially Private Secret Sharing

We first recall a notion of near-indistinguishability used in Differential Privacy, and the notion of differential zero knowledge from [Tal22]:

Definition 4.1 ((ε,δ)-closeness)**.** *Two random variables P and Q are said to be* (ε,δ)*-close, denoted by* $P \approx_{(\varepsilon,\delta)} Q$ *if for all events S, it holds that* $\Pr[P \in S] \leq e^{\varepsilon} \cdot \Pr[Q \in S] + \delta$*, and similarly,* $Pr[Q \in S] \leq e^{\varepsilon} \cdot \Pr[P \in S] + \delta$.

Definition 4.2 (Differential Zero Knowledge)**.** *We say a protocol* π *is* (ε,δ)*-Differentially Zero Knowledge w.r.t. L if there is an efficiently samplable distribution Q such that for all* $x \in L$*, the distribution* $\pi(x)$ *of the protocol's transcript on input x satisfies* $\pi(x) \approx_{(\varepsilon,\delta)} Q$.

In the full version [ROCT23] , we describe a way for a client to share a vector $X \in L = \{X \in \mathbb{Z}^d : \|X\|_2^2 \leq B\}$, while preserving differential zero knowledge. In brief, the client will share each X_i by adding (rounded) truncated Gaussian noise of magnitude large enough to guarantee differential privacy. The client (prover) will sample gaussian noise, truncated to have ℓ_2 norm at most Δ and take the ceiling to get R. It will then secret-share X as $-R$ and $X+R$. Since both X and R have bounded ℓ_2 norm, so do the secret shares. The verifiers check that the received secret shares have bounded ℓ_2 norm, which then implies a bound on the norm of the sum of any valid secret shares. For a large enough q, there can then be no wraparound. Validating the squared norm modulo q then yields :

Theorem 4.3. *Let* $(\varepsilon, \delta) \in (0,1)$ *and* $B \geq 1$. *Set* $q > 4\left(\sqrt{B}+\sqrt{d}+\sqrt{dBc_{\varepsilon,\frac{\delta}{2}}\cdot(1+\frac{2\sqrt{\log 8e/\delta}}{\sqrt{d}}+\frac{2\log 8e/\delta}{d})}\right)^2$. *Then the PINE differential ZK protocol (see the full version) has the following properties:*

Completeness: *If* $\sum_{i=1}^d X_i^2 \leq B$ *and the prover follows the protocol, the verifiers accept with probability* 1.

Soundness: *If* $\sum X_i^2 > B$ *(over the integers), the probability that the verifiers accept is at most:*

$$\left(\frac{2\sqrt{d+2\log(q)}}{q-2\sqrt{d+2\log(q)}}+\frac{2\log(q)+1}{q}\right)^t.$$

Zero-Knowledge: *The protocol satisfies* (ε,δ)*-differential zero knowledge: the view of each verifier can be efficiently simulated up to* (ε,δ)*-closeness.*

The protocol is public-coins, with 3 messages. The prover sends (in addition to the secret shares of x) $4\lceil log_2 q\rceil^2)$ *bits and* $\left(t\cdot\left(4\sqrt{d+2\lceil\log(B+1)\rceil}+1\right)\cdot\lceil\log_2 q\rceil\right)$ *bits in rounds 1 and 3 respectively. The verifiers send the second message of length* $(t\cdot\lceil\log_2 q\rceil)$ *bits.*

5 Performance Evaluation

We provide a further performance analysis for our protocols in different parameter regimes. As in Table 1, we analyze performance in terms of the communication overhead, beyond the communication that is needed to simply send secret shares for distributed aggregation (without any robustness to poisoning attacks). We consider aggregating d-dimensional integer vectors of ℓ_2 norm at most 2^{15} with $d \in \{10^4, 10^5, 10^6, 10^7\}$, where the aggregation is performed over secret-shared inputs in a field of size $q = 2^{64}$ or $q = 2^{128}$ (sending secret shares for the client's data requires $d \cdot \log q$ bits). The (statistical) zero-knowledge error is set to $\delta = 2^{-50}$ throughout.

In Table 3 we analyze PINE's communication overhead for a smaller soundness error 2^{-100}, fixing all other parameters to be the same as in the results of Table 1 (where the soundness error was 2^{-50}). The overhead for **Statistical ZK** is larger by a roughly 2x factor (compared with the results in Table 1): the larger overhead comes from additional repetitions of the sub-protocols. The overhead for **Differential ZK** is, similarly, larger by a roughly 2x factor (compared with the results in Table 1), except in the high-dimensional regime, where the main bottleneck is the increased field size, and the overhead for smaller soundness error is not much larger than the overhead for soundness error 2^{-50}.

In Table 4, we analyze PINE's communication overhead when the field is large ($q = 2^{128}$) for soundness errors 2^{-50} and 2^{-100}. For **Statistical ZK**, comparing with the performance for field size 2^{64}, the larger field size does not change the overhead for soundness error 2^{-50} (vs. Table 1), but the overhead is slightly smaller for soundness error 2^{-100} (vs. Table 3). For **Differential ZK**, the large field size reduces the overhead by a 2x or larger (for high dimensionality) factor (vs. Tables 1 and 3). This is because the main bottleneck in the Differential ZK protocol for high-dimensional data was having a large-enough field. For lower-dimensional data, the larger field size automatically gives a smaller soundness error, which reduces overheads. Indeed, for a field size this large, soundness 2^{-100} comes "for free", at no additional overhead (compared with the overhead for soundness error 2^{-50}).

In Table 5 we analyze **Differential PINE**'s performance as a function of the privacy parameter $\varepsilon \in \{0.1, 0.01, .0.001\}$. The overhead increases by (at most) a constant multiplicative factor for each order of magnitude improvement (reduction) in the privacy parameter. This is again due to the main "bottleneck" being the field size, which needs to grow linearly in $(1/\varepsilon)$ (thus the bit length of a field element grows with $\log(1/\varepsilon)$).

On the precision parameter. As discussed after the performance analysis in Section 1.1, we consider aggregating floating point vectors of Euclidean norm at most 1, and support $b = 15$ bits of precision. Our main focus is on distributed aggregation, where noise will be added to the aggregate before it is revealed to the servers (to guarantee differential privacy). Since we expect noise to be added to the aggregate, there is limited value in increasing the precision for individual contributions.

Further performance evaluation. We provide further evaluations in the full version [ROCT23]. First, we analyze PINE's *runtime* overhead for the prover and the verifier, and find that they are improved by 1-2 orders of magnitude compared to the prior work of [BBCGI19; ISR23]. We also provide more detailed evaluations of statistical PINE's communication overhead for many different choices of soundness and zero-knowledge errors.

	$d = 10^4$	$d = 10^5$	$d = 10^6$	$d = 10^7$
no robustness, # bits sent	$64 \cdot 10^4$	$64 \cdot 10^5$	$64 \cdot 10^6$	$64 \cdot 10^7$
prior work, overhead [BBCGI19; ISR23]	$> 1500\%$	$> 1500\%$	$> 1500\%$	$> 1500\%$
PINE, Statistical ZK, overhead	43.01%	6.27%	0.97%	0.26%
PINE, Differential ZK, overhead	8.92%	2.86%	0.63%	12.76%

Table 3: Communication analysis: our protocols and prior work. Parameters: **field size** $q \approx 2^{64}$ for aggregation, d-dimensional data, **soundness error** 2^{-100}, zero-knowledge error $\delta = 2^{-50}$. For differential ZK $\varepsilon = 0.1$.

	$d = 10^4$	$d = 10^5$	$d = 10^6$	$d = 10^7$
no robustness, # bits sent	$128 \cdot 10^4$	$128 \cdot 10^5$	$128 \cdot 10^6$	$128 \cdot 10^7$
prior work, overhead [BBCGI19; ISR23]	$> 1500\%$	$> 1500\%$	$> 1500\%$	$> 1500\%$
PINE, Statistical ZK, $\rho = 2^{-50}$, overhead	22%	3.18%	0.49%	0.13%
PINE, Statistical ZK, $\rho = 2^{-100}$, overhead	36%	4.58%	0.63%	0.15%
PINE, Differential ZK, $\rho = 2^{-50}$, overhead	4.77%	1.46%	0.32%	0.11%
PINE, Differential ZK, $\rho = 2^{-100}$, overhead	4.77%	1.46%	0.32%	0.11%

Table 4: Communication analysis: our protocols and prior work. Parameters: **field size** $q \approx 2^{128}$, d-dimensional data, **soundness error** $\rho = 2^{-50}$ **and** 2^{-100}, zero-knowledge error $\delta = 2^{-50}$. For differential ZK $\varepsilon = 0.1$.

	$d = 10^4$	$d = 10^5$	$d = 10^6$	$d = 10^7$
no robustness, # bits sent	$64 \cdot 10^4$	$64 \cdot 10^5$	$64 \cdot 10^6$	$64 \cdot 10^7$
prior work, overhead [BBCGI19; ISR23]	$> 1500\%$	$> 1500\%$	$> 1500\%$	$> 1500\%$
PINE, Differential ZK, $\varepsilon = 0.1$, overhead	4.77%	1.46%	0.32%	12.63%
PINE, Differential ZK, $\varepsilon = 0.01$, overhead	17.87%	14.14%	12.86%	25.14%
PINE, Differential ZK, $\varepsilon = 0.001$, overhead	17.87%	26.83%	25.40%	37.66%

Table 5: Communication analysis: **Differential ZK** protocol and prior work. Parameters: field size $q \approx 2^{64}$, d-dimensional data, soundness error $\rho = 2^{-50}$, zero-knowledge error $\delta = 2^{-50}$.

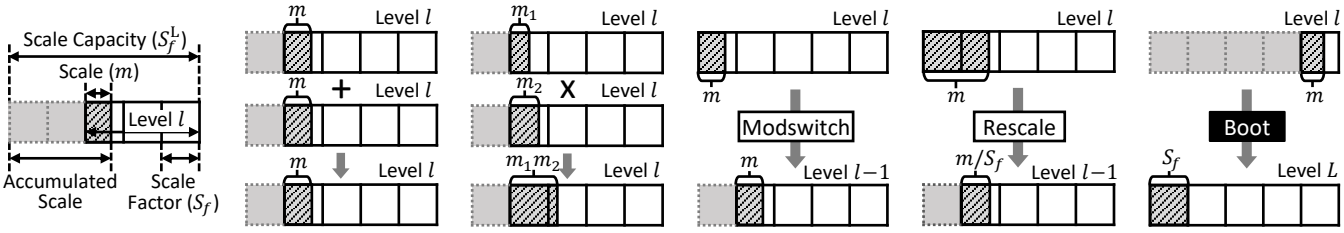
Abstract

By supporting computation on encrypted data, fully homomorphic encryption (FHE) offers the potential for privacy-preserving computation offloading. However, its applicability is constrained to small programs because each FHE multiplication increases the scale of a ciphertext with a limited scale capacity. By resetting the accumulated scale, bootstrapping enables a longer FHE multiplication chain. Nonetheless, manual bootstrapping placement poses a significant programming burden to avoid scale overflow from insufficient bootstrapping or the substantial computational overhead of unnecessary bootstrapping. Additionally, the bootstrapping placement affects costs of FHE operations due to changes in scale management, further complicating the overall management process.



This work proposes DaCapo, the first automatic bootstrapping management compiler. Aiming to reduce bootstrapping counts, DaCapo analyzes live-out ciphertexts at each program point and identifies candidate points for inserting bootstrapping operations. DaCapo estimates the FHE operation latencies under different scale management scenarios for each bootstrapping placement plan at each candidate point, and decides the bootstrapping placement plan with minimal latency. This work evaluates DaCapo with deep learning models that existing FHE compilers cannot compile due to a lack of bootstrapping support. The evaluation achieves 1.21×speedup on average compared to manually implemented FHE programs.

1 Introduction

Fully homomorphic encryption [22] (FHE) has emerged as a promising solution for privacy-preserving computation in untrusted environments, like financial and healthcare applications on a third-party cloud. FHE allows computations on encrypted data, and its decrypted results are identical to those obtained from unencrypted computations. Since Gentry's pioneering work on FHE using lattice-based cryptography [22], many FHE schemes [8,11,12,14,20], and supporting libraries [1, 2, 17, 21, 25, 26, 46, 48, 54] have been proposed. Among the FHE schemes, RNS-CKKS [11] is suitable for privacy-preserving machine learning models as it offers optimized fixed-point arithmetic and SIMD support.

In RNS-CKKS, a ciphertext embeds a scaled integer with the maximum scale capacity, called *coefficient modulus* Q. Each FHE multiplication increases its accumulated scale, like the multiplication of two scaled numbers. When the accumulated scale exceeds the coefficient modulus Q, scale overflow occurs, leading to an unrecoverable result. Thus, programmers should carefully design an RNS-CKKS program with a limited number of multiplications, or insert *bootstrapping* [10] operations that reset the accumulated scale of a ciphertext, enabling a longer multiplication chain. Although existing RNS-CKKS compilers [18, 39, 41] can automatically manage ciphertext scales reflecting constraints of RNS-CKKS operations, their applicability remains limited to small RNS-CKKS programs due to lack of bootstrapping support. Only manual bootstrapping placement [36, 38] has been proposed for a long FHE program such as ResNet, but the manual placement imposes a significant burden on programmers and easily leads to inefficient performance.

Optimizing a long FHE program with manual bootstrapping placement is challenging for three reasons. First, programmers should trace the growth of the accumulated scale of each ciphertext, and insert the bootstrapping operation before scale overflow occurs. Second, a bootstrapping operation has significant latency, which is the most expensive among RNS-CKKS operations. While avoiding scale overflow from insufficient bootstrapping, programmers should reduce the number of bootstrapping operations, not to unnecessarily increase bootstrapping overheads. Third, bootstrapping placement affects scale management. Since bootstrapping resets the accumulated scales of ciphertexts, and RNS-CKKS operations have different latencies depending on their accumulated scale, the bootstrapping insertion points change the latencies of the other RNS-CKKS operations. Therefore, to optimize bootstrapping placement, the number of bootstrapping operations and their performance impact on the other RNS-CKKS operations should be considered together.

(a) Definition (b) Addition (c) Multiplication (d) Modswitch (e) Rescale (f) Bootstrapping

Figure 1: RNS-CKKS operations. Additions and multiplications require the input operands to have the same level l. Additions additionally require the operands to have the same scale m. The `modswitch` and `rescale` operations reduce level l by one; the `bootstrap` operation resets the level l to the initial level $L = 5$.

This work proposes DACAPO, the first automatic bootstrapping placement compiler that heuristically places bootstrapping operations to minimize the overall latency in an FHE program. To reduce the number of bootstrapping operations, DACAPO analyzes live-out ciphertexts, which are used by later instruction at each program point, and classifies program points with a minimal number of live-outs as a candidate set of bootstrapping insertion points. DACAPO identifies a subset of the live-out ciphertexts that remain unused for a certain period without requiring bootstrapping, and categorizes them as bypass edges. DACAPO excludes the bypass edges from the live-outs and thus achieves more precise required bootstrapping counts. To reflect the latency of the other RNS-CKKS operations, such as multiplications and rotations, affected by scale management and bootstrapping insertion points, DACAPO estimates their latency under different scale management scenarios for each bootstrapping point and finds a bootstrapping placement plan with minimal latency among the candidate set.

This work implements DACAPO compiler on top of MLIR [33] with a GPU-accelerated RNS-CKKS library called HEaaN [25]. This work evaluates DACAPO with six deep learning models such as ResNet20, ResNet-44, AlexNet, VGG-16, SqueezeNet, and MobileNet. This work implements the deep learning models with maxpooling and ReLU like the original models and also implements the same models with average pooling and SiLU that require a shorter multiplication chain. The evaluation results show that DACAPO achieves 1.21×speedup on average for diverse deep learning models, compared to the manually implemented FHE programs.

Followings are the contributions of this work.

- The first automatic bootstrapping management compiler, DACAPO, for fully homomorphic encryption;
- A new liveness-aware bootstrapping placement analysis that generates an insertion point candidate set with minimal live-out counts;
- A new cost-aware bootstrapping placement that reflects different FHE computation costs under different scale management affected by bootstrapping placement plan.

2 Background

This section describes RNS-CKKS [11] and scale management for RNS-CKKS programs. In contrast to other FHE schemes [8,12,14,20,22], RNS-CKKS provides better support for fixed-point arithmetic and SIMD parallelism by leveraging approximation (*i.e.,* encrypted computation results could be slightly different from unencrypted ones). These properties make RNS-CKKS well-suited for machine learning applications that can accommodate a certain level of approximation.

2.1 RNS-CKKS Encoding and Encryption

RNS-CKKS introduces two encoding and encryption parameters: *polynomial modulus degree N* and *coefficient modulus Q*. RNS-CKKS encodes a vector containing real numbers into a cyclotomic polynomial [7] whose degree is N. N affects the security level (*e.g.,* equivalent to 128-bit security) and the latency of RNS-CKKS operations. Q determines the maximum coefficients of the polynomials. RNS-CKKS encrypts the plaintext μ into a ciphertext, which is a pair of polynomials $(-a \cdot s + \mu + e, a)$ with random noises (a and e) and the secret key (s). The security of RNS-CKKS relies on the hardness of Ring Learning with Errors (RLWE) [42].

An RNS-CKKS ciphertext has a *scale* and a *level* property, defined as follows. RNS-CKKS deals with a polynomial with integer coefficients and encodes a real number as an integer over a *scale*. For example, the number $x = 1.1$ is encoded as an integer $v = 11$ with the scale $m = 10^1$. The multiplication of two scaled numbers increases the result's scale: *i.e.,* the scale of a ciphertext gradually accumulates on a multiplication. For instance, $y = x \cdot x$ leads to an integer $v = 121$ with the scale $m = 10^1 \cdot 10^1 = 10^2$. The scale is limited by the maximum scale capacity (defined by *coefficient modulus Q*), which is described as a product of the small fixed-size scaling factors S_f: *i.e.,* $Q \approx {S_f}^L$, where L is the initial level. The *level l* denotes the number of scaling factors S_f available in the ciphertext.

Figure 1a illustrates an RNS-CKKS ciphertext with scale and level. The ciphertext has the maximum scale capacity ${S_f}^L$

Table 1: FHE Parameters and their descriptions. The rightmost column represents the values used in actual evaluation.

Parameter	Description	In our evaluation
N	Polynomial modulus degree	2^{17}
Q	Coefficient modulus	2^{1479}
S_f	Rescaling factor	2^{51}
L_{max}	Maximum level of ciphertext	29
L	Level after bootstrapping	16

where the initial level $L = 5$ (depicted with five boxes). Starting from the initial level L, the level l decreases on `modswitch` and `rescale` operations and becomes reset to the initial level L on `bootstrap` operation (which will be explained later). Two dotted gray boxes on the left represent two scale factors consumed by `modswitch` or `rescale` operations, rendering the current level $l = 3$. The *accumulated scale* denotes the total scale accumulated (by multiplications) so far, and it should be lower than the scale capacity ${S_f}^L$. Otherwise, the scale overflow occurs, leading to an irrecoverable result. The *scale* m excludes the consumed scale factors and it should be larger than the predefined minimum scale, called *waterline* S_w, to control the noises introduced by RNS-CKKS operations.

Table 1 shows description and values of FHE parameters used in the evaluation, including a polynomial modulus degree (N) of 2^{17}, and a ciphertext can contain 65536 elements. The evaluation uses a coefficient modulus composed of primes with the same scaling factor (R) of 51 bits, and its value is equal to 2^{1479}. The bootstrapping implementation provided by library consumes 13 levels. In other words, when bootstrapping is performed using parameters with a maximum level of L_{max}, the resulting ciphertext will have 16 levels (L).

2.2 RNS-CKKS Operations

2.2.1 Arithmetic and Rotation Operations

RNS-CKKS supports basic arithmetic and rotation operations, which can be used to implement application algorithms.

Addition (Figure 1b) and **Multiplication** (Figure 1c): RNS-CKKS supports two vectorized arithmetic operations: addition and multiplication. These operations add/multiply two ciphertexts (`CAdd` and `CMul`, respectively) or one plaintext and one ciphertext (`PAdd` and `PMul`). The addition operation requires the levels and scales of two operands to be the same, and produces a ciphertext of the same level l and scale m. On the other hand, multiplication requires only the levels of two operands to be the same. The scale of the resulting ciphertext accumulates to the product of the scales of the operands: *i.e.,* $m = m_1 \cdot m_2$. Table 2 presents the runtime latency of (some) RNS-CKKS operations at different levels measured in the GPU-accelerated HEaaN library [25]. Multiplications are slower than additions. Arithmetic operations at a high level are more expensive than ones at a low level.

Table 2: Latency of FHE operations for different levels (μs)

Operation	Level						
	4	6	8	10	12	14	16
PAdd	24	32	40	47	54	64	70
CAdd	33	44	54	65	74	85	94
PMult	214	304	385	459	533	604	675
CMult	1218	1513	1795	2306	2572	2927	3151
Rot	890	1080	1239	1699	1864	2035	2225
Boot	354762						

Rotation: For vectorized arithmetic operations, RNS-CKKS additionally supports the `rotate` operation that performs a circular shift on a message vector by a given offset: *e.g.,* rotating $(a_1, a_2, ..., a_{10})$ by offset 2 leads to $(a_3, a_4, ..., a_{10}, a_1, a_2)$. The `rotate` operation is a relatively expensive operation, next to a `CMul` operation.

2.2.2 Scale Management Operations

RNS-CKKS further requires programmers to use the following scale management operations to meet the RNS-CKKS constraints (which are irrelevant to application algorithms).

Upscale: The `upscale` operation is a syntactic sugar (not a separate RNS-CKKS) operation that multiplies an operand ciphertext at scale m_1 with a multiplicative identity (*i.e.,* 1) at scale m_2, increasing the scale of the operand to $m = m_1 \cdot m_2$ (by an arbitrary amount). The operation can be used to match the scale of an addition operand if needed.

Modswitch (Figure 1d): The `modswitch` operation consumes one scale factor S_f without affecting the scale of a ciphertext, which in effect reduces the level by one. The operation can be used to adjust the level of an addition or multiplication operand if they do not match.

Rescale (Figure 1e): Multiplications accumulate the scales of ciphertexts. To avoid scale overflow (where the accumulated scale exceeds the maximum scale capacity ${S_f}^L$), RNS-CKKS supports the `rescale` operation that divides coefficient modulus Q by the scale factor S_f. In effect, the result's scale decreases from m to m/S_f (unlike `modswitch`) and its level decreases from l to $l-1$. Note that the `rescale` operation does not change the accumulated scale. To accommodate noises in RNS-CKKS operations, the `rescale` operation should be used only if the scale after rescaling still remains higher than the minimum scale waterline: *i.e.,* $m/S_f \geq S_w$.

Bootstrap (Figure 1f): Even with rescaling, for a program with a large number of multiplications, all available scale budgets will be eventually consumed and the accumulative scale will reach the cap. Further operations become infeasible due to a scale overflow. As a solution, RNS-CKKS supports the `bootstrap` operation that resets the scale and level of a ciphertext. After bootstrapping, the accumulated scale (and the current scale at level L) decreases to scale factor S_f. Table 2 shows the runtime latency of `bootstrap` from a different

level to the maximum level L(=16). The `bootstrap` latency solely depends on the target level and does not depend on the level gap. As reported, `bootstrap` is the most expensive operation in RNS-CKKS: *e.g.,* 3774 times slower than `CAdd`, and 112 times slower than `CMul` at level 16.

3 Motivation

This section discusses the limitations of existing RNS-CKKS compilers and the difficulties in manual bootstrapping, motivating this work: new compiler support for bootstrapping.

3.1 Prior RNS-CKKS Compilers

Existing RNS-CKKS compilers [18, 41] aim to support automatic scale management that takes as input a program that consists of only arithmetic and rotation operations (implementing application computation logic), and inserts scale management operations `upscale`, `modswitch`, and `rescale` (but not `bootstrap`) to produce a new program that satisfies the RNS-CKKS constraints for security and correctness.

Although EVA [18] and Hecate [41] successfully automate many parts of scale management in RNS-CKKS, they both lack support for automatic bootstrapping management. As a result, they have been applied to relatively small deep-learning applications such as LeNet-5 [34], leaving more complex applications with a deep multiplicative depth out of reach.

3.2 Manual Bootstrapping Placement

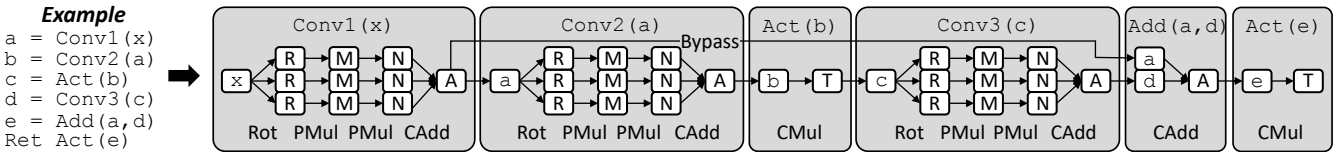
Unfortunately, the state-of-the-art that supports large RNS-CKKS applications is manually adding `bootstrap` operations, which is error-prone and time-consuming. The manual placement is challenging for the following three reasons.

First, to avoid a scale overflow problem and ensure correctness, users should place a `bootstrap` operation before the accumulated scale (after the last bootstrapping) exceeds the maximum scale capacity ${S_f}^L$. Manually tracking the growth of the accumulated scales of a large number of ciphertexts is indeed very difficult because they depend on not only the existing arithmetic and rotation operations, but also newly added `upscale` or `rescale` operations for scale management.

Second, besides correctness, conducting performance-aware `bootstrap` operation placement manually (leading to lower latency) is even harder. As discussed earlier with Table 2, the `bootstrap` operation is much more expensive than any other operations. Thus, in most cases, it is a good idea to minimize the number of `bootstrap` operations (later we show that in some cases, more bootstrapping may count-intuitively lead to better performance).

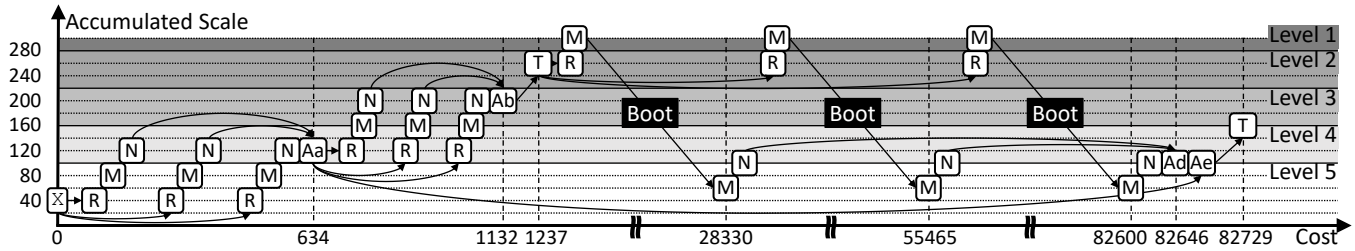
Third, the bootstrapping placement affects scale management and its performance. The `bootstrap` operation changes the scale and level of a ciphertext (like other scale management operations), implying that the location of a `bootstrap` operation has a great influence on the level of the following ciphertexts, impacting the latencies of subsequent RNS-CKKS operations. For example, what should we do if we have multiple solutions with the same minimum number of `bootstrap` operations? Reasoning about the cascading impacts of multiple bootstrapping options is not a trivial task.

4 Key Observations and Insights



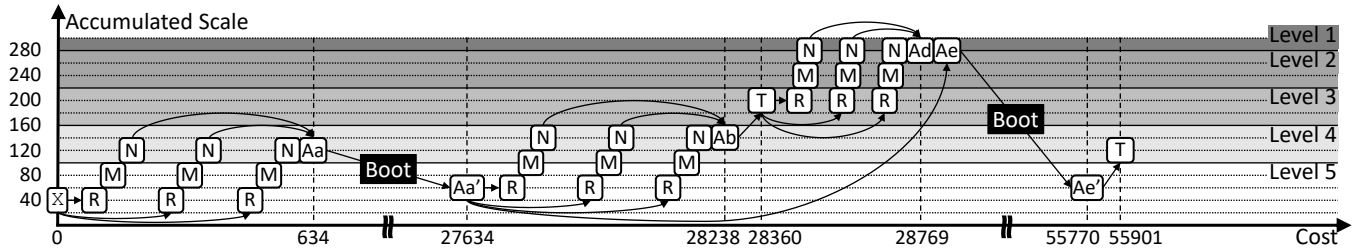
The RNS-CKKS compilers (*e.g.,* EVA [18] and Hecate [41]) can keep track of the scale and level of ciphertexts while placing scale management operations. A naïve compiler-based bootstrapping solution would be to extend them to place a `bootstrap` operation right before the RNS-CKKS operation that exceeds the maximum scale capacity (to avoid a scale overflow). However, we made two novel observations that such a naïve extension (based on an accumulated scale analysis) would lead to inefficient performance.

Observation 1: A simple accumulated scale analysis may introduce (unnecessarily) many `bootstrap` operations, incurring significant performance overhead. Consider a simple deep learning example in Figure 2a that consists of three convolution layers (`Conv1`, `Conv2`, and `Conv3`), two activation functions (`Act`), and one addition operation (`Add`). Figure 2a (right) shows ciphertexts (white box) and RNS-CKKS arithmetic and rotation operations (arrows). A simple convolution layer includes three pairs (channels) of one `Rot` and two `PMul` operations, aggregated by `CAdd` at the end. A simple activation function (`Act`) uses a single `CMul` operation.

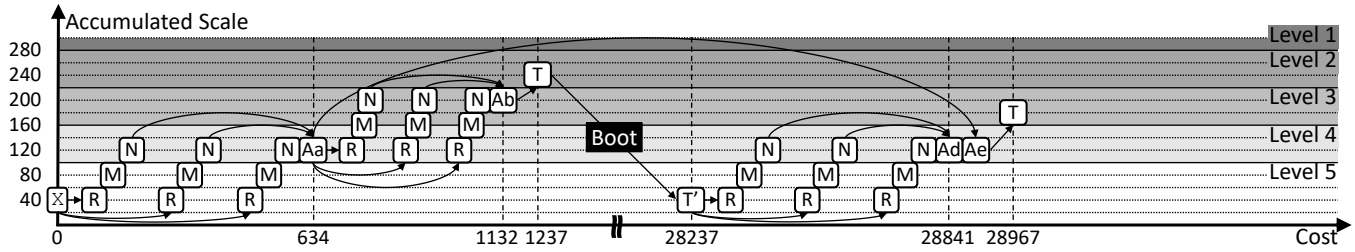


Suppose that the scale of the input ciphertext x is 2^{40}, and its waterline, rescaling factor and the maximum scale capacity are 2^{40}, 2^{60} and 2^{300} (the initial level is 5). Figure 2b illustrates how the accumulated scale (left y-axis) and the level (right y-axis) of a ciphertext change in this example program (while scale management operations are omitted for simplicity). The x-axis reports the time latency, calculated using scaled profiled costs based on Table 2. Figure 2b shows the execution model of a naïve bootstrapping approach in which a `bootstrap` operation is added right before the RNS-CKKS operation that exceeds the maximum scale capacity. During the third `Conv3`, the accumulated scale would become larger than the maximum scale capacity on each of the three second `PMul` operations. To prevent scale overflow, the naïve compiler would add three `bootstrap` operations to reset the scales/levels of three ciphertexts Ms.

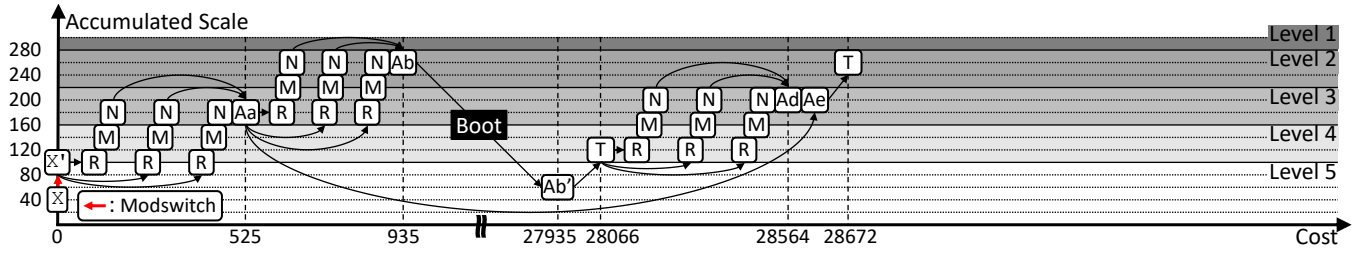
In Table 2, the `bootstrap` operation is much more expensive than any other operation. It is thus often profitable to use fewer `bootstrap` operations (if possible). The next two alternatives (analyzed by our compiler DaCapo) in Figure 2c and Figure 2d demonstrate that it is indeed possible to reduce the latency by placing fewer `bootstrap` operations at better locations. They are based on the following two key insights.



Insight 1A: A ciphertext liveness analysis can help reduce the number of `bootstrap` operations. Our first in-



(a) Example program and its dataflow. The example consists of three convolution layers and two activation functions.



(b) Naïve approach. Bootstrapping is inserted right before the accumulated scale exceeds the scale capacity.

(c) Liveness-aware placement. Bootstrapping is inserted at the latest minimum live-out point before the accumulated scale exceeds the scale capacity.

(d) Bypassed-liveness-aware placement. Bootstrapping is inserted in the same manner as liveness-aware placement but excluding bypass edges from the live-outs.

(e) Cost-aware placement (DACAPO). Bootstrapping is inserted at the best performance points among bypassed-liveness-aware candidates.

Figure 2: Motivating example and its execution models with different bootstrapping placement policies. The example assumes 2^{40} waterline, 2^{60} scaling factor, and 2^{300} scale capacity (the maximum level is 5).

sight is that the naïve approach added three `bootstrap` operations because a ciphertext dataflow diverges and three ciphertexts *M*s are later "used" so they all have to be bootstrapped for correctness. More formally in a compiler term, there were three *live-out* variables *M*s in a dataflow graph that must be bootstrapped. If the optimization goal is to minimize the number of `bootstrap` operations, then it would be beneficial to consider an alternative (and earlier) program point with fewer live-outs, or equivalently, a program point before a dataflow diverges or after it converges.

Based on this insight, DaCapo performs *liveness*-based bootstrapping management. More specifically, DaCapo counts the live-out ciphertexts at each program point, and regards minimum live-out points as candidate bootstrapping points. For instance, Figure 2c inserts the first `bootstrap` operation at the earlier program point with one live-out ciphertext *Aa* (after a dataflow converges from `Conv1(x)` and before it diverges to `Conv2(a)`), even though the accumulated scale is still much lower than the maximum capacity.

Insight 1B: A long-lived unused ciphertext that bypasses other RNS-CKKS operations is unlikely to require bootstrapping, so it is often profitable to exclude the ciphertext from the live-out counts. In a ciphertext dataflow graph (*e.g.,* Figure 2a), a bypass ciphertext implies the ciphertext that was defined but not used for a while. For instance, the ciphretext *A* is defined at the end of the `Conv1(x)`; not used by (bypassing) `Conv2(a)`, `Act(b)`, and `Conv3(c)`; and finally used by `Add(a,d)`. The long-lived ciphertext is represented as a long edge from *A* in `Conv1(x)` to *a* in `Add(a,d)`. Such a long-lived unused (bypass) ciphertext is unlikely to require `bootstrap`. A strict inclusion of those ciphertexts in liveness analysis may unnecessarily increase live-out counts at some program points, and remove bootstrapping placement candidates, thus losing further optimization opportunities. Then, DaCapo would not consider those program points as bootstrapping candidates.

To address them, DaCapo excludes the long-lived (unused-for-a-while) ciphertexts from the live-out counts, achieving better bootstrapping management. For example, consider the ciphertext *T* in `Act(b)`. At that program point, the actual live-out count is two including the short edge from *A* in `Conv1(x)` to *b* in `Act(b)`, and the bypass edge from *A* in `Conv1(x)` to *a* in `Add(a,d)`. The plain liveness-based DaCapo would not consider the program as bootstrapping candidates and produces the bootstrapping result in Figure 2c. On the other hand, once the bypass edge is excluded, the new live-out count will be one. DaCapo could find a better plan in Figure 2d with only one `bootstrap` operation.

Observation 2: Different bootstrapping placements (locations and numbers) may lead to widely different end-to-end latency because bootstrapping may allow other RNS-CKKS operations to be performed at lower levels. As the `bootstrap` operation resets the scale and level of a ciphertext, adding one `bootstrap` in effect can be viewed as partitioning a given program into two smaller sub-programs. Interestingly, if one partition has fewer multiplications (less multiplicative depth), the arithmetic and rotation operations in that partition may be executed at lower levels, resulting in less end-to-end latency. Note that RNS-CKKS operations run faster at lower levels (See Table 2). For the same reason, we also make a rather counter-intuitive observation that fewer `bootstrap` operations do not always lead to lower latency. More `bootstrap` operations imply more partitioning of a given program. Each partition would have fewer operations, which can be performed at lower levels, resulting in less latency. The performance improvement with lower-level operations may be greater than the performance overhead of additional `bootstrap` operations.

Insight 2: A cost-aware bootstrapping analysis is needed for performance. Learned from the above observation, DaCapo leverages the aforementioned liveness analysis to collect different bootstrapping candidates, and compares static cost (latency) estimates among them to select the lowest. For example, compare two different bootstrapping locations between Figure 2d and Figure 2e for the same number (one) of `bootstrap` operations. Figure 2e performs bootstrapping before `CMul` in `Act(b)`, allowing many arithmetic and rotation operations in the first partition (the ones in `Conv1(x)` and `Conv2(a)`) to be performed at level 4 or less after early `modswitch` (shown in a red arrow). On the other hand, Figure 2d performs many of these operations at a higher level 5, leading to higher end-to-end latency.

5 Overview

This work proposes DaCapo, the first FHE compiler that automatically places `bootstrap` operations. Given an input program written in plain operations, DaCapo transforms the plain operations into RNS-CKKS operations with scale management operations including `bootstrap`, and generates LLVM IR codes that invoke GPU-accelerated HEaaN library [25] for RNS-CKKS operations. To support cost-aware bootstrapping placement, DaCapo consists of two components: candidate selector and bootstrapping planner. Figure 3 shows DaCapo's two-step workflow on the left along with an example on the right side, which will be explained later.

Candidate selector identifies candidate points in the program where bootstrapping can be inserted. The candidate selection consists of three steps: liveness analysis, bypass edge analysis, and candidate filtering. The *liveness analysis* step analyzes live-out ciphertexts at each program point, and the *bypass edge analysis* step analyzes long-lived unused edges like the edge from *A* in `Conv1(x)` to *a* in `Add(a,d)` in Figure 2a. Combined, the candidate selector can analyze the number of valid live-out ciphertexts that may need bootstrapping at each program point. The *candidate filtering* step finalizes the candidate points. If the candidate points are too few to generate a correct FHE program due to scale overflow, the candidate filtering step increases the threshold number of live-outs until the scale overflow is resolved.

DaCapo's bootstrapping candidate program points selection implies that it adds `bootstrap` operations synchronously to all the live-out ciphertexts except for bypass ones at those program points. If a compiler bootstraps only a subset of live-out ciphertexts that needs to be refreshed (*i.e.,* not all at once), chances are that the refreshed accumulated scale may be wasted because of the level match constraints of RNS-CKKS arithmetic operations. When the levels of two addition or multiplication operands are different, a scale management

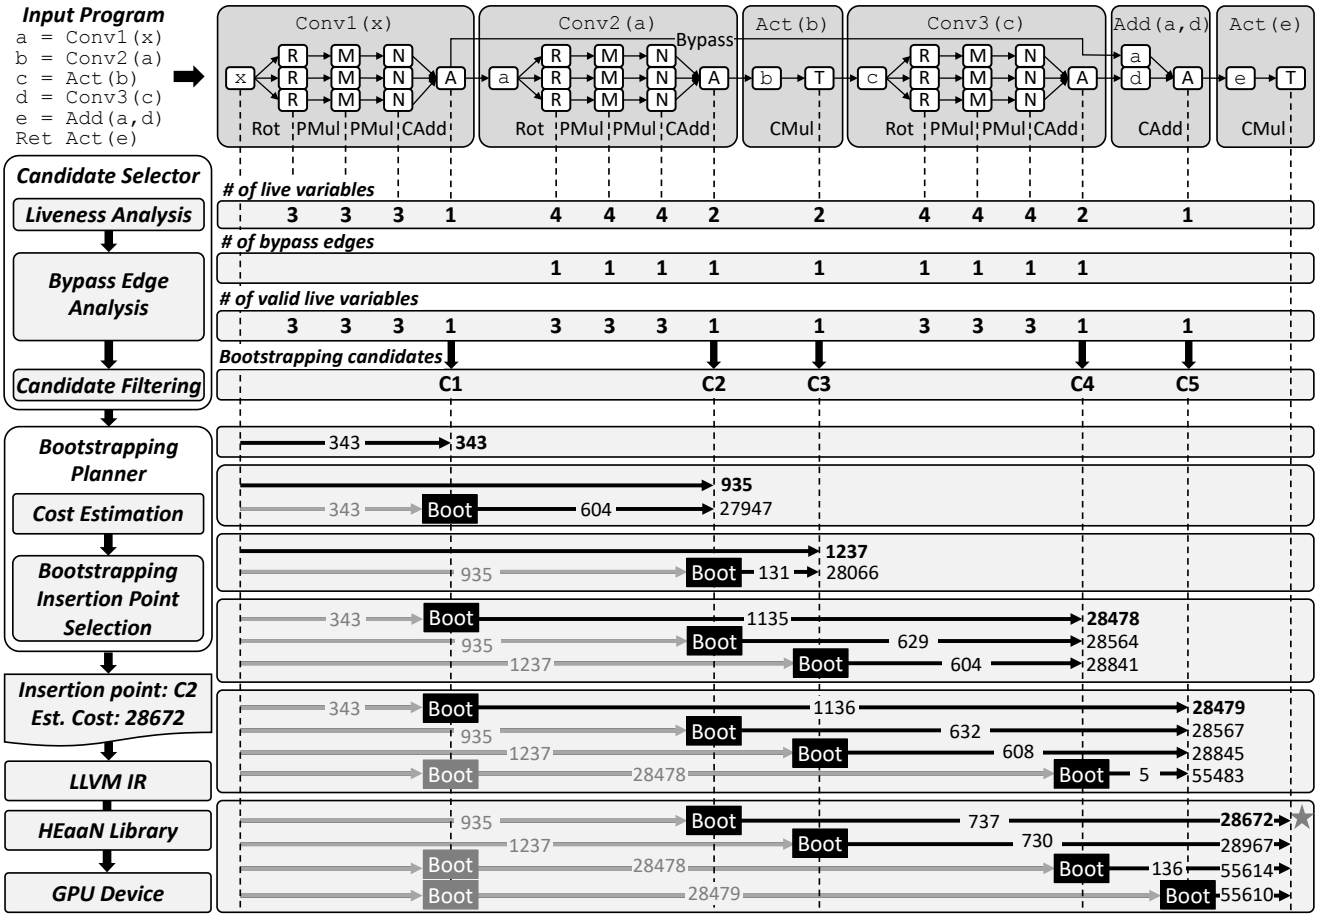


Figure 3: Overview design of DACAPO with the example in Figure 2a. Candidate selector analyzes live-outs and bypass edges, and identifies candidate points where bootstrapping can be inserted. Bootstrapping planner estimates computation costs at each candidate point, and determines the bootstrapping insertion points with minimum overall latency among the candidate points. The bold numbers at the end of each candidate indicate the minimum computation cost. Gray arrows and numbers are the best estimated costs at the bootstrapping insertion point computed in the previous steps. The star indicates the selected plan.

scheme uses `modswitch` to match them to the smaller level. If not all live-outs are bootstrapped, this implies the just refreshed (bootstrapped) accumulated scale may be increased to the stale one to be used for following arithmetic operations. DACAPO avoids such a bootstrapping waste.

Bootstrapping planner computes the costs of RNS-CKKS operations and, determines the bootstrapping placement plan with minimum overall latency among the candidate insertion points from the candidate selector. The bootstrapping planner consists of two steps: cost estimation and bootstrapping insertion point selection. The *cost estimation* step estimates the latency at each candidate point using profiled RNS-CKKS operation costs. Since RNS-CKKS operations have different costs at different levels, this step implicitly executes scale management from the last bootstrapping points to the current candidate points. Among the estimated costs, the *bootstrapping insertion point selection* chooses the plan with the minimal costs, and finalizes the bootstrapping placement plan.

6 Bootstrapping Candidate Selector

This section introduces the bootstrapping candidate selector with an algorithm that analyzes appropriate candidates for bootstrapping placement. The candidate selector analyzes the live-out of each program point via liveness analysis, and identifies the required number of `bootstrap` for each program point by excluding bypass edges (§6.1). Then, the candidate selector finalizes the candidates from the candidate sets grouped by the number of `bootstrap` (§6.2).

6.1 Liveness and Bypass Edge Analysis

Liveness and bypass edge analysis find all the ciphertexts that should be bootstrapped if DACAPO decides to insert `bootstrap` at a program point. With the liveness analysis, DACAPO can find all the live-out ciphertexts that will be used later at a certain program point (*LiveVariable* in Algo-

Algorithm 1: Bootstrap Candidate Selection

```
   Input: Func: Function of an HE application
   Output: Set: Set of candidates
1  Function CandidateSelector (Func) :
2      // Bypass Edge Analysis (Section 6.1)
3      BypassEdges, CandidatesSet ←{}
4      foreach target ∈ Func do
5          BootTarget ← LiveVariable(target) − BypassEdges
6          CandidatesSet[BootTarget.size] += target
7          Managed ← ScaleManagement(Func, target)
8          foreach op ∈ Managed after target do
9              if op.AccumulatedScale > S_th and
10                EndOperation(target) after op then
11                 BypassEdges += {target}
12             if op.AccumulatedScale > S_f^L then
13                 target.Coverage ← op
14                 break
15         end
16     end
17     // Candidate Filtering (Section 6.2)
18     threshold ← 1
19     Candidates ← CandidatesSet[threshold]
20     while not success do
21         success ← true
22         Managed ← ScaleManagement(Func, Candidates)
23         foreach op ∈ Managed do
24             if op.AccumulatedScale > S_f^L then
25                 threshold += 1
26                 Candidates += CandidatesSet[threshold]
27                 success ← false
28         end
29     end
30     return Candidates
31 end
```

rithm 1), and the last program point where the ciphertext is used (*EndOperation* in Algorithm 1). The bypass edge analysis finds ciphertexts that are live but not used during a long computation (that the accumulated scale exceeds the threshold S_{th}), and excludes them from the required bootstrapping counts at a certain program point.

Algorithm 1 illustrates the algorithm for the bootstrapping candidate set generation. First, the algorithm performs bypass edge analysis (line 2-16). For each program point (`target`) in a function, the algorithm analyzes `bootstrap`-required ciphertexts by removing bypass edges from the live-outs (line 5), and adds the `target` into a candidate set with the same number of the required `bootstrap` operations (line 6). Then, the algorithm checks if the result ciphertext of the operation at `target` includes bypass edges, and calculates the coverage of `bootstrap` at `target`. Assuming that `bootstrap` is inserted at the `target`, the algorithm executes scale management on the given function using the proactive rescaling scheme of Hecate [41] (line 7). The algorithm categorizes the result of the operation at `target` as a bypass ciphertext if the result is live after an operation whose accumulated scale exceeds the threshold S_{th} (line 9-11). Furthermore, the algorithm checks the accumulated scale of operations in *managed* and identifies the operations that can be executed without additional `bootstrap` (line 12-14). The remaining algorithm will be explained in §6.2.

Figure 3 illustrates how the liveness and bypass edge analysis analyze the example program. First, the liveness analysis gives the number of live variables for each program point. For example, there are 3 live variables (3 *R*s) after `Rot` in `Conv1`. Note that this analysis counts the live-out variables, not the uses of the variables, so there is 1 live variable after `Conv1`. Then, the bypass edge analysis detects and removes a bypass edge from the live-out variable sets. For example, *Aa* in `Conv1` is live-out until `Add`, but the accumulated scale of *Ad* in `Conv3` before `Add` is 280 (see Figure 2c) that exceeds the threshold S_{th} (*e.g.,* 180). Therefore, the analysis classifies *Aa* as a bypass edge and then removes *Aa* from the live variable set of other operations. Then, the number of live variables after *Ab* (`Conv2`) is reduced from 2 ($\{Aa, Ab\}$) to 1 ($\{Ab\}$).

The S_{th} value, which is heuristically determined by users, impacts the performance of the generated code. A higher S_{th} makes Algorithm 1 detect fewer bypass edges, thus causing DaCapo to insert unnecessary bootstrapping operations for long-lived unused ciphertext. On the other hand, a lower S_{th} makes Algorithm 1 mark more edges with a shorter life-span as bypass edges, so DaCapo may exclude edges requiring bootstrapping from the candidates. Thus, assigning an appropriate S_{th} value is crucial for optimizing the bootstrapping placement. This work uses S_{th} as half of the maximum scale capacity for the evaluation.

6.2 Candidates Filtering

DaCapo generates a candidate set by filtering the bootstrapping targets based on the number of `bootstrap`. If the scale management cannot generate a valid program for a given candidate set, meaning that the accumulated scale of a ciphertext exceeds its scale capacity, the given candidate set needs to be expanded. On the other hand, to minimize the number of `bootstrap`, the algorithm should find the minimal threshold of filtering. Hence, to find the minimal filtering threshold, the candidate filtering gradually increases the threshold from 1 to a value that can generate a valid scale management plan.

Line 17-29, describe the candidate filtering algorithm. The algorithm initializes the candidate set with targets requiring only one `bootstrap` (line 19). The algorithm executes scale management for the candidate set (line 22), and checks if the accumulated scale of a ciphertext exceeds the scale capacity. If so, the algorithm increases the threshold and expands the candidates (line 23-27). If the filtering is finished, the algorithm returns the finalized `bootstrap` candidate set (line 30).

Figure 3 illustrates how the candidate filtering works for the

Algorithm 2: Bootstrapping Planner Algorithm

```
   Input: Set: Candidates
   Output: Set: Bootstrapping Targets
1  Function BootstrappingPlanner (Func, Candidates):
2      Candidates.push (Func.ReturnOp)
3      foreach to ∈ Candidates do
4          foreach from ∈ Candidates do
5              if to before from.Coverage then
6                  Managed ← ScaleManagement (Func,
                                  BestPlan[from] + to)
7                  cost ← EstimateCost (Managed, from, to)
8                  cost ← cost + MinCost[from]
9                  if cost < MinCost[to] then
10                     MinCost[to] ← cost
11                     BestPlan[to] ← BestPlan[from]
12                     BestPlan[to] += to
13         end
14     end
15     return BestPlan[ReturnOp]
16 end
```

example. First, the candidate filtering algorithm only considers the bootstrapping candidate set ($\{C1, C2, C3, C4, C5\}$) that has only one valid live variable $\{Aa, Ab, T, Ad, Ae\}$, respectively. For the candidate set, the algorithm inserts `bootstrap` for each candidate and then performs scale management. If there is no operation whose accumulated scale exceeds the scale capacity, the candidate set is valid. If the candidate set is not valid, the algorithm increases the threshold number of valid live variables to expand the candidate set.

7 Cost-aware Bootstrapping Planner

This section describes the bootstrapping planner that finds bootstrapping insertion positions with minimal latency costs, for the given bootstrapping placement candidates from bootstrapping candidates selection (§6). Since `bootstrap` operation resets the scale and level of a ciphertext, depending on the bootstrapping placement, the scale management results vary, and thus the latency (level) of each ciphertext varies also. To optimize the bootstrapping placement plan reflecting the varying latency, the bootstrapping planner estimates the cost for each candidate and decides the placement plan with minimum overall cost. Here, this work employs a simple cost estimation that adds the profiled latency of each RNS-CKKS operation (*e.g.,* Table 2).

Algorithm 2 illustrates the bootstrapping placement plan decision algorithm. For each *to* candidate, the algorithm analyzes the minimum estimated cost from the beginning of the program to the *to* program point. Iterating other *from* candidates before *to*, the algorithm executes scale management from *from* to *to*, estimates its latency cost, adds the estimated cost and the minimum cost at *from*, and finds the minimum cost by comparing the added result with the existing minimum estimated cost at *to*. Note that the scale management result is memorized while not reflected in the algorithm. Since the scale management of subprograms before and after `bootstrap` is decoupled, and the input scale and level of the succeeding subprogram only depend on `bootstrap`, the minimum cost can be computed by adding the current estimated cost and the minimum cost at *from*. The algorithm returns the bootstrapping plan at *ReturnOp* as the final placement plan.

Figure 3 illustrates how the bootstrapping planner algorithm works in the example. First, the planner executes scale management and estimates the cost of the partial program. For example, the planner estimates the cost of a partial program until $C1$ as 343. Then, to find a bootstrapping placement plan with the minimal estimated cost until the next candidate $C2$, the planner considers two different cases. For the case that `bootstrap` is not inserted at $C1$, the planner estimates the cost (935) in the same way as $C1$. For the case that `bootstrap` is inserted at $C1$, the planner reuses the previous estimation result for $C1$ (343), and adds the latency of `bootstrap` (27000) and the latency of the partial program from $C1$ to $C2$ (604), calculating the resulting cost (27947). The planner compares the estimated costs of two cases and selects the lower one (no `bootstrap`). The selected plan for $C2$ is reused for the other candidates such as $C3$, $C4$, $C5$, and *Ret*.

8 Evaluation

The evaluation section first describes our experimental setup in §8.1 and demonstrates the overall performance improvement of DaCapo compared to manually implemented programs in §8.2. We also show the effectiveness of DaCapo by comparing the bootstrapping counts in §8.3, and highlight its practicality by analyzing the compile time in §8.4. Furthermore, we present the accuracy of performance estimation in §8.5. Lastly, we perform the latency sensitivity study with varying waterlines for each benchmark application in §8.6.

8.1 Experimental Setup

This paper evaluates multiple complex deep learning models with two different activation functions, including ResNet-20/44 [24], AlexNet [31], VGG16 [49], SqueezeNet [29], and MobileNet [27]. ResNet-20 was initially introduced as a HE-friendly model in [38], and we use the improved versions of ResNet-20/44 presented in [36]. The activation functions were implemented based on the algorithm proposed in [37]. In detail, we use the Remez algorithm to approximate SiLU as a 96th-order single polynomial (multiplicative depth of 7). On the other hand, ReLU employed a minimax composite polynomial approximation using degrees {15, 15, 27} (multiplicative depth of 13) in [37]. For linear operations such as convolution, we adopt the multiplexed parallel convolution

Table 3: Classification accuracy for multiple CIFAR-10 images using models on the RNS-CKKS scheme generated by DaCapo.

Model	ResNet-20		ResNet-44		AlexNet		VGG16		SqueezeNet		MobileNet	
	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU

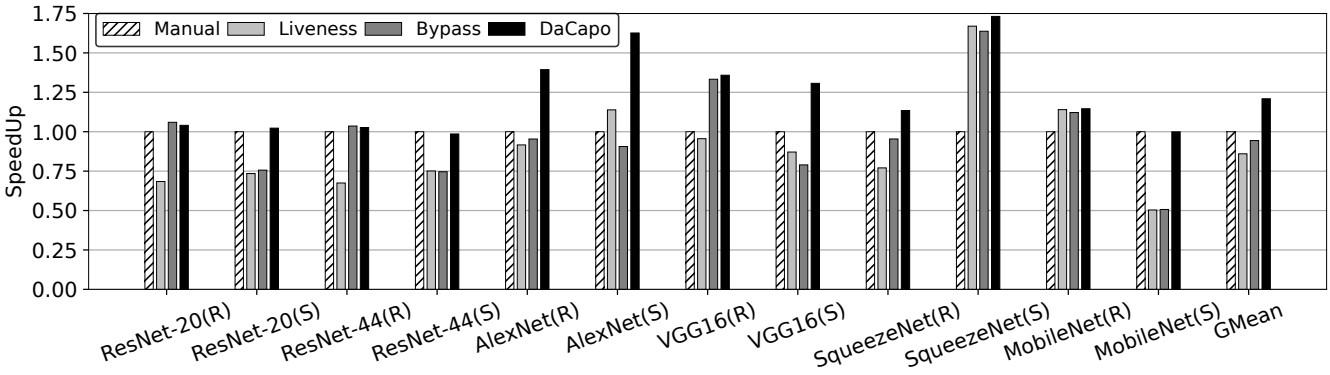

Figure 4: Speedup of algorithms based on the Manual with waterline 2^{40}. The activation functions utilized in each deep learning model are denoted as (*R*) for ReLU and (*S*) for SiLU.

technique introduced in [36], which enables the compact representation of sparse output data across multiple channels. The evaluation includes a total of 12 benchmark results, considering two activation functions and pooling layers: ReLU with max pooling (R), and SiLU with average pooling (S).

We implemented the above deep learning benchmark applications using a GPU-accelerated RNS-CKKS library HEaaN [25]. To facilitate development, we implemented common neural network operators such as convolution (`Conv`) and activation functions ReLU and SiLU on the RNS-CKKS scheme.

We validate our implementation by comparing the accuracy using 1,000 CIFAR-10 images between PyTorch's and the DaCapo programs (with a waterline of 2^{40}). Table 3 reports the classification accuracy results. ResNet-20(R), SqueezeNet(R) and (S), and MobileNet(R) exhibited a minor difference of 0.1% in accuracy. The usage of approximate activation functions introduced a maximum error of 13 bits, leading to negligible differences in accuracy.

Given the lack of bootstrapping compilers, our evaluation uses manually implemented bootstrapping placement (**Manual**) as the baseline. According to the state-of-the-art ResNet-20/44 implementation with bootstrapping [36], which inserts `bootstrap` operations before activation functions only when deemed necessary, we manually insert bootstrapping operations for the benchmark applications. The manual insertion, verification, and optimization take approximately 4 hours for each benchmark for a single waterline. Since an incorrect placement of bootstrapping causes FHE operation errors such as ciphertext scale overflow, sophisticated time-consuming placement analysis and verification are required. For this version, `bootstrap` operations are added between each layer. In addition, the sign function used in ReLU and maxpooling cannot be executed without bootstrapping, so we incorporate additional bootstrapping at the point where the second 15th-degree term is multiplied. The manual implementation assumes a scale management waterline of 2^{40}.

We compare DaCapo's three different variants with the manual implementation (**Manual**). **Liveness** only considers the number of live-out values at program points (without bypass edge or cost analysis). This method greedily utilizes the scale budget in that it inserts `bootstrap` synchronously while maximizing the utilization of the scale capacity by inserting `bootstrap` into the closest candidates when the accumulated scale exceeds the scale capacity. Figure 2c represents this scheme. **Bypass** considers more `bootstrap` candidates by excluding the bypass edges. Like Liveness, it greedily maximizes the scale capacity utilization but does not perform cost-aware bootstrapping. Figure 2d is an example of this scheme. **DaCapo** use all the proposed liveness, bypass, and cost analyses, as illustrated in Figure 2e. It regards the latency of all operations and determines the placement of `bootstrap` based on the bypass-aware candidates set.

This evaluation runs on Intel(R) Core(TM) i7-12700 for CPU and NVIDIA GeForce RTX 3090 with 24GB memory for GPU, utilizing unified virtual memory (UVM).

Table 4: Bootstrapping counts for each benchmark in manual placement and DACAPO

Model	ResNet-20		ResNet-44		AlexNet		VGG16		SqueezeNet		MobileNet	
	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU
Manual	37	19	85	43	66	12	54	20	58	18	53	27
DACAPO	37	19	85	43	67	12	53	20	57	19	61	27

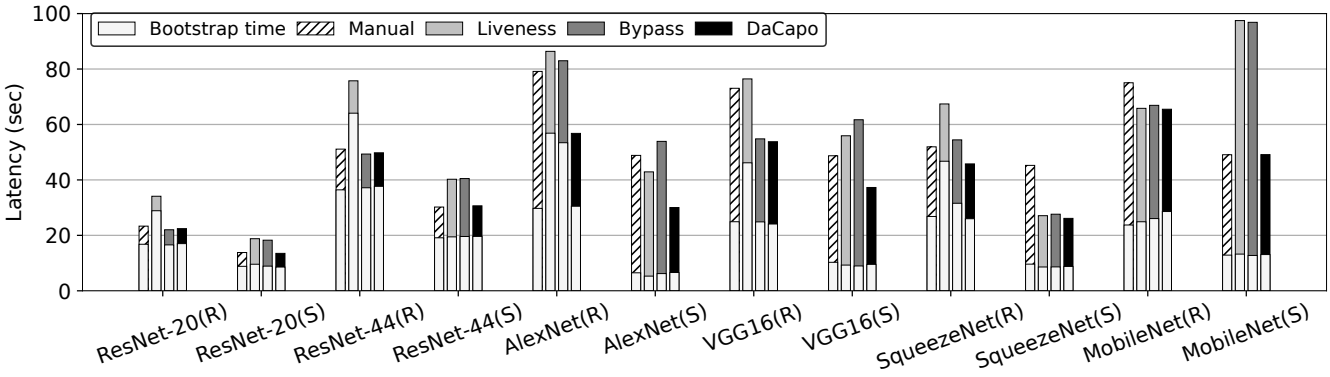

Figure 5: Inference time for a single image. The white portion of bar represents the latency introduced by bootstrapping.

8.2 Performance Evaluation

Figure 4 represents the speedup of inference time for a single CIFAR-10 image achieved by each approach (Liveness, Bypass, and DACAPO) compared to Manual.

In Figure 4, Liveness allows for effective reduction of # `bootstrap`, which achieves comparable performance to Manual in VGG16(R) and VGG16(S), and even improves the performance in cases like AlexNet(S) and SqueezeNet(S). The main reason Liveness improves the performance is that the compiler considers the bootstrapping points the user cannot consider, such as the points within an activation function. Bypass increases the number of valid liveness candidates, finding more beneficial `bootstrap` candidates. In ResNet-20/44(R) and VGG16(R), improved latencies can be observed by identifying appropriate points considering liveness. However, in the case of VGG16(S) and AlexNet(S), the total latency actually increases as shown in Figure 5, due to increased latencies in other operations. The geometric mean of speed up for DACAPO is 1.21×. The reason why DACAPO achieves better results compared to Manual is that DACAPO takes into consideration the aspects that users may overlook. DACAPO has the ability to analyze the detailed RNS-CKKS operations that make up deep learning model APIs. While users can analyze the provided library and insert `bootstrap`, due to the variability of scale management with each function call, the optimal point for `bootstrap` can vary each time. DACAPO, on the other hand, is aware of scale management variations based on the placement of `bootstrap`, allowing it to discover a lower latency plan than Manual.

8.3 Bootstrapping Counts

In Table 4, the number of `bootstrap` operations is similar between Manual and DACAPO. However, in Figure 5, DACAPO yields apparently better latency for AlexNet, VGG16, and SqueezeNet because DACAPO places the bootstrapping where the latency of arithmetic is reduced. Interestingly, in the case of MobileNet, DACAPO involves a higher number of `bootstrap` operations, yet it still achieves a lower total latency. This is strong evidence that the latency of arithmetic operations has an impact on the overall latency, although each arithmetic operation has multiple orders lower latency than bootstrapping. In the case of MobileNet(R), there are a large number of channels leading to increased `rotate` and multiplication operations, which outweigh the latency of `bootstrap`, increasing the number of `bootstrap` operations can actually result in a lower total latency by lowering the levels of intermediate operations. This demonstrates that simply minimizing the `bootstrap` count does not guarantee optimal results.

8.4 Compile Time

Table 5 shows the total compile time and bootstrapping management time for each benchmark, along with a comparison of the number of operations and `bootstrap` candidates. Benchmarks with ReLU have more candidates because the composite polynomial approximation of ReLU has multiple points with a single live-out. For all the benchmarks except AlexNet, the management time is less than 5 minutes, which is acceptable as usual. To discuss the scalability of the algorithm, we perform an in-depth analysis of the compile time.

Table 5: Compile time and bootstrapping management time by DaCapo on the RNS-CKKS scheme (sec)

Model	ResNet-20		ResNet-44		AlexNet		VGG16		SqueezeNet		MobileNet	
	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU	ReLU	SiLU
# Ops	8784	9144	19412	20204	53533	50535	45798	44766	21404	19264	44919	45411

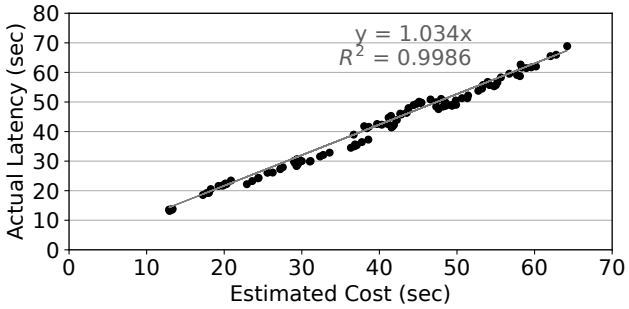

Figure 6: Precision of the estimation results. The x-axis represents the estimated results by DaCapo based on profiled data, and the y-axis indicates actual latency.

In bootstrapping management, time-consuming parts are bypass edge detection and the bootstrapping plan decision. The bypass edge detection algorithm, which calculates coverage through scale management for each operation, has a time complexity of $O(N^2)$, where N is the number of operations. On the other hand, Algorithm 2 has a time complexity of $O(D \times d \times N)$, where D is the number of `bootstrap` candidates and d is the maximum number of `bootstrap` candidates within the coverage of a certain `bootstrap` candidate.

Comparison between the ResNet-20(S) and the AlexNet(S) shows the impact of the number of operations on the bypass edge detection clearly ($(50535/9144)^2 = 30.54$ vs $336.5/14.4 = 23.37$). The scale management unit [41] will greatly reduce the effective number of operations, enhancing its scalability. On the other hand, the comparison between AlexNet(R) and AlexNet(S) clearly shows the impact of the number of candidates on the plan decision algorithm. Since the intermediate feature maps cannot be packed in a single ciphertext in AlexNet(R), the candidate filtering threshold is larger than other benchmarks, increasing candidates a lot. We believe that further research on a fine-grained filtering threshold that reflects the program context can improve the scalability of the plan decision algorithm.

8.5 Performance Estimation

To evaluate the accuracy of the latency estimation used in Algorithm 2, we compared the estimated latency with the actual latency with 108 data points using 12 benchmarks across 9 different waterlines in Figure 6. The equation, $y = 1.034x$, is a regression model between the estimated and actual costs, and R^2 indicates predicted latency closely aligns with the actual latency. Since the coefficient of the regression model and the R^2 value (0.9986) are close to 1, the overall precision is quite satisfactory. The small variances in the coefficient and R^2 are caused by the memory transfer latency in UVM. We use a GPU that has 24GB of physical RAM, whereas the memory requirement exceeds the capacity in some benchmarks. Therefore, UVM was used for the experiment to fulfill the memory usage, which might have imposed an additional latency to the actual execution time compared to the estimated time in the memory-starving benchmark. Nonetheless, the variance in the performance estimation will not degrade the efficacy of the bootstrapping plan decision, because the penalty of memory starvation will affect the bootstrapping placement plans of the same benchmark consistently.

8.6 Waterline Sensitivity

Figure 7 illustrates the latency for deep learning benchmarks with respect to the waterline. The approximation of the activation function has a maximum 13-bit error. To align the error caused by RNS-CKKS operations with the approximation error of activation functions, the waterline needs to be larger than 2^{30} in our measurement. The latency of Manual is plotted as a point based on a waterline of 2^{40}. A lower waterline gives a different scale management plan that slows down the scale accumulation, leading to different optimal positions for bootstrapping placement. Greedy bootstrapping placements (Liveness and Bypass) can find reasonable positions as observed in ResNet-20 and SqueezeNet but result in a significant variance of latency for AlexNet and MobileNet, because the position of `bootstrap` significantly changes the latency of arithmetic operation. On the other hand, DaCapo exhibits lower variation with respect to the waterline and shows a decreasing trend of total latency as the waterline decreases. For Figure 7k, there is a small variance depending on the waterline. The variance comes from the scale management scheme (the proactive rescaling of Hecate) that does not optimize the latency of arithmetic operation consistently and produces sub-optimal scale management plans. Hecate [41] conducts

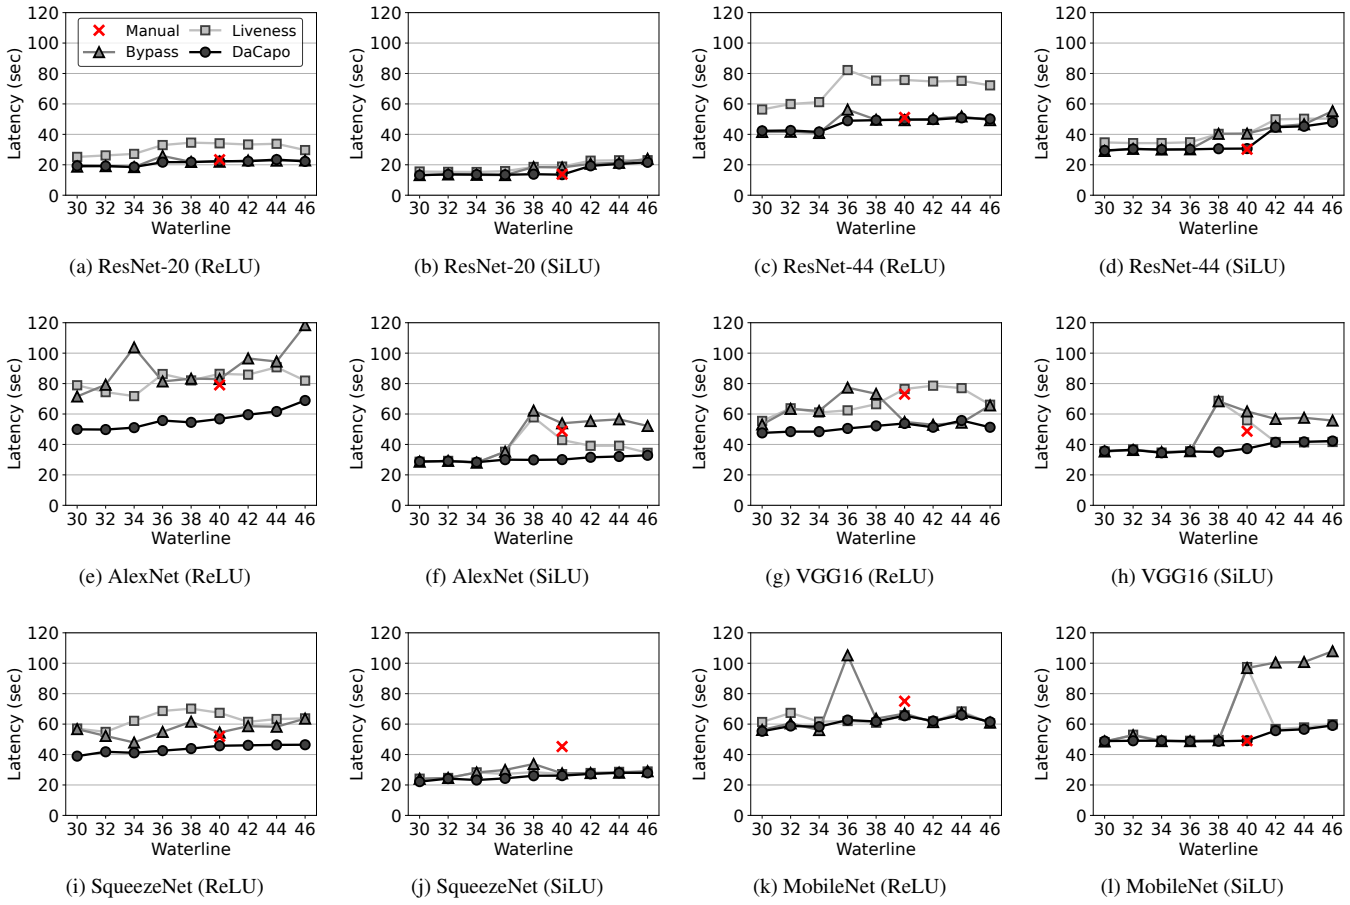

Figure 7: The latency of each benchmark corresponding to different waterlines (lower is better). Manual results are represented by one point based on waterline 2^{40}.

space exploration to find the optimal points but requires significantly longer compile time due to the larger benchmark size. Further improvement on the scale management scheme could lead to improvements in this aspect.

9 Related Work

FHE compilers. The existing compiler works [4–6, 9, 13, 15, 18, 19, 35, 39–41, 43, 50, 51, 53], have proposed optimization techniques to improve performance, accuracy, and programmability. EVA [18] introduces the concept of *waterline* which signifies the minimum required scale and automates inserting scale management operations. However, EVA misses the opportunity for optimization as it uses fixed-factor rescale. To address the limitation of EVA, HECATE [41] proposes downscale operation which enables proactive rescale and finds an optimal scale management plan by using space explorations. ELASM [39] points out that using a fixed waterline in HE applications does not reflect errors during scale management. With a new error-latency-aware scheme, ELASM produces better latency and error results than prior works [18,41].

DaCapo and the existing compilers such as Hecate and ELASM have complementary relations. This work focuses on how to partition DNN models using bootstrapping, while the other compilers focus on scale management optimization of each partition. The bootstrapping management algorithm of DaCapo can be applied in conjunction with any scale management scheme. However, simply applying Hecate or ELASM to this work is impractical due to their high exploration overheads. Hecate and ELASM optimize ciphertext scales by exploring scale management spaces, and scale management space exploration takes huge compilation overheads. Since DaCapo generates multiple different bootstrapping insertion candidates, and optimizes ciphertext scales that are reinitialized at each bootstrapping insertion point, exploration-base scale management like Hecate and ELASM would severely amplify the compilation time. Thus, this work adopts only a part of Hecate such as the proactive rescaling scheme to manage ciphertext scales, while excluding the scale management space exploration from Hecate.

In addition, performance improvement is achieved through effective data layout and parallelization methods for ciphertexts. CHET [19] automatically selects the encryption parameters and data layout while ensuring security and accuracy of the target tensor circuit. EVA [18] and ALCHEMY [16] also provide data packing, but still lacks usability as programmers have to perform vectorization manually. Coyote [43] allows automatic vectorizing for arbitrary applications considering data movement. HECO [50] incorporates circuit optimizations to reduce noise growth, as well as target hardware and scheme-specific optimizations, enabling developers to achieve performance similar to experts. However, none of the compilers support large benchmarks that require bootstrapping.

Privacy Preserving Machine Learning (PPML). A Convolution algorithm for homomorphic encryption is proposed by Gazelle [30], and [3,28,32,44,47,52] perform Convolution Neural Network (CNN) based on this algorithm. These works adapt multi-party computation to perform non-linear functions on secure side, which compromised the advantages of homomorphic encryption and required significant communication overhead. [38] first implements the standard ResNet-20 with the RNS-CKKS FHE with bootstrapping, but a substantial amount of bootstrapping operations and convolutions lead to performance degradation. To improve the efficiency of the application, [36] constructs an efficient very deep standard CNN model on FHE, which minimized the bootstrapping runtime by applying multiplexed packing and multiplexed parallel convolution algorithm. All existing PPML are hand-optimized and do not reflect scale management. Additionally, programmers need to manually insert bootstrapping for each change in waterline and model structure, which increases their burden and might create target programs inefficiently.

Automatic Bootstrap Placement. Previous work [45] proves that finding the minimal number of `bootstrap` for a given FHE program and corresponding bootstrapping placement is an NP-complete problem. They propose heuristics for bootstrapping placement based on a mixed-integer linear programming method. Compared to DaCapo, they only consider the multiplicative depth not reflecting scale management, and do not consider the latency of the other operations. Furthermore, they do not automatically generate the `bootstrap`-managed code to reduce the programming burden.

This work proposes an automatic bootstrapping management compiler to reduce the burden on developers and enable easy privacy-preserving use of large-size models. Also, the results show improved performance to manual-implemented models and demonstrate the minimum number of bootstrapping counts does not always result in better performance.

10 Conclusion

This paper introduces DaCapo, which is the first automatic bootstrapping management compiler. DaCapo efficiently restricts bootstrapping candidates through liveness analysis, considering bypass edges. Additionally, DaCapo finds the bootstrapping plan with the minimum cost based on these candidates. The results demonstrate that DaCapo consistently outperforms manually implemented FHE programs on deep learning models, achieving an average speedup of 1.21×.

Appendix A Existing RNS-CKKS Compilers

Existing RNS-CKKS compilers propose automatic scale management schemes that insert scale management operations like `rescale` and `modswitch` to the input program that does not include scale management operations with optimizing performance and error.

EVA [18] proposes the first scale management algorithm that attempts to minimize the accumulated scale. A smaller accumulated scale is preferred as it allows the compiler to use smaller encryption parameters coefficient modulus Q and polynomial modulus N at the same security level, which in turn is expected to result in better performance. To this end, EVA regards the minimum scale of input ciphertexts to a program as the minimum scale requirement, called *waterline* S_w, of all ciphertexts. Then it inserts a `rescale` operation if the scale after rescaling is higher than the waterline: *i.e.,* $m/S_f \geq S_w$. Besides, EVA uses `upscale` and `modswitch` to meet the same level and scale requirements of arithmetic operations as needed.

Hecate [41] introduces a new scale management operation, called *downscale*, which combines `upscale` and `rescale` operations and supports decreasing the scale of a ciphertext by an arbitrary amount. Note that `rescale` can only reduce the scale by the fixed rescale factor S_f. Hecate makes use of the downscale operation to proactively bring the scale of a ciphertext down to the waterline S_w, and shows that it can achieve a lower accumulated scale than EVA. Furthermore, Hecate shows that a lower accumulated scale does not always lead to better performance, and presents a greedy latency-aware scale management algorithm based on static cost estimation. Recall that scale management operations `modswitch` and `rescale` change the levels of ciphertexts, affecting the latencies of the following arithmetic and rotation operations (Table 2). Combined with `downscale` and a greedy search algorithm, Hecate demonstrates a better performance (lower latency) than EVA.

ELASM [39] improves Hecate by reflecting the noise of RNS-CKKS operations. Because the RNS-CKKS operations add operation-specific and scale-independent noise to the result, the scale of the result affects the error of the operation by dividing the noise by the scale. To incorporate error awareness into the scale management scheme, ELASM proposes a noise-aware waterline that controls the waterline of each operation in a fine-grain manner reflecting the operation noise. To control the error level, ELASM controls the waterline based on the user-level compilation parameter called Scale-to-Noise-Ratio (SNR). Furthermore, ELASM proposes an efficient error estimator and error-aware exploration-based optimizer called Error-Latency-Aware Scale Management (ELASM) based on the error estimation. Combined with a noise aware waterline and an efficient error estimation scheme, ELASM achieves 4.2-bits better error and 16.7% better performance compared to Hecate.

Table 6: Function Parameters of AlexNet. Based on the multiplexed parallel packing method presented in [36], we implemented the convolution and pooling layers, using the same parameter notation.

Layer	n_i	n_o	f_h	f_w	s	h_i	h_o	w_i	w_o	c_i	c_o	k_i	k_o	t_i	t_o	p_i	p_o	q
ConvBN1	1	2	3	3	1	32	32	32	32	3	96	1	1	3	96	16	1	6
AvgPool1	2	1	3	3	2	32	16	32	16	96	96	1	2	96	24	1	2	96
ConvBN2	1	1	5	5	1	16	16	16	16	96	256	2	2	24	64	2	1	128
AvgPool2	1	1	3	3	2	16	8	16	8	256	256	2	4	64	16	1	4	256
ConvBN3	1	1	3	3	1	8	8	8	8	256	384	4	4	16	24	4	2	96
ConvBN4	1	1	3	3	1	8	8	8	8	384	384	4	4	24	24	2	2	192
ConvBN5	1	1	3	3	1	8	8	8	8	384	256	4	4	24	16	2	4	128
AvgPool3	1	1	3	3	2	8	4	8	4	256	256	4	8	16	4	4	16	64

Appendix B Parameters Used in Evaluation

Table 6 shows the function parameters that are used in each component of the AlexNet structure. ConvBN refers to a function that combines convolution and batch normalization, and AvgPool represents average pooling. The implementation of convolution and pooling layers is based on the paper from [36]. n_i and n_o denote the numbers of input and output ciphertexts. The tuples $\{w_i, h_i, c_i\}$, $\{w_o, h_o, c_o\}$ represent input and output tensors. A kernel with a size $f_w \times f_h$ strides by s. The remaining parameters such as k_i,k_o,t_i,t_o,p_i,p_o, and q are related to the multiplexed parallel convolution method presented in [36] Finally, the fully connected layer is implemented using the diagonal method in [23].

SoK (or SoLK?): On the Quantitative Study of Sociodemographic Factors and Computer Security Behaviors

Abstract

Researchers are increasingly exploring how gender, culture, and other sociodemographic factors correlate with user computer security and privacy behaviors. To more holistically understand relationships between these factors and behaviors, we make two contributions. First, we broadly survey existing scholarship on sociodemographics and secure behavior (151 papers) before conducting a focused literature review of 47 papers to synthesize what is currently known and identify open questions for future research. Second, by incorporating contemporary social and critical theories, we establish guidelines for future studies of sociodemographic factors and security behaviors that address how to overcome common pitfalls. We present a case study to demonstrate our guidelines in action, at-scale, that conduct a measurement study of the relationships between sociodemographics and de-identified, aggregated log data of security and privacy behaviors among 16,829 users on Facebook across 16 countries. Through these contributions, we position our work as a systemization of a *lack* of knowledge (SoLK). Overall, we find contradictory results and vast unknowns about how identity shapes security behavior. Through our guidelines and discussion, we chart new directions to more deeply examine how and why sociodemographic factors affect security behaviors.

1 Introduction

Sociodemographic factors — people's social, cultural, or demographic attributes (e.g., gender, race, socioeconomic status, age, or internet skill) — shape their lived experiences, i.e., what happens in their lives, how they are impacted by what happens, and how they make decisions. Prior works find that sociodemographics *do* impact computer security behaviors, e.g., that women may choose weaker passwords than men [62] or that older users choose stronger passwords [3]. These findings suggest that gender and age influence password selection and thereby computer security, potentially motivating interventions that target the underlying causal mechanisms.

The field of computer security has considered the role of the human for decades, e.g., Saltzer and Schroeder's recognition of the importance of psychological acceptability of security solutions in the 1970s [91], and Whitten and Tygar's foundational 1999 paper catalyzed the formation of the field of *usable security* [120]. Focus on the role of sociodemographic factors in computer security behaviors is, however, comparatively new [84]. Given the potential impact of these factors, it is vital to examine the current state of knowledge with respect to sociodemographics and computer security behaviors.[1] With this understanding, it becomes possible to focus future efforts on addressing knowledge gaps and, ultimately, to help improve computer security for everyone.

Our first two research goals are:

- **Goal 1.** Collect and synthesize current knowledge about the quantitative relationship between sociodemographic factors and computer security behaviors.
- **Goal 2.** Enumerate existing knowledge gaps about sociodemographics and computer security behaviors.

Through a focused literature review of 47 papers in selected technical security conferences and a high-level survey of 151 papers in the wider literature, we synthesize trends, e.g., that people of different genders may focus on different security behaviors, as well as identify open opportunities for future research. We focus on quantitative studies, a primary method researchers use to measure security behaviors in relation to specific sociodemographic factors, like gender. Knowledge gaps exist when pertinent sociodemographic factors are omitted in analyses. For example, in our set of 47 papers between 1999 and 2023, we find that 38 consider (binary) gender whereas only 3 consider income, 5 consider race, and 9 consider Internet skill; none consider non-binary gender. We also observe different levels of depth with respect to how sociodemographic factors are analyzed and how differences by factors (if any) are interpreted.

After reviewing the current state of knowledge sociodemographics and behaviors, we identify our third goal:

- **Goal 3.** Formulate guidelines for future research on so-

[1] For brevity, we use 'security' to consistently refer to security and privacy.

ciodemographic factors and security behaviors.

To demonstrate the use of our guidelines in practice and at-scale, we apply the guidelines to conduct and report the results of a case study. Our measurement study uses de-identified, aggregated log data from Facebook to analyze the relationship between security behaviors on the platform and selected sociodemographic factors. We confirm several trends observed through our literature review, while adding nuance to others. Finally, we critically consider the knowledge gaps illuminated by our investigation — particularly, the lack of understanding about *why* sociodemographic factors and security behaviors might be correlated — and chart directions for future research.

2 Background and Motivation

Demographics uses statistics to study trends in human populations [79, 80]. Sociodemographics encompass demographic factors as well as social factors defined by formal institutions, e.g., governments [97], or informal institutions, e.g., sociocultural norms [109]. Conventional studies of sociodemographic factors are positivist, i.e., asserts that knowledge can be empirically measured and there *exists* a correct measurement that scientists can strive for [73]. In presuming objectivity, conventional demography overlooks the historical and political processes that shaped the categories themselves [40, 103, 109].

Categorization abstracts away richness to allow scientists to focus on selected characteristics. As an inherently reductive activity, categorization renders some research more tractable but may not accurately represent lived realities [5, 39]. By assigning people to static, finite groups, those who shift between groups or exist outside those groups, for example, will be systematically misinterpreted [1, 48, 95]. Further, categorization schemes are typically designed by historically and socially privileged groups in ways that can embed power imbalances [68, 79, 90, 105].

***Critical demography*, as an alternative to conventional demography, incorporates the reflexive study of how categories are socially constructed.** As such, it "necessitates an open discussion and examination of *power* in society. Specifically, critical demography elucidates how power both affects and is impacted by demographic processes and events" [40]. Thus, critical demography offers a theory-driven paradigm to study how people behave, informed by social and political history [40], towards epistemological diversity and addressing inequity [73]. Prior work has applied critical demography approaches to deepen knowledge and practice, e.g., in computing education [69]. We apply a critical demography approach to synthesize prior work on sociodemographic differences in security behaviors, but also to map what is not yet known.

3 Literature Review Methods

What is currently known about how sociodemographics affect behavior, and what gaps remain? To scope to studies of users' actual security or privacy behaviors, we excluded studies of intended behavior, concerns, knowledge, or attitudes. As we were also interested in quantitative studies, we only included works that compared behavior between sociodemographic groups, i.e., we excluded work that investigated only one group within a sociodemographic factor.

3.1 Identifying Relevant Work

To identify potentially relevant studies, we defined unique search queries for selected conferences (see Section 3.2) and used the advanced search features of the ACM DL, IEEE Xplore, and the USENIX databases to search full-length research articles (see Table 1). Since these databases do not contain NDSS papers, we also obtained an NDSS paper archive scraped by other researchers. We wrote a `pypdf` [23] script to extract and search text directly from the PDFs using the search strings shown in Table 1. Two researchers independently reviewed paper titles and abstracts of search results to apply the scoping criteria described above and iteratively resolved disagreements to select the final dataset.

Relevant studies are also published in venues beyond computer science conferences; we used Google Scholar to find popular studies from any venue, including journals of business, information science, social science, or grey literature. We then defined two sets of keyword searches (see Table 1), which yielded over 6 million results, so one researcher reviewed the first 3 pages of search results. Finally, we followed citations from papers in our dataset that referred to relevant work, adding 20 studies not identified through search strings. We set no explicit time boundaries for our dataset.

3.2 Full and Focus Datasets

Our final "full" dataset consisted of 151 works. Most papers were published in academic venues such as conferences or journals, but we also included 4 theses, 3 Pew Research studies, and 1 arXiv paper. The full dataset reflects a growing interest in security behaviors with respect to sociodemographic factors across venues and academic disciplines. Much of the dataset (76 papers) was in information science or social science domains and spanned a wide range of venues, from computing (e.g., *Computers in Human Behavior*) to communications and media (e.g., *New Media & Society*) to marketing and business (e.g., *Journal of Interactive Marketing* and *Journal of Management Information Systems*) to social sciences (e.g., SSRN). Another 20 papers were in computer science publications. The distribution of venues is long-tailed since we had 70 papers each from unique domains. We defined a "focus" set of 47 papers by identifying seven conferences

Table 1: Summary of literature review search methods. We used Google Scholar to write custom **search strings** to identify relevant studies in selected computer science **venues** and **databases** as well as in non-CS venues. For each search, we show the **number of results** and **number of included** studies satisfying our scoping criteria. †We implemented manual keyword searches of PDFs scraped from ndss-symposium.org. *We manually reviewed only the first 3 search result pages.

Venue	Database	Search String	# Results	# Included
FOCUS DATASET: Selected Computer Science Venues				
ACM CHI	ACM DL	In abstract: [security OR privacy] AND [behavior OR habits OR practices] and in body text: [gender OR sex OR age OR technical expertise OR education OR race OR culture OR internet skill]	213	14
IEEE S&P	IEEE Xplore	*same as CHI*	90	2

SOUPS	ACM DL	*same as CHI*	77	17
ACM CCS	ACM DL	*same as CHI*	508	7
ACM CSCW	ACM DL	*same as CHI*	62	4
NDSS	ndss-symposium.org†	*same as CHI*	62	1
FULL DATASET: Beyond Selected Computer Science Venues				
Various	Google Scholar	[cross cultural OR large scale OR demographic] AND [behaviors] AND [security OR privacy]	270K+*	97
Various	Google Scholar	[password OR authentication OR update software OR secure drop OR phishing emails OR encryption OR WiFi OR anti-virus OR HTTP SSL warnings OR tracker blockers OR information disclosure OR self disclosure OR IoT OR VPN] AND [behaviors].	5.8M+*	11

most likely to include papers of interest: four computer security conferences (IEEE S&P, USENIX Security, CCS, NDSS), two HCI conferences with a tradition of including security and privacy (ACM CHI, ACM CSCW), and one conference at the intersection of HCI and security (SOUPS).

3.3 Qualitative Analysis

We qualitatively analyzed papers in our "full" set by coding behaviors studied (dependent variables) and sociodemographic factors considered (independent variables). For further analysis on our "focus" set, we also coded whether a significant relationship was (or was not) found[2] as well as where the study was conducted, the research methods used, and any research sample limitations.

We created our codebooks via a series of iterative coding sessions between two coders. First, a primary coder prepared an initial codebook by inductively coding all papers. A second coder then independently coded a subset of the papers using the same codebook. The two coders then met to resolve inconsistencies and, if necessary, clarify and adjust the codebook. If adjustments were made, the primary coder then recoded the rest of the dataset. This process was repeated until the codebook no longer changed. We also verified our resulting codebook with a prior work's codebook on security behaviors [89]. Table 2 presents the behaviors codebook and paper counts; codebooks for other topics are presented in Appendix A.1.

[2]Because studies sometimes studied multiple sociodemographic factors for a given behavior, we coded each relationship separately.

3.4 Positionality

The authors' particular social, cultural, political, and historical context influence the way we discuss sociodemographic factors in this work. As researchers who have predominately lived and worked in the U.S., have English as a first language, and have had opportunities to pursue or achieve academic degrees in computer science, our perspective is limited by the privileges these experiences afford, relative to different experiences. Our motivation for this work is also shaped by experiences of marginalization by gender, culture, race, and age. As researchers with substantial experience studying human factors in security, we aim to improve the security of all people, not only those who have been historically prioritized in security research (i.e., users who are predominantly men, white, wealthy, highly educated, and live in the U.S.). We seek to raise the voices of those at the margins, in alignment with standpoint theory's premise that non-dominant social groups contribute critical knowledge towards scholarship and action towards justice [11].

3.5 Limitations

We sought as exhaustive a list of papers as possible to study sociodemographic factors and security behaviors, but we likely missed some relevant papers. During paper collection, we ultimately included less than 25% of our search results because many papers use sociodemographic keywords without satisfying our criteria, i.e., they do not quantitatively compare groups within a factor. Relevant work is also published outside the seven venues of our focus papers, but we believe our

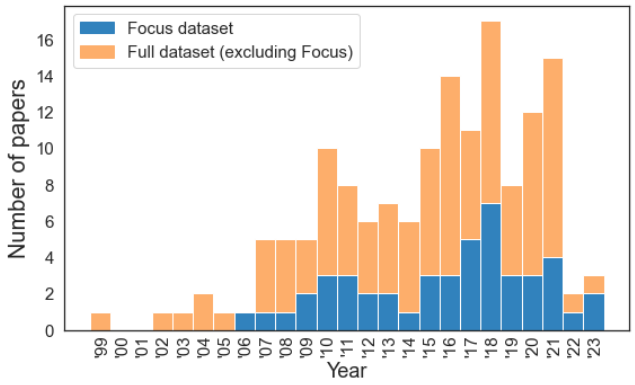

Figure 1: Number of papers in focus and full datasets investigating sociodemographics and security behaviors over time.

methods captured a set of papers large enough for meaningful analysis and discussion.

Our goal was to focus on sociodemographic factors related to security behaviors. As such, we scope to papers that measure security behaviors directly, e.g., through observational data, log data, and self-reports about actual behaviors. Future work may seek to focus on the substantial literature on additional topics, such as attitudes, opinions, or perceptions.

Since our goal was to conduct a formative literature review of security behaviors with respect to sociodemographic factors, we did not attempt to evaluate the "validity" of any paper. The replication crisis in psychology [102] reminds us that robust quantitative findings must be repeatedly tested and confirmed, which we leave to future work.

4 Literature Review Results

We first survey the locations, methods, and behaviors investigated in the full dataset of 151 papers (Section 4.1) and then explore methodological considerations in our 47 focus papers (Section 4.2). Next, we synthesize results about eight sociodemographic factors—gender, age, education, technical expertise, Internet skill, geography, race, and income—from the focus papers (Sections 4.3-4.8). Table 3 provides an overview of sociodemographic factors studied with respect to security behaviors and whether differences among groups were found.

Throughout this section, we enumerate trends as **T#** and opportunities for future work as **O#** to facilitate later comparison with our measurement study results. We present a summary of all trends and opportunities in Table 4.

4.1 Survey of Full Dataset

Since 1999, the publication year of the first study in our dataset, papers on sociodemographics and security have steadily increased (see Figure 1).

Table 2: The number of security behaviors studied by papers in our **full** (N=151) and **focus** (N=47) dataset. Counts do not sum to 151 or 47 due to papers that study multiple behaviors.

Security Behavior	Full	Focus
Network and Web, e.g., VPNs, use private browsing, use anti-tracker tools	44	9
Phishing and Spam, e.g., phishing susceptibility	38	9
Social Sharing, e.g., disclosing info. on social media, changing privacy settings	35	11
Authentication and Accounts, e.g., password creation or reuse, 2FA	23	12
Device, e.g., anti-virus software, mobile lock screens	21	8
Composite: combined security behaviors from above that cannot be disaggregated	14	5

Most studies are conducted in the U.S. or Western Europe O4. A plurality of studies in the full dataset (N=151) were conducted in the U.S. or Western Europe (60), followed by Asia (20), Africa and the Middle East (9), Australia (6), and South America (3).[3] Studies in the focus dataset (N=47) show the same trend: U.S. or Western Europe (33), Asia (5), Africa and the Middle East (3), Australia (3), South America (2).

Studies reflect a significant interest in network and web security behaviors as well as phishing and spam, but comparatively less in other behavior types O14. A complete breakdown of behaviors studied by papers in our full and focus datasets is presented in Table 2. The largest portion of our full dataset investigated network and web-related behaviors (44 papers), such as using VPNs or avoiding public WiFi, or using private browsing and other anti-tracking tools or practices. The second largest portion investigated phishing or spam susceptibility, a much narrower set of behaviors than network and web yet studied by nearly as many studies (38 papers). Less commonly studied were social sharing behaviors, e.g., disclosing information or changing privacy settings on social media (35), authentication and account behaviors (23), and device-related behaviors (21). Finally, 14 papers studied composite security behaviors, or combinations of the above types of behaviors, with regression analyses that we could not disaggregate.

Security behaviors are primarily investigated through self-report methods O15. For our full dataset, the vast majority, i.e., 109 studies, were based on self-reports of security behavior. Less common were the 32 studies that used experimental measurement methods, e.g., in-lab or online experiments, or the 15 that used observational methods, e.g., log data or installed software on user devices. For the focus dataset, 32 were self-reports, 12 used experimental measurement methods, and 8 used observational methods. The significant preference for self-report methods likely reflects the relative convenience of collecting data from participants simply by asking them, but

[3] Counts do not sum to 151 due to studies conducted in multiple locations.

self-reporting may not be wholly accurate given participant biases, e.g., social desirability biases [83]. Future work should confirm these results with more ecologically valid methods.

4.2 Methods Considerations in Focus Dataset

For the focus dataset, we were interested in how prior work ensured that the research was robustly designed and conducted for the sociodemographics and security behaviors of interest.

A sizeable proportion of investigations did not mention sociodemographic factors until the results section of the papers O16. We analyzed focus dataset papers to determine if they motivated their study of sociodemographics in the research questions or introductory section (i.e., considered) or whether sociodemographic factors were mentioned only in the results section (i.e., post hoc). Because clearly defining independent variables, e.g., gender, and their levels or conditions, e.g., woman/man/nonbinary, is essential to control for confounding factors between conditions [81], not considering the role of sociodemographics until the results may imply an incomplete methodology. Further, consistently reporting the variables and relationships of interest before beginning statistical testing is important to avoid cherry-picking non-null results [63]. We found 74 instances where factors were considered in advance and 45 instances where sociodemographic factors were studied post hoc.[4] Studying sociodemographic relationships to security behavior is not warranted merely because relevant data was collected; therefore, confirming the results of papers that conducted a post hoc study of sociodemographics is an opportunity for future research to ensure that the findings were not spurious.

The majority of papers had limited samples, i.e., samples not representative of broader populations or balanced among groups O17. To assess the generalizability of studies in our focus dataset, we coded whether papers were representative (i.e., sample attributes matched broader population attributes), or balanced (i.e., equally across factor groups) for analysis. We found only 7 instances of factors being balanced and 18 representative; the vast majority (96) were limited,[5] i.e., not controlled in any way (snowball or convenience samples), or had no description of recruiting considerations. Future work should expand on addressing limited samples.

4.3 Gender

Gender is used in varying contexts and includes a person's gender, but also how gender is constructed in a societal context, i.e., referring to socially established gender roles [49]. It is often conflated with sex, i.e., bodily attributes, though these are distinct concepts [49]. Gender has received the most attention in security research (38 of 47 focus papers) relative to other sociodemographic factors.

Existing research primarily uses self-report methods, which could be biased by gendered differences in self-reporting O2. Prior work finds gender stereotypes that men are overconfident when it comes to security and privacy [119]. As described above, sociodemographic differences in behavior tend to be investigated through self-report methods, a trend that holds for gender specifically: of 28 papers that found gender differences, 21 used self-report methods. Thus, gender differences could be because men are more likely to self-report behaviors than women, regardless of true adoption rates.

Prior work suggests men may focus more on technical security behaviors, while women may focus more on privacy behaviors T1. One set of papers found that men were more likely to take certain protective actions related to network and web security, e.g., use tracker blockers [60], take protective actions against trackers [13], and use private browsing [29], although no differences were found for heeding SSL warnings [106]. Two papers studied composite security behaviors, finding that men were more likely to adopt predefined sets of security and privacy protective practices [118, 126] (although no differences were found in "triggers" prompting security behaviors [18]). Finally, one paper investigated how the sources for security advice differ between genders [87], finding that men were more likely than women to source advice from service providers. Taken together, these findings suggest gender differences in "technical" security behaviors, though it is unclear whether these differences result from self-reporting biases, prior computing experience, attitudes towards computers [122], or something else.

Another set of papers found that women were more likely to engage in security and privacy behaviors on social media and personal devices. Women were more likely to have private profiles on Facebook or Myspace [27, 107], post non-publicly on Facebook [24] and Snapchat [30], and avoid actions that expose online profiles they viewed [41]. Teen girls were found to be more likely than teen boys to adopt risk-coping behaviors (e.g., deleting posts, untagging photos, faking personal information) as well as seek privacy advice [43]. Prior work also found differences in disclosure content: men were more likely to disclose COVID-19 distress in May 2020 than women [125], but generally women were more likely to share memes portraying subjects positively [34]. Though prior work found inconclusive evidence about gender differences in device behaviors — adopting lock screens [31, 115], Android updating [59] — in others, women were found to be more likely to use webcam covers [56] and women 18-23 were more likely than men or people of other age groups to deny Android permission dialogs [2]. Taken together, these findings align with prior work (outside our literature review) [45, 57, 82, 92, 111] indicating that women focus on information protection and engage in privacy-preserving self-censorship.

[4] Papers would have multiple instances if they studied multiple factors; thus, counts do not sum to 47.

[5] Counts do not sum to 47 because of papers studying multiple factors.

Results were mixed on gender differences with respect to authentication and susceptibility to phishing and spam. Research on authentication behaviors is mixed: two papers found that men's passwords were stronger against offline attacks [3, 62], but men aged 46-49 were more likely to share passwords than others [47]; another paper did not find sharing differences by gender [74]. Further, researchers found that women were more likely to reuse passwords with slight modifications [99], less likely to remember graphical passwords [8], and less likely to enable 2FA in response to experimental prompts [28], but other researchers found no difference in password reuse [78] or in whether they change password managers [66]. Future work should investigate whether gender differences in authentication behaviors are due to methodological differences, context, or other reasons **O8**.

Two papers found that women were more likely to click on phishing and spam [86, 100], although three other papers did not find significant gender differences in this regard [21, 52, 101], and one found that women were less likely to visit malicious URLs than men [98]. Papers not finding gender differences were published in 2006, 2007, and 2009, while papers finding differences were published in 2010 and 2018. One explanation could be that phishing and spam increasingly targeted women in 2010, and people of different genders now receive different types of phishing and spam [86] **O9**.

Existing research primarily investigates binary (assumed cisgender) individuals, excluding non-binary and transgender people O1. Most papers mention only women and men, and few papers conduct statistical testing with non-binary individuals, often opting to filter them out during data processing. Non-binary people constitute a far smaller proportion of study participants, posing a challenge for parametric statistical testing that could be resolved with use of nonparametric tests or different study designs. Further, almost no papers discuss transgender individuals, while other work conflates gender and sex by referring to participants as female and male when discussing gender, against best practices [94]. Research should distinguish between cisgender and transgender people only when relevant, but given that transgender people experience significant harm [116] and erasure [108], omitting this aspect of gender may reflect cisnormativity.[6]

4.4 Age

Age granularity in the security literature varies from a single year to multiple decades and can be modeled as a numeric or categorical variable. Age is the second most studied sociodemographic factor (in 30 of 47 focus papers).

Prior work suggests that age may have been correlated with differences in password behaviors in the past, but is no longer T2. Two papers published after 2017 found no significant differences by age in switching password managers [66] or password reuse [77] (also found by a 2010 paper [99]). Supporting a theory of change in the past decade, a 2012 paper found that older users chose stronger passwords [3] but a study from the following year did not find such correlations [62]; similarly a 2011 paper found older users were more likely to share passwords [47], but evidence from a study seven years later did not support this finding [74],

Older users may behave more securely, while younger users focus on privacy T3. When studying a combined set of internet *security* behaviors, prior work found that older adults behaved more securely [118, 126], while younger users were more likely to adopt a combined set of *privacy* practices [126], e.g., use private browsing [29], use tracker blockers [60], and have Android lock screens [31] (though older users in Singapore may differ as they were more likely to adopt privacy practices [9]). The distinction between security and privacy behaviors may be partially explained by the finding that people 60+ were more likely to learn from automatic requirements or service providers than younger people [87]: formal sources may emphasize security as prevention of universal harm but privacy as a personal choice. Thus, older users were found to be more likely to enable 2FA in response to prompts [28] and deny Android permissions dialogs [2] as well as be more likely to be prompted by social triggers to behave securely [18]. However, differences by age were not found in responses to SSL warnings [106] or Android auto-updating [60].

With respect to online sharing, older users were more likely to post publicly than younger users [24] though less likely to specifically disclose distress during the COVID-19 pandemic [125] or share a security news event [19].

Similar to mixed results for phishing susceptibility by gender, prior work presents inconclusive findings about the relationship between age and phishing susceptibility O10. Three papers found that younger participants were more susceptible to phishing [36, 52, 100], while two found no correlations by age [21, 101].

4.5 Education

Formal education imparts knowledge and skills to students and increasingly includes information about computing. Educational systems and institutions vary greatly, including nationally and internationally, but can be broadly grouped into primary, lower and upper secondary, and tertiary (also called higher ed) [114].

Education does not seem to be correlated with secure behavior T4. Of the 14 papers that investigated relationships between education and security behaviors, four found significant correlations: more educated users were more likely to delete cookies and history [7] as well as adopt a composite of 30 security, privacy, and ID theft practices [126]. However,

[6] *Cisnormativity* is the assumption that everyone is or should be cisgender.

Table 3: Relationships between sociodemographic factors and security behaviors for papers in our focus dataset. For each sociodemographic factor (rows) and category of security behaviors (columns), we show X / Y, where X is the number of papers that found differences by factor for behavior, and Y is the total number of papers studying that factor and behavior. Summing counts do not sum to totals due to papers that study multiple factors or behaviors. Auth. = Authentication, Tech. Exp. = Technical Expertise, Composite = multiple behaviors studied together.

	Accounts & Auth.	**Device**	**Network & Web**	**Phishing & Spam**	**Social Media & Sharing**	**Composite**	**TOTAL**
Gender	6 / 9	4 / 6	3 / 4	3 / 6	10 / 10	3 / 4	28 / 38
Age	3 / 9	2 / 3	2 / 3	3 / 5	5 / 6	4 / 4	19 / 30
Education	- / 4	- / 2	1 / 2	- / 2	- / 1	3 / 3	4 / 14
Tech. Exp.	3 / 6	2 / 3	4 / 4	4 / 5	0 / 0	1 / 1	7 / 12
Geography	1 / 1	1 / 1	2 / 2	2 / 2	2 / 2	2 / 2	10 / 10
Internet Skill	2 / 2	- / -	1 / 1	2 / 4	1 / 1	1 / 1	7 / 9
Race	- / -	- / -	- / -	- / -	2 / 3	2 / 2	4 / 5
Income	- / 1	- / -	- / -	- / -	- / -	2 / 2	2 / 3
TOTAL	12	8	9	10	11	5	47

studying a composite of four behaviors to combat viruses and hackers, Wash et al. find that compared to those with a high school diploma, those who did not complete high school were more likely to adopt security behaviors [118]. Similarly, compared to those who held a BA, those who did not hold a BA were more likely to report learning security advice from automatic software updates [87].

On the other hand, 10 papers do not find significant correlations between education and account sharing [74], password strength [123], password reuse [77], switching of password managers [66], Android auto-updating [59], webcam cover use [56], public sharing behaviors on Snapchat [30], SSL warning behaviors [106], or phishing susceptibility [21, 52].

Differences in correlations between education and security behavior are not well understood. There may exist several reasons for these disparate results. First, while prior work notes that those with lower educations are more concerned about being the victim of a computer scam, losing financial information, and being the target of harassment [58], it is unclear how the varying computer knowledge held by those with different educational backgrounds affects the ability to employ secure behaviors. Education does not necessarily include computing or security education; indeed, prior work found that while people with less education rely on less authoritative sources of security advice, they report fewer negative incidents, perhaps suggesting that formal advice sources — including formal educational environments — fail to provide effective security education [88]. Further, a bachelor's degree education varies significantly by institution, such that high-level education categories reduce critical nuances. Education may not result in a linear increase in security behavior but may vary by context. Future work should investigate the relationships between education and security behaviors to better understand the underlying causal mechanisms at play.

There is a lack of research on students at levels besides secondary or post-secondary O3. Of 14 papers studying education and security behaviors, four conducted studies in U.S. and Canadian universities (e.g., university students, staff, faculty) and another seven conducted studies with U.S. recruitment/crowdworker populations, which are more likely to have attended or completed college than the average [38]. Only the remaining three papers were not conducted in the U.S. or Canada, revealing a striking over-representation of Western university-affiliated users in education-related results. Future work should consider a wider range of educational levels, in different or outside of educational systems.

4.6 Technical Expertise, Use, and Skill

Aside from general education, users have varying levels of experience with technology (i.e., technical expertise) or the internet specifically (i.e., internet skill).

Users with more technical expertise may use more technical security tools and take more protective actions T5. People with greater technical expertise were found to be more likely to use private browsing [29], identify security threats [71], and cite school (as opposed to required sources or device prompts) as a source of security advice [87]. Those with computer and mobile skills were more likely to take defensive security measures [7]. Greater technical expertise was also associated with higher adoption of multiple security practices [6, 42], although no correlation was found between technical expertise and webcam cover use [56].

Relatedly, internet use may suggest higher adoption of security practices, e.g., users who logged in from multiple locations chose stronger passwords [3], and users more active on Facebook were more likely to enable 2FA in response to prompts [28]. Prior work also demonstrates that people with more internet skill cite different sources of advice [87], which may contribute to these behavioral differences.

We observe an inconclusive relationship between technical expertise and password-related behaviors O12. Unlike other security behaviors, technical expertise did not have a clear relationship with password choices. Two papers studied

Table 4: A summary of trends and opportunities for future research from our literature review.

T#	Trends in Findings
T1	Women seem to focus more on information protection, while men seem to focus more on technical security.
T2	Older users may have had different password behaviors in the past, but no longer.
T3	Older users seem to exhibit more security-related behaviors while younger users focus more on privacy.
T4	Education does not seem to be correlated with secure behavior.
T5	Users with more tech expertise/use seem more likely to adopt technical security tools and take protective actions.
T6	Geography seems to be strongly correlated with differences in security behaviors.
O#	**Opportunities for Future Research**
Who is being studied: Lack of Focus around Specific Groups	
O1	Lack of research on non-binary and transgender people's security behaviors.
O2	Lack of research on gender differences in self-reported behaviors.
O3	Lack of research on education at levels besides (post-)secondary.
O4	Majority of papers conducted in U.S. and Western contexts; relative lack of research in other locations.
O5	Lack of research on geographical differences beyond granularity of countries.
O6	Lack of research on race and security behaviors.
O7	Lack of research on income and security behaviors.
What was found: Contradictory or Unclear Results	
O8	Mixed results on authentication behavior $\sim$ gender.
O9	Mixed results on phishing and spam susceptibility $\sim$ gender.
O10	Mixed results on phishing susceptibility $\sim$ age.
O11	Mixed results on phishing susceptibility $\sim$ internet skill.
O12	Mixed results on password behaviors $\sim$ technical expertise.
O13	Unclear patterns of geographical influence on security behaviors.
How: Methodological Issues	
O14	Significant interest in network/web behaviors and phishing/spam, but less on other behaviors.
O15	Security behaviors are primarily investigated through self-report methods.
O16	Many papers did not declare an interest in sociodemographic factors in the motivation of the work.
O17	Most papers had limited sample generalizability.

people affiliated with universities, one finding that participants in the computer science department chose stronger passwords than those in business [62], but the other found no conclusive evidence that technical expertise (including departmental affiliation) was correlated with stronger passwords [123]. Further, two papers found no correlation between technical expertise and password reuse [99] or password manager switching [66].

There is an inconclusive relationship between internet skill and phishing susceptibility O11. Two papers found that greater internet skill or knowledge about phishing correlated with less phishing or spam susceptibility [86, 100], while three others did not find correlations between internet skills or phishing susceptibility [21, 36, 101]. A potential explanation comes from outside the literature review: prior work suggests activity level on a platform (which is itself weakly correlated to internet skill) may have more explanatory power than the coarser measure of internet skill [86].

4.7 Geography and Race

Geography is a proxy and umbrella term for a range of sociodemographic factors, including nationality, language, population density, political history, culture, internet penetration, freedom of speech, and more. Geography also shifts over time since politics and culture reshape the societies living between socially constructed boundaries.

Race refers to groups of people who share cultural, social, and physical similarities. It has been shaped through historical narratives of identity to be a tool of power, particularly for discrimination and the justification of colonialism [68, 90, 105]. Though racialized science continues to advance myths of biological differences between races, race is a powerful determinant of the privileges that an individual has access to, e.g., education, wealth, health.

All papers in our focus dataset studying geographic factors with respect to security behaviors were significantly correlated with behaviors T6, but effects lacked clear cross-cultural patterns O13. While the ten papers investigating correlations between geography and security behaviors find differences in many types of behaviors, these results are often sparsely populated, and it is not clear why these patterns appear or how they do, or do not, generalize to other geographical regions. German and French participants were found to be twice as likely to take protective actions against tracking than those in the UK [13]. Compared to U.S. and U.K. users, German internet users tended to adopt more advanced, active privacy methods, such as proxies, Tor, and providing false information [12]. U.S. users were more likely to take security-protective actions because of proactive triggers, whereas people in India were more likely to act in response to social triggers [18]. Password strength varied by primary language spoken: passwords chosen by Indonesian-speaking users were found to be the weakest; German- and Korean-speaking users tended to choose relatively strong passwords [3]. Android lock screen usage also varied by country, e.g., 76.4% in the U.K. compared to 50.4% in Italy [31].

Phishing and spam susceptibility also differed by geographic location. Users who live in countries that have more spam are less likely to click it [86]. South Koreans were more likely to fall for phishing attacks in Korean than English, while Japanese participants were more likely to fall for phishing in English than Japanese [36]. On social media, rural U.S. users were more likely to set profiles to private than urban U.S. users [27], and Saudi women were more likely to block people on WhatsApp than Indian women [20]. Compared to U.S. users, U.K. users were less likely to dismiss cookie banners but more likely to not read consent text [4].

Few papers discuss geographical factors beyond the granularity of a country O5. Geographical factors describe a wide range of sociodemographic variance beyond national identity; however, the majority of papers focus only on these differences. Of ten papers, eight segregate geographical differences by nationalities [4, 13, 18, 20, 31, 36, 86], while only two discuss variations by language spoken [3, 36], and only one considers urbanization differences within the same country [27]. Future work can continue to illuminate how security behavior changes based on sociodemographics other than national identity, such as within a country, in cultures that extend beyond nations, or WEIRD vs. non-WEIRD societies [55].

Race is an infrequently studied sociodemographic factor in research on security behaviors O6. Race is a function of culture and was only studied in five papers. Trends are difficult to ascertain because these papers investigated distinct behaviors and used different racial categorizations (we report using those papers' terminology). With respect to security, prior work found that white people were more likely to take certain protective security actions than Asian Americans and Pacific Islanders as well as Black or African Americans, though American Indians and Alaska Natives were more likely than white people to use security settings [118]. White people were more likely to solicit security advice from family and friends than Hispanic people [87]. With respect to privacy, while one paper found that racial minorities were more likely to publicly post on Snapchat [30], another found that compared to African Americans, white people were more likely to disclose distress on social media [125]. One paper did not find racial differences in Facebook profile privacy settings [74].

4.8 Income

Income determines not only the financial resources that one has to spend, but it may also indirectly influence the time or energy that one can put towards security behaviors.

More research is needed on relationships between income and security behaviors O7. Only three papers studied relationships between income and security behaviors: one found no differences in account sharing [74], while another found that people with lower incomes were more likely to adopt a combined set of security and privacy behaviors [126]. People at different income levels learn from different sources; those with higher incomes were more likely to learn from school, work, or device prompts [87].

5 Guidelines for Future Sociodemographic Research on Security Behaviors

Our literature review documents a significant and growing interest in studying how sociodemographic factors relate to security behavior. Based on our review, our own domain expertise, and sustained discussions amongst the research team, we developed guidelines to support strong and valuable research contributions. We iteratively refined these guidelines throughout our research process, including during our measurement study (see Section 6). We offer these guidelines to assist researchers in both their research and reviewing process. However, we caution: the guidelines are not a checklist to guarantee quality work, there may be cases when they do not apply, and norms and best practices continually evolve.

Factor Selection. The selection of which sociodemographic factors to analyze should be done deliberately and stated as a research interest in the motivation (e.g., in the introductory section) for the work. Many papers in our literature review did not explicitly declare studying sociodemographic differences but presented correlations with sociodemographic factors in the results (see Section 4.2), which may indicate spurious correlations **O16**. Additionally, multiple studies are necessary to establish robust evidence of factor correlations, as demonstrated by the replication crisis in psychology research [61, 102].

G1: Identify at the beginning of the study the specific sociodemographic factors, if any, you intend to study. If you investigate sociodemographic differences, commit to reporting the results even if they do not show differences, i.e., null results. Consider study pre-registration [10].

Group Selection. Within all sociodemographic factors, there are groups that are privileged or marginalized. We found many opportunities for research about different groups, e.g., groups marginalized by gender (see Section 4.3) **O1** or race (see Section 4.7) **O6**. Researchers choose to study a subset of groups for practical or other reasons. If so, describe how the scope was chosen and how the sample studied relates to the broader population.

G2: Consider and justify which groups are included in or excluded from your study.

Method Selection. Epistemic diversity allows researchers to explore a wider range of research questions. Consider research methods that make different types of contributions [124], including but not limited to: quantitative, qualitative, or mixed

methods [53]; descriptive, experimental, or speculative; cross-sectional or longitudinal [15, 26]. If relevant, consider causal inference methods [17, 76].

Most papers in our literature review used statistical hypothesis testing, which is primarily valuable to identify factors for correlations but not causation. Few papers in our literature review modeled sociodemographic factors as control factors (see Cho et al. as an exception [9]). Further, many papers we reviewed used self-report methods **O15**, which are convenient for formative work but not suitable for establishing robust results.

G3: Consider using diverse research methods, acknowledging the benefits and limitations of each.

Result Interpretation. When interpreting results, remember that complex factors could lead to any observed differences. Avoid "essentializing" (reducing individuals to assumed group characteristics) and over-generalizing findings. In interpreting results, state not only what can be implied from the results, but also what cannot: for example, "We found a significant correlation between this factor and this behavior, which might be due to methodological choices or factors outside the scope of this study." This is particularly important for studies conducted on limited samples **O17**.

G4: When sociodemographic differences are observed, exercise caution in describing the results. Consider posing several causal interpretations for observed differences.

Author Positionality. Weighing the advantages and disadvantages of disclosure [54], if appropriate and safe to do so, include positionality statements in your work. In some cases, the risks to researchers may not merit disclosure. Further, we caution against positionality statements that merely list identities without reflexivity as to how these identities influenced the research process. When included thoughtfully, such statements provide context for readers about researcher motivations and the potential influence of researcher backgrounds. For example, a majority of existing research in our literature review is U.S.-centric and studies people affiliated with universities **O3** and **O4**, which is likely the result of the (undiscussed) positionality of researchers as primarily professors and graduate students at Western universities.

G5: Be aware of your own positionality and identity as a researcher and critically reflect on how it might affect your research questions, hypotheses, and interpretation of your findings [40].

6 Case Study: Measuring Sociodemographics and Security Behaviors on Facebook

We now instantiate our guidelines in our own case study to concretely demonstrate their application for future researchers. We iteratively refined the guidelines in the process, resulting in the version in Section 5.

Unlike most prior work that uses self-reports, we leverage de-identified, aggregated log data to shed light on how users' real security behavior correlates with sociodemographic factors. Security is often a secondary goal, so users may incorrectly recall actions and self-report based on social desirability [50, 67] or researcher demand [72]. Thus, real-world security behavior offers high ecological validity and an important complement to self-report studies.

6.1 Measurement Methods

This study was conducted by combining de-identified, aggregated log data about security behavior with the results of a 16,829 respondent survey run on Facebook in 16 countries during December 2019. Respondents were recruited through both web and mobile interfaces via a message at the top of their social media feeds. The survey was translated into the respondent's local language by professional translators with native language proficiency.

Our *dependent variables (DVs)* were four security behaviors: **Security settings visited** ($\pm$ 45 days of survey date), **Security settings acted on** ($\pm$ 45 days of survey date, only among respondents who visited), **2FA enabled** (ever), and **Stronger password** (i.e., those not yet identified as potentially more vulnerable to attack[7]).

Based on the available log data about Facebook users, we chose six sociodemographic factors to study **G1**. These factors were: **Age**, **Gender** (binary[8]), **Educational attainment**, **Geographic location** (16 countries in four regions), **Internet skill**, and **Technical knowledge**. Appendix B.1 details these factors and how they were determined. We also included four available *independent variables (IVs)* regarding Facebook use based on the de-identified platform data: **Tenure** (how long the respondent had an account), **L30** (how many of the last 30 days the respondent had logged in to their account), **Time spent** (how much time the respondent spent on the platform over the last 30 days), and **Friend count** (number of social connections on the platform).

Analysis. We analyzed our data with logistic regression models because of the scale of our data **G3**. We weighted our

[7] See https://www.facebook.com/help/124904560921566 for details on Facebook's password guidelines and https://www.facebook.com/notes/760840091433907/ on identifying potentially vulnerable passwords.

[8] Due to cross-cultural differences in prevalence of non-binary gender reporting, we study only those who reported a binary gender to allow for interpretable comparisons across countries. As underscored in **O1**, we encourage future work on those of non-binary genders.

sample to represent the population of the broader social media platform on age, gender, tenure, and L30 in order to maximize the generalizability of our results. To examine the relationship between security behavior and our independent variables, we constructed weighted logistic regression models, with security behavior as the boolean DV and the other variables listed above as the IVs (see Appendix B.2). We also controlled for two interactions that had correlations with $\rho > 0.3$: *l30∗time spent* — there is a correlation between the number of days and amount of time spent on the platform — and *location∗tenure* — there is a correlation between geographic location and platform tenure since the platform was introduced to different markets at different times. Regression models were fit using 5-fold cross validation. The variance in AIC between the five folds was always less than 3%.

Limitations. Our measurement study considers users of only one social media platform, although this platform is one of the largest and most diverse online platforms. Though we studied users in 16 countries, this represents a minority of countries globally **G2**. Further, racial categories differ greatly by sociocultural context, which is why our measurement study across 16 countries did not study race **G2**.

Ethics. We analyze de-identified, aggregated log data of users on Facebook who voluntarily completed survey data. There was no manipulation of any user's experience, and no personal identifying information was used. Our research procedures were vetted and approved through an internal review process.

Positionality. We echo our positionality statement from Section 3.4 in conducting this measurement work **G5**. Additionally, we note that one author engaged in a paid collaboration with Meta, which allowed them to access and analyze the de-identified, aggregated log data.

6.2 Measurement Results

In interpreting our results, we emphasize that all findings describe only associations between sociodemographics and behaviors, and we do not make causal claims **G4**.

Gender: On Facebook, women were more likely than men to take action regarding security settings, but no gender differences were found with respect to password strength or use of 2FA. We do not find significant differences in likelihood to *visit* security settings, but women were more than 1.4 times as likely to *action* security settings than men ($OR = 1.44, p < .01$). These results may support **T1** if actioning security settings is interpreted as an information protection behavior. Given that other work on the same platform we study finds that people tend not to make a clear distinction between security and privacy [85], women actioning security settings would align with other information protection behaviors. We found no significant differences in likelihood to have a stronger password or use 2FA by gender. While this null result could mean there is no relationship between gender and these behaviors, it could also mean that Facebook users are unique in not having gender differences, but differences could be found in studies of users of other services.

Age: While older Facebook users were less likely to visit their security settings, action their security settings, and use 2FA, those age 50+ were more likely to use stronger passwords. Compared to those aged 25-34, older adults were significantly less likely to *view* their security settings, with the odds of those between 35-49 being 0.74 times as likely to visit their security settings ($OR_{35-49} = 0.74, p_{35-49} < .05$) and those 50+ being 0.63 times as likely ($OR_{50+} = 0.63, p_{50+} < .05$). We also found significant differences in their use security settings, with the odds of older adults *actioning* their security settings being lower ($OR_{35-49} = 0.55, p_{35-49} < .001$; $OR_{50+} = 0.38, p_{50+} < .001$) and the odds of them using 2FA being lower, as well ($OR_{35-49} = 0.79, p_{35-49} < .05$; $OR_{50+} = 0.63, p_{50+} < .05$). However, the odds of adults 50+ having a stronger password was higher ($OR_{50+} = 2.08, p_{50+} < .05$). These findings appear to support **T2**, i.e., that older adults are more likely than younger to adopt security behaviors like passwords.

Education: On Facebook, education levels were correlated with the likelihood of using 2FA. Compared to users with no post-secondary education, users with some college ($OR = 7.14, p < .01$) or a bachelor's degree or more ($OR = 5.40, p < .01$) were more likely to use 2FA. However, education *was not* correlated with visiting or actioning security settings or having a stronger password, in alignment with **T4**.

It is possible that users with higher educational levels had to previously comply with their institution's 2FA IT policy and thus were more likely to reengage with 2FA on Facebook. Those with higher educations may also be more comfortable with computer systems and security tools like 2FA. Future work can continue to investigate post-secondary institution's influence on 2FA adoption by comparing with users not affiliated with post-secondary institutions, towards **O3**.

Technical expertise: On Facebook, technical expertise was correlated with stronger passwords and 2FA use. Technical knowledge of passwords was correlated with having a stronger password ($OR = 1.88, p < .05$) and using 2FA ($OR = 1.33, p < .05$), as was knowledge of the reaction feature on Facebook ($OR = 1.75, p < .05$; $OR = 1.37, p < .01$for stronger password and 2FA, respectively). Knowledge of QR codes was also correlated with greater use of 2FA ($OR = 1.49, p < .001$), while knowledge of downloads was not correlated with any security behavior. Since downloads are the oldest technology feature we asked about, the trends we find in our measurement study seem in alignment with our literature review, i.e., that technical expertise correlates with increased likelihood to take secure actions **T5**.

Internet skill: On Facebook, internet skill was correlated

with all behaviors except having a stronger password. Internet skill was correlated with visiting ($OR = 1.41, p < .01$) and actioning ($OR = 1.44, p < .05$) security settings as well as using 2FA ($OR = 1.84, p < .001$).

Platform-specific use: Tenure on a platform was correlated with all security behaviors, while use in the past 30 days was not correlated with any. Platform tenure in years was correlated with all four security behaviors, specifically to be less likely to visit ($OR = 0.95, p < .01$) or action ($OR = 0.95, p < .05$) security settings, less likely to have a stronger password ($OR = 0.91, p < .05$), but more likely to use 2FA ($OR = 1.84, p < .001$). This may be due to those with longer standing accounts having already adjusted their settings and due to changes over time in password advice (those creating accounts earlier may have received less password education at the time of account creation). Friends and time spent were also positively correlated with use of 2FA ($OR = 1.02, p < .01$; $OR = 1.13, p < .05$), though use in the last 30 days was not correlated with any security behaviors.

Geography: On Facebook, users in Africa, the Middle East, and Asian geographic markets differed significantly from the Western market in terms of security behavior. The odds of users in Asia visiting security settings were higher than users in the West ($OR = 1.94, p < .05$), lower compared to the same group to have a stronger password ($OR = 0.16, p < .001$), and no different for actioning security settings and using 2FA. Users in Africa and the Middle East were less likely to have a stronger password ($OR = 0.24, p < .05$), but other behaviors were not significantly different. Users in Latin America were not significantly different from Western users on any of the four security behaviors we studied. Geographic differences in our case study broadly align with **T6**, i.e., that geographic differences are significant but with unclear patterns **O13**.

7 Discussion

Having presented a systematization of knowledge of sociodemographics and security behaviors (Section 4) and guidelines for researchers (Section 5) and applied them in our own measurement study (Section 6), we now critically consider our *lack* of knowledge in this space.

7.1 The Missing "Why?"

This work reveals many correlations between sociodemographic factors and security behaviors, but little insight into *why* these correlations exist. The trends we synthesize and the opportunities we highlight begin to pose hypotheses for underlying causal relationships, but much work remains. Without understanding why, interpreting results becomes arduous and different studies can yield seemingly contradictory results. For example, when correlational studies find that one sociodemographic group adopts a security behavior less than another, is this the result of sample differences, different threat models, user interface designs that assumed one group as "default" users [14], or some other reason? Sociodemographic factors also do not exist in isolation but are correlated and influence each other; though this work did not investigate (reflecting papers in our literature review) intersectionality [16], only through understanding *why* each identity influences behavior can intersectional analyses be conducted.

Drawing implications for interventions to change behavior when the *why* is still missing is a tenuous proposition. We can neither know what interventions might encourage adoption of security behaviors nor whether such interventions are necessary, desired, or even helpful. Worse, if we assume incorrectly, subsequent actions or discussions may have a negative impact, e.g., perpetuating gendered stereotypes about computer security and privacy behaviors [119]. Recent related work on underlying causes of differences in security threats, rather than on behaviors, takes initial steps toward a causality-focused framework, e.g., identifying higher-order factors like prominence and marginalization that put particular groups at higher risk of security threats [93, 117].

7.2 Towards Answering "Why?"

What should be next for this field of research on sociodemographics and computer security and privacy? To close the knowledge gap, future work should explore not only *what* differences exist among sociodemographic groups in security and privacy, but *why* these differences exist.

Epistemic Diversity of Methods. Seeking to understand the causal relationships underlying sociodemographics and security behaviors cannot be achieved solely through quantitative methods. That does not mean establishing correlations has no value; the field as a whole must grapple with *why*, and individual papers provide incremental steps towards an answer.

In addition to the inferential methods used in the quantitative papers we analyzed, qualitative methods, e.g., in-depth interviews, observational studies, and ethnographies, can be used to explore the missing *why*. Such methods are increasingly used in security and privacy research to study the needs and practices of specific marginalized and vulnerable user groups but should also be used to draw out the underlying sociodemographic factors and their relationships to behavior. Especially by critically comparing privileged and marginalized groups, qualitative methods can assess existing hypotheses about causal relationships or pose new relationships and mechanisms of effect.

There are also other quantitative methods to consider beyond correlation and regression analyses. For example, structured equation modeling (SEM) involves constructing a model with causal relationships and statistically evaluating relationships as well as effect magnitudes [113]. Other analyses in-

clude causal inference methods [75], Bayesian methods [51], or quantitative meta-analyses. Each method has strengths and limitations that future work can explore.

Towards Social Theories. Overall, we recommend that security and privacy researchers learn from other fields that rely on social theories. Social theories, i.e., scientifically plausible principles that seek to explain certain phenomena by posing causal hypotheticals, pose richer explanations for how people behave, which avoids essentializing a group of people. For example, when women take fewer security measures than men, some might interpret this to mean that men are fundamentally better suited to security tasks. Instead, women's choices may reflect systemic educational inequities, where women were discouraged from learning about technical topics, or other reasons. Research must be careful to avoid attributing differences to innate group characteristics, e.g., racial essentializing [90]. Relevant social theories support robust interpretation when differences are found and can also indicate how a lack of difference can be meaningful.

Social theories from other fields can also help illuminate gaps in security behavior research, i.e., understudied factors that also merit study. Papers we analyzed focused most often on factors such as gender and age, but factors that have been more deeply studied in other fields and could inform security research include (dis)ability, marital status, religion, migration status, socioeconomic status, and race.

Finally, social theories facilitate critically challenging assumptions inherent in some perspectives on sociodemographics and security. This includes (1) questioning whether certain security behaviors are desirable for certain groups and in certain contexts since "spending more time on security is not an inherent good" [37]. Further, (2) the security behaviors studied may not address (or be trusted to address) the needs of all communities, especially those most marginalized [64, 121], and (3) sociodemographic categorizations themselves, and the types of security behaviors studied, are not the only ways to organize the space and may not be the most salient to users. As research continues to explore sociodemographic differences in security, incorporating theoretically informed inquiries presents the greatest opportunity to build on current methods and knowledge.

8 Related Work

Qualitative Studies of Marginalized Populations in Security and Privacy. A sizeable and growing body of literature investigates the experiences, behaviors, and needs of populations underrepresented in security and privacy research. These works often overlap with sociodemographic factors, e.g., targets of intimate partner violence [112] who are disproportionately women, refugees [104], LGBTQ+ individuals [25], and Muslim-American women [92]. Other studies investigate vulnerable populations due to their work, e.g., journalists [65], content creators [110], and sex workers [64]. These studies have been overwhelmingly qualitative, i.e., providing rich insights rather than quantitatively generalizable results.

Meta-Analyses of User Studies. The need for cross-study synthesis grows as the number of user studies of security behavior increases, e.g., about which methods are common [22], or expert vs. non-expert users [46]. Prior meta-analyses also investigated marginalized [93] and at-risk users [117], specifically developing unifying frameworks. We focus on sociodemographics as the unifying frame because they are a powerful latent cause of differences; ultimately, marginalization relies on our contemporary, socially constructed sociodemographic categories. Aside from a recent preprint investigating geographic diversity in security and privacy research [35], we are unaware of other meta-reviews taking a sociodemographic lens, though sociodemographic meta-reviews in HCI are more common, e.g., culture [44] as well as gender, race, and class [96].

9 Conclusion

We broadly survey scholarship (151 papers) that quantitatively studies sociodemographic factors and computer security behaviors, and we synthesize methods and results in a focused review of 47 papers. Taking a critical demography approach, we enumerate five trends in existing research and fifteen opportunities for future research (Table 4). We establish five guidelines for conducting quality sociodemographic research investigating security behaviors (Section 5) and apply those guidelines in a case study of the real security behaviors of 16,829 Facebook users. Taken together, this work documents the current state of knowledge on how people's identities relate to the security and privacy actions they take and charts new directions towards greater security, privacy, and equity.

10 Acknowledgements

We thank our reviewers and especially our shepherd for their helpful feedback. We are also grateful to Alannah Oleson, Matthias Fassl, and the UW Security and Privacy Research Lab (including Rachel Hong, Alexandra E. Michael, Christina Yeung) for insightful conversations on framing, methods, and impact. We thank Maximilian Golla and Aleksei Stafeev for sharing an NDSS paper archive. This work was supported in part by the U.S. National Science Foundation under Awards 2205171 and 2206950 and the Graduate Research Fellowship Program (DGE-1746047). The fifth author did a portion of this work while working as a contractor for Meta.

A Literature Review

A.1 Codebooks

We developed three codebooks for our literature review and detail here the topics we coded for, labels within each codebook, as well as definitions and/or examples of each label.

Type of Security Behavior: See Table 2.

Recruitment / Sample Characteristics

- **Representative**: successfully matched sample and population characteristics during recruitment
- **Balanced**: similar number of participants in factor groups for analysis, including work that happened to have balanced samples
- **Limited**: sample characteristics were uncontrolled, e.g., snowball / convenience samples, data collected based on non-sociodemographic criteria and descriptively reports sociodemographic data

Study Methods

- **Self-report**: participants reporting security actions, e.g., interviews conducted in-person or via telephone, surveys
- **Measurement (Observational)**: scraped public data, log data (e.g., from a university, company), or data from software on participants' devices (e.g., mobile app or browser)
- **Measurement (Experimental)**: controlled condition or direct interaction involved, including non-lab study (e.g., MTurk experiment, experiment on social media) or lab study (e.g., in-person, in-lab studies)

A.2 Full List of Papers

Tables 5, 6, and 7 show all papers in our literature review.

B Case Study

B.1 Sociodemographic Factors

We provide here more details on the sociodemographic factors we study in our case study in Section 6. Based on the available log data about Facebook users, we chose six sociodemographic factors to study:

- **Age**, self-reported, bucketed into three groups; 25-34 (46.3%), 35-49 (31.8%), 50+ (21.9%); min: 25, median: 36, mean: 40.14, max: 100
- **Gender**, gender (encoded as binary): women (43.5%), men (56.5%)
- **Educational attainment**, self-reported, scaled per country (e.g., for Brazil, médio incompleto, superior completo, especialização), bucketed into three groups: high school equivalent or less (45.5%), some college (23.6%), BA or higher (30.8%)
- **Geographic location**, one of 16 platform-inferred countries grouped into four regions: *Western* (30.8%): France, Italy, U.S., U.K.; *Latin America* (17.4%): Brazil, Mexico; *Africa and Middle East* (22.4%): Egypt, Kenya, Nigeria, Turkey; *Asia* (29.4%): India, Indonesia, Myanmar, Pakistan, Philippines, Vietnam
- **Internet skill**, measured via Web-Use Skills Index [32, 33], a standardized and validated self-report measure (min: 1.5, median: 3.75, mean: 3.66, max: 5).
- **Technical knowledge**, measured via Pew Research's password knowledge question [70] and three additional questions designed in the same style to assess familiarity with downloads, QR codes, and reacting to posts on the platform of study. Questions ask, "Which of the following best describes" and gives 5 answer options. (Password: 54.1% correct[9]; Download: 61.5% correct; QR: 39.6% correct; Reaction: 46.9% correct)

B.2 Regression Results

Table 8 shows regression results for our case study (see Section 6).

[9] Pew Research [70] found that 75% of U.S. survey respondents answered this question correctly; in our dataset 79.2% of U.S. respondents did so.

IoT Market Dynamics: An Analysis of Device Sales, Security and Privacy Signals, and their Interactions

Swaathi Vetrivel[*], Brennen Bouwmeester[†], Michel van Eeten[‡], and Carlos H. Gañán[§]

Delft University of Technology

Abstract

We explore the relationship between the Security and Privacy (S&P) of IoT devices and their sales, considering the S&P signals in the context of these sales. We obtained expert S&P ratings of IoT devices from a European consumer association and the corresponding sales data from a leading Dutch online store. We complemented this with additional information like user ratings, the number of reviews and update support duration from two Dutch online stores. Our regression model shows that, holding other variables constant, a one-standard-deviation increase in S&P ratings corresponds to a noteworthy 56% boost in sales. Crucially, we observe a possible correlation between price and demand for S&P; at lower prices, the sales of IoT devices are directly proportional to the S&P rating, but this relationship diminishes as price increases. Further, we find that the presence of update support duration information, intended as a security signal, corresponds to higher S&P ratings and, all else being constant, also corresponds to a 69% increase in sales. While the exact causal mechanisms for the boost in sales remain unclear, our findings suggest positive incentives might be at play for IoT devices offering S&P at affordable prices and presenting relevant S&P information at the point of purchase.

1 Introduction

A widespread consensus among security researchers states that many consumer Internet-of-Things (IoT) devices exhibit vulnerabilities that compromise user privacy and security. Despite the severe consequences of these vulnerabilities, ranging from individual breaches of privacy [11] to large-scale DDoS attacks [3, 28], there is no dent in the growth of IoT devices. The consumer IoT market is projected to grow steadily at 5% per annum from 2023 to 2028, reaching a market volume of around US$232 billion by 2028 [49].

Observers argue that the sale of insecure IoT devices indicates market failures, namely externalities and information asymmetry [7, 12, 27, 44]. Externalities arise since manufacturers escape the consequences of poor security once the devices are in the market. Similarly, consumers might also undervalue security, since many of the negative effects of their compromised devices end up with third parties, as in the case of DDoS attacks. Despite this lack of incentives, recent studies show that consumers not only care for IoT security and privacy, but they are also willing to pay more for it [15, 19]. However, it is unclear if these preferences for Security and Privacy (S&P) will translate into actual purchase decisions due to the lack of relevant S&P information during purchase. This information asymmetry implies consumers cannot factor S&P in their decisions, which in turn, implies devices with better S&P are not rewarded with higher sales. However, is this conjecture supported by empirical evidence?

In this study, we empirically examine this conjecture by conducting a comprehensive three-fold analysis of consumer purchase decisions on online stores. We analyse the purchase decisions using sales as a proxy, investigate information asymmetry in the context of these decisions, and explore whether presence of information intended to act as a security signal is associated with higher or lower sales.

Specifically, we first examine whether consumer preferences for IoT S&P are reflected in their real life purchase decisions. Using expert ratings of IoT S&P, including expert update ratings, obtained from the main consumer association in the Netherlands and the corresponding monthly IoT sales data from a leading Dutch online retailer, we answer the research question '*To what extent does the expert security and privacy rating of an IoT device correlate with its sales*?' Next, we study the information asymmetry in the context of these purchase decisions by evaluating whether information presented to consumers on online stores contain S&P signals. The information on online stores, like user product ratings, already serves as signals for device quality and vendor reputation [41] and influence purchase decisions [10, 13, 54]. Moreover, some user reviews on online stores also contain

S&P related information [50]. In the absence of relevant S&P information, these signals of quality might act as proxies for S&P. To systematically examine if these signals are consistent with the S&P of an IoT device, we ask '*To what extent are expert ratings of S&P consistent with user ratings?'* We also analyze the presence of update support duration, presented as part of the product information on Dutch online stores due to a government mandate. It was intended to act as a security signal since IoT devices without updates can become unsafe [1]. We compare this to ratings from the consumer association asking '*To what extent are expert ratings of updates consistent with presence of update support information?*' Third, we also examine if the presence of update support duration is associated with a difference in sales through our final research question *'Does the availability of update support information of IoT devices on online stores correspond to higher sales?*'

To answer these research questions, we used three data sets. The Dutch consumer association, through its access to the technical labs commissioned by the European network of consumer associations, gave us access to expert ratings for four IoT device types: IP cameras, smart printers, smart speakers and smart watches. The expert ratings include the S&P rating, the update rating, and the overall device rating, an aggregate rating from various tests. From the leading Dutch online retailer mentioned earlier, we obtained the monthly sales data for the tested devices and the average prices they were sold at per month. The retailer opted to remain unnamed, and we will refer to them as "Winkel". Finally, we complemented the sales data with web scrapes of the product pages at Amazon.nl and at Winkel. We collected the average user rating, number of reviews and product description including update support duration information for the tested devices.

To the best of our knowledge, this is the first study to use ground truth data on sales from a large e-commerce retailer. Although we focus on the Dutch market, prior research shows that IoT device popularity is similar across a variety of countries [29]. Moreover, we want to emphasise that this is an observational study. While we study the relationship between IoT device sales and other factors, we do not claim to establish causality. Rather, we want to test whether the observational data is consistent with our current notions of lack of reward for IoT devices with better S&P.

To answer our first research question, we construct regression models. We find that, after controlling for other factors like price of the device, a one standard deviation or 1.5 unit increase in the expert S&P rating corresponds to a remarkable 56% increase in sales. In contrast, an increase in the expert overall rating corresponds to only a 17% increase in sales. Moreover, we observe that the relationship between sales and expert S&P ratings is moderated by price. Across all IoT device types, at lower prices, higher S&P ratings correspond to higher sales, but this relationship diminishes as the price increases.

For our second research objective of evaluating information asymmetry, we find mixed results. We don't find any evidence of correlation between the expert S&P ratings and the user ratings. With respect to the update support duration information, we find that a mere 4.3% of the product links under consideration contain complete update support duration information on both the online stores, while 27.8% of the links contain complete information on at least one of the stores. However, our findings indicate that the few IoT devices with complete update support information on both Amazon and Winkel exhibit a significantly higher expert rating for updates. This suggests that availability of update support duration information on online stores is reflective of the general update practices of manufacturers and can reduce information asymmetry.

For our third research question on the difference in sales due to presence of update support information, we extend the regression model, built to answer our first research question, with update information status on Amazon.nl and Winkel. We find that, after controlling for the other factors, devices with complete update support information on Winkel correspond to 69% higher sales. This suggests that there are some positive incentives at play for sellers and manufacturers that provide the additional information although the exact mechanism of the incentive is beyond the scope of our research. Our empirical study thus provides a nuanced perspective on IoT device interactions driven by real-world sales data and expert IoT ratings. Theoretically, our findings help understand how barriers to security from economic theory, like information asymmetry and externalities, play out in real markets.

Finally, although tangential to our research goals, our data allows us to capture one additional scientific benefit: we can quantify to what extent public data from online stores can be a proxy for ground truth on sales, since we obtained the latter from Winkel. We find that the number of reviews on Winkel is a reasonable proxy for the sales data from Winkel. In contrast, the number of reviews on Amazon.nl showed low correlations with the Winkel sales data. This suggests that although the proxy is useful, it specific to the retailer.

The paper is structured as follows: In Section 2, we review related research on consumers' IoT purchase decisions and information asymmetry. Section 3 provides details on the datasets used. Section 4 explores the relationship between expert S&P ratings and sales, answering our first research question, while Section 5 and Section 6 address our second and third research question respectively. Section 7 discusses our findings and offers recommendations, and Section 8 concludes the paper.

2 Related Work

In this section, we elaborate on related studies on various aspects of consumer purchase decisions in the market for IoT devices. We also present other work that evaluated the security and privacy of IoT devices using different techniques.

2.1 Consumer purchase decisions and signals for S&P

There has been a fair amount of prior work that studied consumer purchase decisions on online stores. Several studies have found evidence that high user ratings on online stores correlate with higher sales of products [10, 18, 34, 54]. Similarly, several studies have noted that the volume of reviews on the platforms also influence sales [2, 13, 31, 45].

With regard to S&P and purchase decisions, interviews with retail customers highlighted that the point of purchase is an opportune moment for informing consumers about the security of the devices purchased [37]. Other studies delved deeper into this in the IoT context, analysing purchase decisions when adequate information about the S&P of the device is provided. Blythe, Johnson, and Manning [5] find evidence that providing clear security information before purchase can promote secure device selection. Gopavaram et al. [20] found that consumers were willing to pay more for privacy when there were clear indicators of the privacy level. Emami-Naeini et al. [15] empirically confirmed these findings in an incentive compatible user study and showed that consumers are willing to pay more for S&P when relevant information is presented.

There has also been prior work that evaluated different modes of presentation of S&P. Various forms of information labels have been proposed including graded labels, labels denoting S&P features, and labels indicating approval through independent assessment [23]. Emami-Naeini et al. [17] received positive feedback for labels with a similar design to food nutrition labels. Morgner et al. [35] found support for provisioning update support duration information, particularly from those perceiving higher risks from use of IoT devices. Although security labels have not yet found widespread adoption in the market, display of update support duration information has been in effect on Dutch online stores since 2020.

Based on these studies, we consider average user ratings, number of reviews and update support duration information as possible variables that influence purchase decisions. Moreover, to increase the generalizability of our findings, we collect these variables from two popular online stores in the Netherlands – Amazon.nl and Winkel.

2.2 Estimates of IoT device popularity

Earlier studies have estimated the popular devices in the market, which can be taken as an indicator of their sales, in a variety of ways. These studies are typically positioned as device identification in the wild and they use various techniques to identify the brand, make and model of deployed IoT devices. Several of these use network traffic to identify IoT devices [33, 43, 46, 51], however, we do not include them here since these analysis are local to the network from which the measurement was done and cannot be generalized. Other techniques that allow for more generalizability include passive sampling of network scans and active experiments done as ISPs and IXPs [42] and DNS fingerprints [38]. Taking a different approach, Kumar et al. [29] conducted a large-scale empirical study of IoT devices installed in homes of users of Avast antivirus software. They show that barring a few exceptions, the popularity of the four IoT device types that we consider – IP cameras, smart printers, smart speakers and smart watches – are largely similar across geographies.

2.3 Estimates of security of popular IoT devices

Junior et al. [24] estimated the security of popular IoT devices by analyzing the vulnerabilities present in their companion apps. For device selection, they started with the 100 most popular smart hubless devices on Amazon and then filtered it to devices that use WiFi for communication and then further to the categories of smart plugs, bulbs and infrared controllers. They find many devices share a common app and that 50% of apps corresponding to 38% of devices do not use proper encryption techniques. Moreover, there are papers [48, 53] that evaluate the security of popular IoT devices without specifying the metric used to define popularity for the device selection which lends their results incomparable with ours. In our work, we use sales figures for popularity and estimates of device security and privacy from the tests conducted by commissioned labs across Europe.

2.4 Correlation between S&P and sales

To the best of our knowledge, there are no studies that estimate the relationship between IoT device security and privacy, and its sales. However, earlier studies have analyzed the relationship at the level of a firm – between a firm's security and privacy posture and its stock market evaluation. Boroomand et al. [6] found that as a firm's investment in data privacy increases, its market valuation decreases. They attribute this to information asymmetry – firms' are not able to communicate their increased investment in privacy and consumers are not able to reward it despite valuing privacy. A similar study [52] evaluated the effect of investment in Data Privacy and Security (DPS) on the market value of two kinds of firms – those dealing with Business Data Analytics (BDA) and those that do not. They found DPS investment decreases a firms systematic risk and that these effects are higher for non-BDA firms when compared to BDA firms.

3 Dataset Description

In this section, we describe the three datasets from four sources that we used in our study. First, we received expert IoT device ratings from *Consumentenbond* (CB), a consumer welfare organization in the Netherlands. Next, the ground

truth of sales data of IoT devices was generously provided by 'Winkel,' a leading online retailer in the Netherlands. Both of these datasets contain competitive data and are therefore typically confidential, sensitive, and strategically significant, which often restricts their availability for research. However, Consumentenbond and Winkel were exceptionally generous in providing these datasets for our study. Finally, we collected publicly visible attributes on online stores that prior work (Section 2) has identified as influencers in purchase decisions: user rating, number of reviews, and information on update support duration. We collected these from the IoT device product pages of two sources, the websites of Winkel and Amazon.nl, the Amazon store for the Netherlands. Table 1 provides an overview of the sources and the data obtained from each of them. In the following sections we describe these data sets. We use the term user ratings to refer to the average user ratings on Amazon and Winkel, and expert ratings to refer to the CB ratings.

Table 1: Overview of the collected data.

Dataset	Data Source	Data obtained
Expert IoT device ratings	Consumentenbond (CB)	Security and privacy ratings Update ratings Overall device rating
IoT sales data	Winkel	Monthly sales figures Average price per month
Information from product pages	Amazon and Winkel	User rating Number of reviews Update support duration

3.1 Expert IoT device ratings from Consumentenbond

The Consumentenbond is a non-profit consumer welfare organization in the Netherlands.[1] It works on a membership model and currently has about 420,000 members (about 5% of all Dutch households). Through a network of professional technical test labs commissioned by various European consumer associations, they conduct independent tests of various devices and provide valuable advice to consumers to enable informed purchases.

We received all the test results for the four IoT devices types tested by CB - IP Cameras, smart printers, smart speakers, and smart watches. All the tests were conducted between 2016, the start of IoT device testing by CB, and 2023. The testing process remained largely stable over this time period, with most devices being tested soon after their release date. In some cases, often due to the devices gaining popularity after their initial release, there were delays between device release date and the testing date.

The tests conducted and ratings given by CB are exhaustive and span a broad range, however, we only used the three expert ratings that were relevant for our study – the S&P rating, the update specific rating and the overall device rating. The S&P rating is an aggregate of the results of different sub-tests evaluating the password policy, number of vulnerabilities, updates and privacy concerns like data sharing. The heterogeneity in the device types, in terms of attack surface, privacy concerns and device functionality, leads to the necessity of device specific tests. Thus, the S&P sub-tests per device type vary both in number and type. Unfortunately, our confidentiality agreement with CB prevents us from sharing the test specifics and details on how the S&P rating is derived, but for each device type, the areas covered by the sub-tests are added in Appendix A.1. The update rating captures the clarity about update availability, and in the case of smart speakers, also the automatic update options available on the companion mobile apps. Although the update rating is included in the S&P rating, we also analyze it independently, as updates represent one of the most visible aspects of manufacturers' commitment to security from a consumer perspective. The overall rating is an aggregate of the S&P rating, update rating and other ratings like ease of use, and some device specific ratings like sound quality. Figure 1 shows the distribution of all three expert ratings across the different device types, the ratings are between 1 and 10. Although the S&P ratings are skewed towards higher values in some cases, we find enough variation among the ratings for a meaningful analysis of the relationship between S&P and market performance.

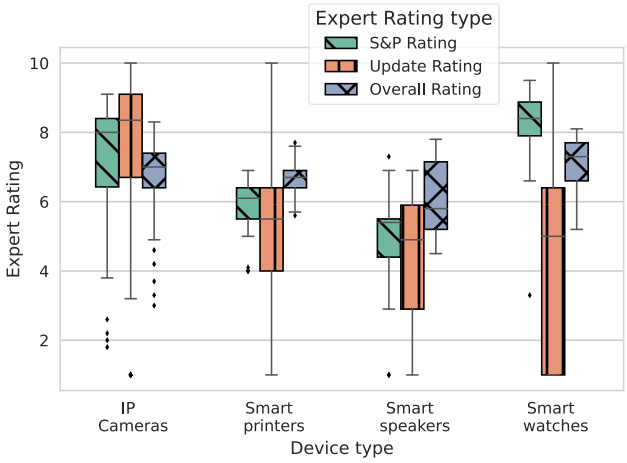

Figure 1: Distribution of expert ratings across the four device types

In total, we had the expert ratings for 469 IoT devices (130 IP cameras, 174 smart printers, 31 smart speakers and 134 smart watches) tested by the Consumentenbond. The average S&P rating across the four device types is 6.9 with the lowest being 1 for a smart speaker and the highest 9.5 for a smart watch. As seen in Figure 1, even within the same device type, there is a wide spread in the S&P ratings. This suggests that

[1] https://www.consumentenbond.nl

despite the potential disincentives for manufacturers to focus on S&P, at least some IoT devices have better S&P than others. We also observe variance across the four device types. The average S&P rating is the lowest for smart speakers (4.8) followed by smart printers (6) and IP cameras (7.3), with smart watches having the highest average S&P rating (8.3). The low average S&P rating for smart speakers is primarily due to the low scores of the companion mobile apps. It is important to note that these ratings are from the device population that was tested by CB and cannot be generalized to the device types.

The average update rating across all devices (5.2) is lower than the S&P rating (6.9). Smart watches have the lowest average rating for updates (4) closely followed by smart speakers (4.4) and smart printers (5), while IP cameras have the highest average of 7 for updates. The lower average update rating across IoT devices aligns with findings from other studies that indicate that update deployment tends to be slower for IoT devices [39]. The overall rating has an average of 6.8 across the device types with the lowest being 3 for an IP camera, and the highest 8.1 for a smart watch. In contrast to S&P rating and update rating, the average overall ratings across the device types do not show much variation.

3.2 Sales data of IoT devices

As mentioned earlier, we got sales data of IoT devices from a leading online retailer in the Netherlands. This was for a period of almost four years, from January 2019 to August 2023, and contained two datasets. The first dataset had the sales figures and average prices of IoT devices that were tested by CB. We used European Article Number (EAN), a unique 13 digit identifier for products, to match the CB test results with the Winkel sales data. The unit for the sales figures is the number of items of each device that were ordered and also reached the customer. Like most online retailers, Winkel also uses dynamic prices that are determined by a range of factors. For the purpose of this study, along with the monthly sales data, we obtained the monthly average prices at which the devices were sold for 385 devices (113 IP cameras, 132 smart printers, 28 smart speakers and 112 smart watches) that were tested by CB. We were not able to obtain the sales data for 18% of the devices tested by CB either due to the devices not being sold on Winkel or because we did not have the EAN code to match the devices with the sales data.

The second dataset had the sales figures and average prices of IoT devices within the same device type category that were not part of CB's testing. Comparing these two allowed us assess the selection bias in the devices tested by CB. To ensure the tests are relevant for a larger customer base, CB uses third party market research data to select and evaluate the more popular devices. When we compare tested vs. non-tested devices, we can indeed see that the tested devices have higher sales. Figure 2 shows the cumulative distribution of sales over the years of devices tested by CB and those not.

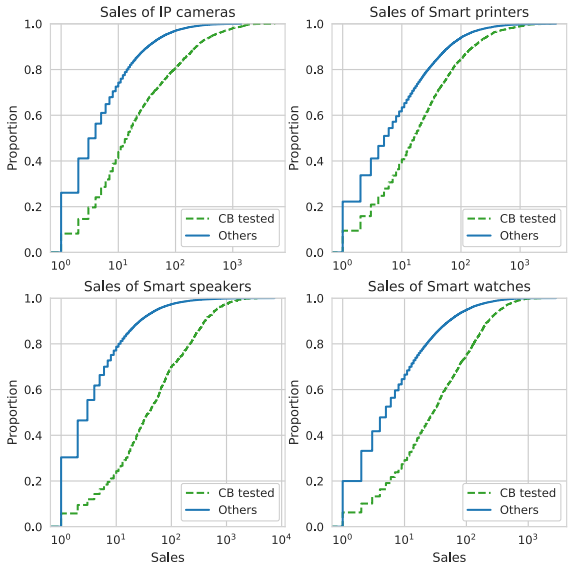

Figure 2: CDF of sales of devices tested by the Consumentenbond and those not

Across all the device types, the average sales per month of devices tested by CB is 91.36 (min: 1, median: 19, max: 5,353) while its 20.7 (min: 1, median: 4, max: 7,394) for others that were not in the CB data set. The comparison also underscores the rationale behind CB's choice to prioritize testing popular devices. As observed, approximately 20% or more of the devices across all the device types that CB has not tested have recorded only a single sale. We also find that the devices tested by CB are marginally more expensive than the other devices, especially for smart speakers and watches. The ECDF of the price comparison is added in the Appendix A.2.

3.2.1 Corroborating Winkel sales data with country level sales

To ensure that the sales data obtained from Winkel is representative of the national trends, we compared it to a commercially available Dutch market study data that is occasionally used by CB for device selection. Although we did not have this data for smart printers and speakers, for IP cameras and smart watches, a Spearman's Rank correlation test revealed a statistically significant and high positive correlation between the two data sets (0.72 and 0.75). This suggests that although there might be slight differences in the sales across specific stores, the sales data from Winkel is reflective of the national trends in sales of IoT devices.

3.3 Information from Product Pages

As noted earlier, we complemented the sales data with information scraped from two popular online stores, including

user ratings, the number of reviews, and the duration of update support. We collected this data by scraping the product pages of the devices under consideration on Amazon.nl and Winkel. The preliminary collection was done between May and June 2023, with some missing details added in July 2023. Out of the 469 devices with expert S&P ratings, there were 14 devices that were not found on either platform. Of the remaining 455 devices, at the time of collection, 335 were found on both, 32 were found only on Amazon[2] and 88 were found only on Winkel.

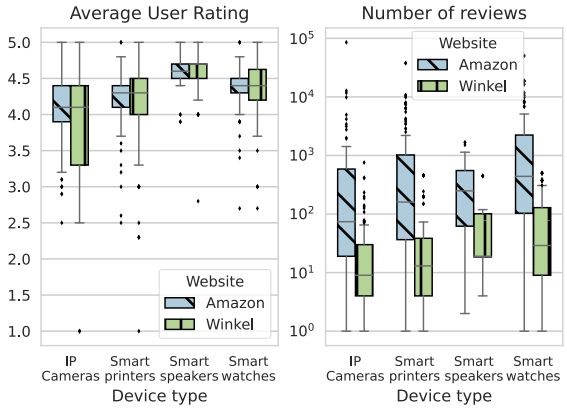

Figure 3: Distribution of user ratings and total reviews on Amazon

3.3.1 User ratings and number of reviews

In total, we scraped the details of 367 devices from Amazon, across 455 product links (122 IP cameras, 170 smart printers, 39 smart speakers, and 124 smart watches). On Winkel, we scraped details of 423 devices across 505 product links (140 IP cameras, 185 smart printers, 45 smart speakers, and 135 smart watches). On both Amazon and Winkel, the number of product links is higher than the number of devices because, for some devices, we found multiple product links due to variations in colours, sellers, or device bundles. In all such cases, we collected information from all the product links and treated them as separate instances rather than aggregating them per device to allow for a detailed analysis of update support information.

Figure 3 shows the distribution of user ratings and number of reviews on both the platforms. We find that the mean of user ratings are comparable across both the websites, 4.26 on Amazon and 4.17 on Winkel. However, the differences in number of reviews is staggering. The average number of reviews on Amazon is 1792, while it is 64.85 on Winkel, a mere 3.6% of the average number of reviews on Amazon. This is likely due to Amazon's policy of aggregating reviews across all of its websites rather than a difference in popularity between Amazon.nl and Winkel. For instance, Amazon.nl also has reviews from Amazon.com, the US Amazon store and Amazon.de, the German Amazon store.

[2]Unless otherwise specified, all references to Amazon are limited to Amazon.nl

3.3.2 Update support information

As mentioned in the Introduction, after a government intervention, sellers agreed to provide consumers with information about the availability of updates for smart devices at the time of purchase [1]. Note that there is a distinction here between seller and manufacturer. The seller acts as an intermediary between the manufacturer and consumer, listing the products on the e-commerce store and managing the sales. As per the intervention, manufacturers must provide the information to the sellers, who, in turn, update it on the online store to inform consumers. This was agreed upon in 2020. We started our data collection in May 2023, approximately three years after this policy came into effect allowing us to also analyse the presence of update support duration information as a security signal.

Our study reveals differences in how the update support duration information is displayed on each website. On Amazon, the update information is presented as a date (e.g., '13 April 2030'), and the update support field is part of the product's technical specifications. On Winkel, the update availability is specified using three fields under 'Introduction and support' within the product specifications table. These three fields are *Introduction year, Introduction month,* and *Support with updates.* The update support is specified in terms of the number of months from introduction (e.g., 'At least 24 months after the date of introduction'). While this clarifies the manufacturer's commitment to update support, some products have incomplete information as not all three fields are filled out.

Of the 455 products on Amazon, only 54 have a valid date; for the majority, the field is either empty or says 'Unavailable.' We categorise both empty and unavailable update information as invalid. Moreover, for six of the 54 products, the date is in the past (e.g., '30 June 2022'), and for one, it says ('1 January 2099'). However, we conservatively count these as valid since it is beyond this research's scope to verify if the updates for these devices continued past 2022 or will continue till 2099. Of the 505 products on Winkel, 231 had no information on updates whatsoever, 113 had valid information with all three fields complete, and 161 had partly valid information. That is, there was information about the duration of update support, but the Introduction year or month fields were empty or vice versa. We tag these as 'partly valid.'

Figure 4 shows the distribution of update statuses across the device types. On Amazon, we find that none of the smart printers have any valid information about updates; among the other device types, there is little variation – they all contain similarly minuscule percentages of valid information. Similarly, on Winkel, smart printers have the highest percentage

of invalid information (78%). However, around 46.6% of IP cameras and 37.5% of smart speakers have valid information, while 71.5% of smart watches contain partly valid information – they provide information on the updates but fail to mention additional information on introduction year and month.

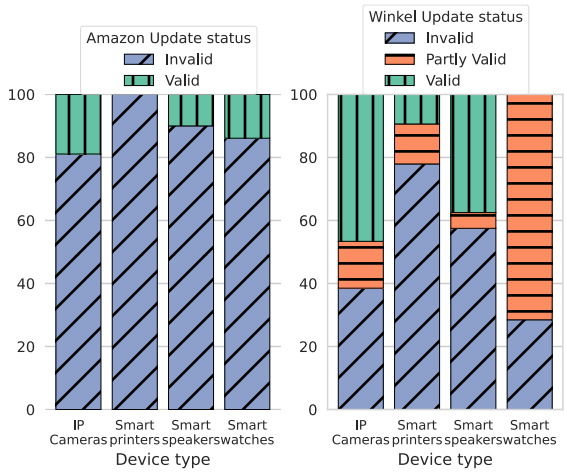

Figure 4: Distribution of Amazon and Winkel update statuses across device types

3.3.3 Comparison of Update support information on Amazon and Winkel

We find that for the 335 devices across 417 product links available on both websites, there is substantial divergence in the update statuses. Table 2 provides a comparison of the update field information. Only 18 devices, a meagre 4.3% of devices that are available on both platforms, provide valid update information on both websites, while an additional 27.8% provide valid information on one website but not on the other (7.9% have valid information on Amazon but not on Winkel and 19.9% on Winkel but not on Amazon). This suggests that the provisioning of update information is dependent on seller practices rather than the device-specific update support information provided by the manufacturer. Further, for none of the 18 devices with valid update statuses on both websites does the update support duration match. On Amazon, 14 of the 18 devices mention update support until 'April 2030,' whereas on Winkel, most devices mention update support for 24 months after introduction, with varying introduction years and months. This further highlights the role of sellers in provisioning this information and the difficulty in ensuring accuracy of such information.

4 Relationship between S&P and Sales

In this section, we analyse the datasets described so far to answer our first research question on the relationship between

Table 2: Comparison of update status between Amazon and Winkel for devices found on both

Amazon update status	Winkel update status	Count
Invalid	Invalid	163 (39.1%)
Invalid	Partly Valid	120 (28.8%)
Invalid	Valid	83 (19.9%)
Valid	Invalid	11 (2.6%)
Valid	Partly Valid	22 (5.3%)
Valid	Valid	18 (4.3%)

security and privacy of an IoT device and consumer purchase decisions with sales as a proxy. To achieve a holistic understanding of the interplay among various factors, we also consider the variables previously identified in the literature as influencers on sales, rather than restricting ourselves solely to S&P. Moreover, in order to comprehensively assess the interplay and associations of the different variables with the sales, we used a Generalised Linear Regression (GLM) model modelled using the glmmTMB package in R [8]. Since our dependent variable, the sales of IoT devices, is a count data, we had two options for the GLM – Negative Binomial and Poisson Models. The sales data exhibited over dispersion, meaning the variance was larger than the mean. Therefore, we used the Negative Binomial model since it accommodates excess variability. Moreover, to generalise interactions among variables across different device types, we employed a Mixed Effects model. This approach treats device type as a random effect and considers other variables as fixed effects, allowing us to derive broad-level inferences independent of device-specific variations in the test protocols.

4.1 Explanatory Variable Selection

Our explanatory variables of interest are price, the expert S&P, update and overall ratings from CB, user rating and number of reviews on Amazon and Winkel. Prior to running the model, we conducted multicollinearity tests to remove explanatory variables that are highly correlated with each other. This ensures stability and reliability of our parameter estimates by mitigating issues that arise from high correlations among explanatory variables. We used Generalised Variance Inflation Factor (GVIF) to check for multicollinearity. Following suggested guidelines, we excluded the expert update rating from our analysis due to its GVIF value exceeding 5 [36]. This left us with eight remaining variables, Device type, price, expert S&P rating, and Overall rating from CB, user rating and number of reviews from Amazon and Winkel. The GVIF of the variables included in the model is added in Appendix A.3.

Moreover, we conducted bi-variate correlation tests between the dependent variable and the explanatory variables to get a sense of how each explanatory variable relates to the dependent variable, and validate its inclusion in the model. To control for multiple comparisons, we adjusted our p-values

using the False Detection Rate (FDR) approach, implemented through the Benjamini & Hochberg method in the stats package in R [40]. There were no changes in the significance levels of the correlation tests after the adjustment. We explore these correlations briefly before analysing the results of the model.

4.1.1 Correlation between sales and price

We first analyse the correlation between the price and sales to better understand the price sensitivity of IoT devices. Since neither data followed a normal distribution, we used Spearman's rank correlation test. The results, as shown in Table 3, reveal a statistically significant weak negative correlation between price and sales for IP cameras and smart printers and a moderate positive correlation for smart speakers. This suggests that consumers possibly perceive IP cameras and smart printers as utilitarian, where price and affordability plays a decisive role in their purchase decisions. This observation may also be influenced by the competitive dynamics in these markets, where companies often compete on price. In contrast, for smart speakers which often come with advanced features and innovations, consumers might be more willing to pay a premium for additional features. Moreover, smart speakers are often part of a larger ecosystem and consumers invested in these ecosystems might be willing to pay more for compatibility.

Table 3: Correlation between sales and price from Winkel

Device type	Spearman correlation
	Total sales vs. average price
IP Cameras	-0.251^{**}
Smart printers	-0.339^{***}
Smart speakers	0.517^{***}
Smart watches	0.071
Aggregate	0.006

*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

4.1.2 Correlation between sales and expert ratings from CB

Next, to understand if and to what extent S&P features and the overall device quality as indicated by the CB expert ratings correspond with the sales of a device, we performed pair-wise correlations between each of them (Table 4). We found no significant correlations between the expert S&P rating of a device and the sales. This implies that a direct linear relationship between a device's S&P posture and its sales is not readily evident. We find statistically significant correlations between sales and expert overall rating across all devices and also at the aggregate level. Due to the significant correlations between the expert overall ratings and sales, we include it in the model. Moreover, despite the lack of correlation, we also include the expert S&P rating to gain a deeper understanding of the underlying relationship between S&P and sales which might be more complex than a linear association.

Table 4: Correlation between sales and CB ratings

Device type	Spearman correlation	
	Total sales vs	
	Expert S&P rating	Expert Overall rating
IP Cameras	0.088	0.216^{**}
Smart printers	-0.035	-0.286^{***}
Smart speakers	0.100	0.358^{**}
Smart watches	0.037	0.333^{***}
Aggregate	0.052	0.195^{***}

*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

4.1.3 Correlation between price and expert ratings from CB

Next, we explore the relationship between the average price and the expert CB ratings. As seen in Table 5, the price of IP cameras and smart watches exhibit a modest positive correlation with the expert S&P rating. In contrast, for smart speakers, we find a moderate negative correlation between the price and S&P rating. However, smart speakers are a unique case. Within the 27 smart speakers in our sample, four smart speakers with the highest sales collectively account for approximately 56% of all smart speaker sales. These four devices have prices higher than average and expert S&P ratings lower than average. This indicates that the negative correlation is possibly influenced by the disproportionate presence of these devices, and cannot be generalised.

With respect to expert overall rating, we find moderate positive correlations between the sales and average price at the aggregate device level and also at the individual device level for all devices except IP cameras. The lack of correlation for IP cameras might be due to various factors like a more mature market, diverse manufacturers, differentiated market segments based on price and features, or other market factors. Nonetheless, the high degree of associations between the average price and expert CB ratings for the other device types suggests that these two variables exhibit interaction, which could, in turn, influence sales. To accommodate this interaction, we incorporate an interaction term between price and expert CB ratings in the model.

4.1.4 Correlation between sales and user rating and number of reviews on Amazon and Winkel

We find many significant positive correlations between sales and both user ratings and number of reviews from Amazon and Winkel (Table 6), validating their inclusion in the model.

Table 5: Correlation between average device price and expert CB ratings

Device type	Spearman correlation	
	Average price vs	
	Expert S&P rating	Expert Overall rating
IP Cameras	0.259**	0.160
Smart printers	0.112	0.633***
Smart speakers	−0.486***	0.756***
Smart watches	0.429***	0.559***
Aggregate	0.092	0.44***

*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

Moreover, this analysis allows us to determine to what extent publicly available information like number of reviews can serve as a proxy for sales. We find that the sales of IoT devices show a statistically significant positive correlation with the number of reviews on both Amazon and Winkel. This is true at both the aggregate level, across all the device types, and also at the individual device level. The only exception is the correlation between the sales of IP cameras and the number of reviews on Amazon.

Furthermore, we find that the correlation between the sales and the number of reviews on Winkel (0.8) is much higher than on Amazon (0.259). This implies that the number of reviews on a platform can act as a reliable indicator for sales on that platform. Since Amazon aggregates its review count across all of its stores, the number of reviews on Amazon may not be a reliable proxy for sales.

Table 6: Correlation between total device sales and consumer metrics from Amazon and Winkel

Device type	Spearman correlation			
	Total sales vs			
	Amazon user rating	Winkel user rating	Amazon total reviews	Winkel total reviews
IP Cameras	0.529***	0.439***	0.094	0.762***
Smart printers	0.189	−0.001	0.278***	0.777***
Smart speakers	0.488**	0.397**	0.376**	0.651***
Smart watches	0.213**	−0.191*	0.338***	0.767***
Aggregate	0.415***	0.193***	0.259***	0.802***

*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

In contrast, with respect to the user rating, the reverse is true. The correlation between the sales and user rating on Amazon (0.415) is higher than the correlation with the user rating on Winkel (0.193). This suggests that even on the same platform, user rating is a poor indicator of popularity. However, since, similar to the number of reviews, the user ratings on Amazon are aggregated from different stores like Amazon.de, Amazon.com, etc., the Amazon ratings seem to be a marginally more reliable indicator of popularity. It is worth noting that the devices in our data set have a selection bias of being popular in the Netherlands and Europe, and within this set of devices Amazon user rating shows a moderate correlation with sales. Without further research, we cannot conclude if the finding will hold true in other geographies or for other devices.

4.2 Model Evaluation

Next, we outline the steps involved in Modelling. As mentioned earlier, we use a Mixed Effects Negative Binomial Model, treating the explanatory variables as fixed effects and the device type as a random effect. This helps us understand the overall trends that affect all devices while also capturing device type specific variations. To validate our decision to include the device type as a random effect, we compared the fit of two models using likelihood ratio test [30]. The first model contained device type as a fixed effect, and the second as a random effect. The p-value from the likelihood ratio test was significant ($p < 0.001$), indicating that the model with device type as a random effect was a better fit.

Moreover, as a preprocessing step, we scaled and centered the variables to ensure uniform influence and improve model convergence and interpretability. Scaling adjusts variables to have similar scales, preventing larger values from dominating. Centering sets variable means to zero, easing interpretation and providing a meaningful intercept.

We added the eight variables identified in the previous section in a step-wise forward manner. We explored different ways of ordering the fixed effect variables during the step-wise forward training but found that the ordering does not make any difference to the results. We therefore picked an intuitive ordering for ease of presentation. In the model presented, we start with the intercept only model, then add the device type, the average price, the expert S&P rating and the expert overall device rating, followed by user ratings and number of reviews on Winkel and Amazon. Further, as mentioned earlier, we added interaction terms between price, expert S&P rating and expert overall rating of CB. This enabled us to evaluate how the relationship between these variables and sales varies with changes in the other variables. This resulted in eight distinct models, which are shown in Table 13 in Appendix A.6.

To evaluate which model is best suited for our data, we checked the goodness of fit using Akaike Information Criterion (AIC), Bayesian Information Criterion (BIC) and Log-likelihood, following best practices from literature [9, 14, 22, 26]. AIC balances fit and complexity, guarding against over fitting, while BIC penalises complexity, promoting simpler models. Lower AIC and BIC values signify better model fit [9, 14, 26]. Log-likelihood quantifies how well a statistical model explains observed data, with higher values indicating better fit [22]. Moreover, in a mixed effects model, two R^2 types are used to assess the model: Conditional R^2, which gauges the explanatory power of the fixed effects and Marginal R^2, which measures the combined explanatory

power of both fixed and random effects. Higher values for both indicate improved model fit.

Based on these criterion, amongst the models in Table 13 (Appendix A.6), we identified Model 8 to be the best fit for our data. It has a lower AIC, BIC and higher log likelihood. Moreover, although the conditional R^2 is slightly lower than the previous model, it has the highest marginal R^2 amongst all the models. This indicates that the entire model, including the fixed and random effects, best explains the variation in our dependent variable, the total sales.

4.3 Model Interpretation

The Incidence Rate Ratios (IRR) of each of the explanatory variables in our model is shown in Figure 5. The IRR quantifies the multiplicative change in the rate of occurrence of an outcome (in our case, the sales) when the explanatory variable changes by one standard deviation, after controlling for the other variables. An IRR of 1 suggests no change, while greater and lesser than one denotes an increase and decrease in sales respectively. The interaction terms added between price, expert S&P rating and expert overall rating allows us to see the combined effect of these variables on the sales. Table 7 shows the mean and standard deviation of all the explanatory variables in the model.

Table 7: Mean and Standard Deviation of Explanatory Variables

Explanatory Variable	Mean	Standard Deviation
Avg Price	€179.10	€112.70
Expert S&P Rating	7.05	1.48
Expert Overall Rating	6.94	0.65
Winkel User Rating	4.18	0.64
Amazon User Rating	4.27	0.38
Winkel Total Reviews	67.21	120.11
Amazon Total Reviews	1966.33	6665.94

To address our first research question regarding the relationship between expert S&P ratings and consumer purchase decisions of IoT devices, we found that, when holding other variables constant at their mean values, an increase in the expert S&P rating by one standard deviation accounts for a 56% increase in sales (IRR of 1.56). In contrast, an increase in the expert overall rating by one standard deviation corresponds to only a 17% increase in sales (IRR of 1.17). Additionally, a one standard deviation increase in price corresponds to a 27% decrease in sales (IRR 0.73). Moreover, the significant interaction term between price and expert S&P rating indicates that the interaction between them dampens the effect of either variable on sales by 20% (IRR 0.8). On the other hand, the interaction between expert overall rating and S&P rating, corresponds to an increase in sales by 18% (IRR 1.18).

Figure 6, generated using the sjPlot package [32] in R, shows the interaction between price, expert overall rating and S&P rating. We observe that an increase in expert S&P rating corresponds to marginally higher sales for higher values of overall rating (the rightmost plot of Figure 6). Moreover, across all three plots, we observe that effect of S&P rating on sales is higher for lower values of price, and this effect gradually diminishes as the price increases. After a certain price point, changes in the S&P rating have little impact on sales.

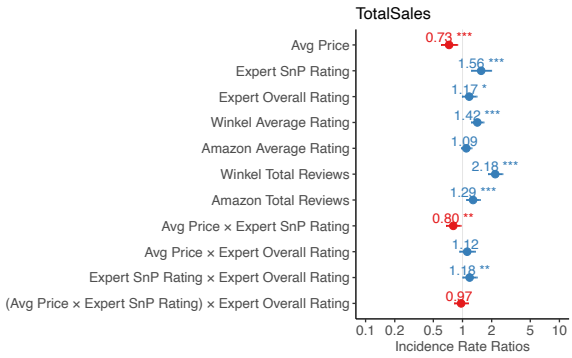

Figure 5: IRR from the Mixed effect Negative Binomial Model (*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$)

This finding highlights the crucial relationship between price and S&P of a device. From our bi-variate correlation analysis (Table 5) we observe a positive correlation between the price and expert S&P rating for IP cameras and smart watches. The model results reveals the context of these positive correlations and suggests that an increase in S&P rating, while possibly corresponding to a marginally higher price, also corresponds to higher sales. Moreover, as observed via the interaction effects, the amplifying effect of S&P on sales is higher for lower prices, and gradually decreases as price increases. A crucial takeaway from this is that at the same price level, IoT devices with better S&P perform better in the market in terms of sales. In the next section, we evaluate whether this better performance can be attributed to the presence of S&P signals.

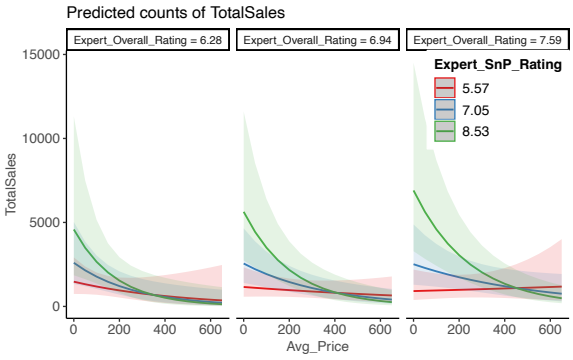

Figure 6: Interaction effects of Price, expert S&P rating and expert Overall rating on Total sales

With regard to the other explanatory variables, we see that the highest IRR (2.18) is for total reviews on Winkel. An increase in the number of reviews on Winkel by one standard deviation corresponds to a 118% increase in sales. In contrast, an increase in the number of reviews on Amazon by one standard deviation corresponds to only a 29% increase. This aligns with the results from our bi-variate correlation analysis: the number of reviews on Winkel is better proxy for the Winkel sales data than the number of reviews on Amazon.

With respect to user ratings, we observe no significant effect of the Amazon user rating on total sales, but the IRR for the Winkel user rating is 1.42. This indicates that while a change in the user rating on Amazon does not correspond to any change in the sales, an increase in the Winkel user rating by one standard deviation corresponds to a 42% increase in sales. This contradicts with our bivariate correlation analysis (Table 6), which shows positive correlation for both Amazon and Winkel user ratings, suggesting that the linear relationship between Amazon user rating and sales is possibly influenced by other confounding variables. Moreover, the increase in user rating on Winkel corresponding to an increase in sales underscores the role of consumer metrics in influencing the purchase decisions of consumers. In an online store, such mechanisms play a crucial role in signalling device quality and stimulating trust [41]. With respect to the random effect of the device type, we observe a variance of 0.234. This suggests that only a minimal amount of additional variability in sales can be explained by the IoT device type.

5 Relationship between expert ratings and information from product pages

In this section, we address our second research question assessing whether user ratings and update support duration information align with expert ratings. This allows us to evaluate the presence of S&P signals and the extent of information asymmetry in the context of the purchase decisions we analysed in Section 4.

5.1 Relationship between expert S&P ratings and average user rating

We first analyse the correlation between the expert S&P rating – which also includes the expert update rating – and the user ratings on Amazon and Winkel. Table 8 provides an overview of the Spearman correlations between the expert ratings and the Amazon and Winkel user ratings. Since our primary aim is to analyse if these ratings act as signals for S&P, we do not analyse the relationship with the expert overall rating. However for the interested reader, we present the correlation between user rating and overall ratings in the Appendix A.4.

At the aggregate level, across all the device types, we observe a low negative correlation between the expert update rating and the user rating on both Amazon and Winkel. Moreover, at the individual device level, although the expert update rating for smart speakers shows a low positive correlation with both the user ratings, the update ratings of both IP cameras and smart printers show a negative correlation with the Winkel user rating. The negative correlations could be a reflection of consumers' negative experiences with the update process [21] or a consequence of consumers not being able to account for good update practices into the user rating due to lack of visibility or information. Although invisibility is considered a desirable feature in security design [4], it can also lead to consumers not being able to account for security in their rating of the device.

Table 8: Correlation between CB S&P and update ratings and user ratings on Amazon and Winkel

Device type	Spearman correlation			
	Expert update rating vs		Expert S&P rating vs	
	Amazon user rating	Winkel user rating	Amazon user rating	Winkel user rating
IP Cameras	−0.007	−0.215**	0.012	−0.104
Smart printers	−0.134	−0.376***	0.141	0.416***
Smart speakers	0.380**	0.324*	−0.118	−0.323*
Smart watches	−0.005	0.098	0.204**	0.008
Aggregate	−0.152***	−0.23***	−0.011	−0.077

*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

Regarding the expert S&P rating, we find that, at the aggregate level, across all device types, there are no significant correlations between the expert S&P rating and the user ratings on both Amazon and Winkel. At the individual device level, we observe a modest positive correlation between the expert S&P rating for smart watches and smart printers and the user ratings on Amazon and Winkel respectively. In contrast, the S&P rating of smart speakers shows a moderate negative correlation with the Winkel user rating. The negative correlation, taken together with the couple of low positive correlations shows that user rating cannot serve as a reliable indicator of the S&P posture of an IoT device. Rather, the user ratings likely reflect the overall consumer experience rather than an evaluation of the S&P posture of the device. Moreover, the differences in the correlations between the expert ratings and the user ratings across the device types is inline with earlier work that found that percentage of references to S&P varied across reviews for different IoT device types [50].

5.2 Relationship between update ratings and update support information

Next, we turn to analyzing the provisioning of the update support information and the expert update ratings of CB, to better understand if the update statuses are reflective of general update practices of manufacturers. If they are, they can serve

as signals for S&P and help consumers make more informed purchase decisions with respect to IoT S&P. Table 9 shows the mean values of expert update rating for the different update information statuses on Amazon and Winkel. We observe that on both Amazon and Winkel, devices with valid update support information have a higher update rating. To check if the differences between the two groups on Amazon (Invalid and Valid), and the three groups on Winkel (Invalid, Partly valid and Valid) are significant, we use two different tests. For Amazon, we use the Mann-Whitney U test and for Winkel, we use Kruskal-Wallis test with an additional post-hoc Dunn's test if the results are significant.

Table 9: Mean values of update rating for different values of update status on Amazon and Winkel

Update Status	CB Update rating
Amazon	
Invalid (397)	5.2
Valid (48)	5.9
Winkel	
Invalid (191)	5.1
Partly valid (151)	4.7
Valid (103)	6.4

Our results shows that the differences on both Amazon and Winkel, among the different groups are significant. The statistically significant higher expert update ratings for devices with valid update support duration information imply that the mere availability of update support duration information reflects manufacturers' practices regarding updates. This might then serve as a signal for security, reducing the information asymmetry for IoT devices. Note that the this signal is only available for a minor percentage of devices under consideration: only 22.4% of devices on Winkel and 11.8% of devices on Amazon had valid information. Moreover, for the 18 devices for which the information was available on both websites, the update support duration was not consistent. Nonetheless, we verify if there is a correlation between the presence of valid update support information and higher device sales in the next section.

6 Relationship between Update Information Status and sales

In this section, we address our third research question on the relationship between provisioning update support information and sales. To do so, we extend the model and add categorical variables for update information status for Amazon and Winkel, in addition to the other explanatory variables. The results are shown in Table 12 in Appendix A.6. As mentioned earlier, on Amazon, the update status has two values, Invalid and Valid while on Winkel it has three values Invalid, Partly Valid and Valid. Table 10 shows the IRR for the update statuses. We find that, after controlling for the other factors in our model, the status of invalid on Amazon corresponds to a 34% decrease in sales (IRR 0.66) while a valid update status on Winkel corresponds to a 69% increase in sales. This implies that the presence of update support duration information, which serves as a reasonable signal for the S&P of an IoT device (from section 5), also corresponds to a positive change in sales. Although the underlying causal mechanisms are unclear, this suggests that there are positive incentives at play that will reward sellers and manufacturers who adopt initiatives like IoT security labels [16, 23, 47]. Moreover, our results align with other research [35] indicating that the availability of update support duration information has an impact of 8% to 35% on consumers' purchase decisions.

Table 10: IRR for Update Statuses on Amazon and Winkel

Update Status	IRR
Amazon Invalid (397)	0.66**
Amazon Valid (48)	0.87
Winkel Invalid (191)	0.79
Winkel Partly valid (151)	1.1
Winkel Valid (103)	1.69*

*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

7 Discussion and Recommendations

Before we discuss our results and offer recommendations, we want to emphasise that this is an observational study. We have analysed the relationships between the variables but this is insufficient to establish causality. We found that despite the lack of S&P signals for a majority of devices, there is an alignment between consumer preferences for S&P – as established in prior work [15, 20] – and their purchase decisions, although the underlying causal mechanisms are unclear. We also find that the relationship is moderated by the price of the device. At lower prices, devices with higher S&P ratings correspond to higher sales while this relationship diminishes as the price increases.

Previous studies on security labels [15, 20] have found that consumers are willing to pay more for S&P when provided with information about it. Our results corroborate these findings and additionally suggest that, in the absence of security labels, the willingness to pay more for S&P exists up to a certain price point, beyond which the demand for S&P decreases. This dual emphasis on both security and price highlights the nuanced nature of consumer preferences in the IoT market.

This also underscores the challenge for manufacturers to balance better S&P at affordable prices. As we observe in our study, at the aggregate level, across all device types, and also for IP cameras and smart watches, the expert S&P rating positively correlates with price, suggesting that increase in S&P corresponds to an increase in price. This highlights a dilemma for manufacturers. They can focus on S&P at the

risk of increasing the price and losing out on sales, or they can offer devices at comparable price points and enjoy higher sales. Note that the model results show that a one standard deviation increase in price (112.7 EUR or 121.35 USD), is associated with a 27% decrease in sales. While it is beyond the scope of this study to determine what types of security controls are feasible to implement within 112.7 EUR, a crucial takeaway is that at the same price points, IoT devices with one standard deviation or 1.5 unit increase in S&P correspond to a 56% increase in sales. This suggests that manufacturers who manage the balancing act between S&P and price stand to gain significant benefits.

With regard to the user ratings, we find limited correlation between the user ratings and expert S&P ratings suggesting that only a minority of the reviews and associated ratings might express S&P concerns that align with expert evaluations. This indicates that most consumers may either lack the ability to discern the S&P features of a device or may not consider them significant factors in their evaluations and ratings. Alternatively, even when factored into ratings, their S&P concerns might not align with expert evaluations, possibly due to friction with S&P configurations like 2FA [15, 50].

This emphasises an important aspect that needs to be balanced with S&P – usability. As the results of our correlation with expert update ratings highlight, better update ratings correspond to lower user ratings (Table 8). This could be a consequence of consumers not being able to account for good update practices into the user rating due to lack of information. It could also be a reflection of consumers' negative experiences and friction with the update process [21]. This emphasises the importance of designing S&P features with a focus on user experience and aiming to decrease such friction.

Moreover, increased transparency about the S&P features of an IoT device that informs users about the steps needed for the added S&P will enable better management of consumer expectations. As the results from our third research question show, on Winkel, devices for which complete update support information was available correspond to a 69% increase in sales. Although it requires further research to understand the underlying causal mechanisms for the boost in sales, our results, in line with other user studies [35], suggest that there might be positive incentives at play for IoT devices that contain S&P information at the purchase point. Crucially, availability of S&P information at purchase might increase the price point till which consumers are willing to pay more for better S&P. Thus, initiatives like security labels will yield benefits not only for the consumer, in terms of more informed purchase decisions, but may also for reward manufacturers and sellers with higher sales.

To that end, as our study results show, sellers play a key role in publishing relevant information on online stores. Three years after the mandate on provisioning update support duration information, we find that only 4.8% of devices analysed contain valid, albeit different update support duration on both stores. This implies that any effort aimed at improving manufacturer compliance, for security labels and the like, should also consider the various sellers who operate as intermediaries between manufacturers and consumers on e-commerce platforms. Although the onus is on the manufacturers to provide the information to the sellers and on the online store to enable provisioning of the information on the product pages, the task of updating the relevant information in the product pages still falls to the sellers. In the ongoing discussions on stakeholders in the realm of S&P IoT devices, these intermediaries are often overlooked. This oversight causes us to miss their perspective, which is important for the successful implementation of security labels. Unlike traditional brick-and-mortar stores, where these labels can be physically displayed on products with minimal intervention from store owners, online stores rely on sellers to present information as they deem appropriate. As we see with the case of update information, even if the online store has the provision to display this information, it often remains empty or has incomplete information. Therefore, it is vital to emphasise the necessity of transparency regarding the S&P features of a device, not only to the manufacturers, but also to the sellers.

7.1 Limitations

The expert ratings used in our study come from the tests conducted by the network of European technical test labs commissioned by various consumer associations in Europe. Although other tests using different constructs of S&P might arrive at different ratings, we believe these trusted ratings serve as a good indicator of the overall S&P posture of the device. A limitation of the testing of consumer associations is that they maximize for consumer benefit and therefore focus on devices that are popular in the market. While this introduced some selection bias in our data, the observed S&P ratings were diverse enough to meaningfully answer our research question.

Further, although our sales data is from a single e-commerce store in the Netherlands, we find that it is well aligned with the national market study data (refer subsection 3.2.1). Moreover, while any study based on a single country raises questions on generalizability, prior work estimating the popularity of IoT devices across geographies found that across all regions, 100 vendors account for nearly 90% of all IoT devices [29]. This suggests that while there might be minor differences in device popularity across regions, there is an over arching uniformity in vendor distribution which makes the implications from our findings applicable to e-commerce stores across geographies. Moreover, although including user reviews would have led to a richer analysis, we excluded them since prior work found that only 9.8% of user reviews of IoT devices contain references to S&P [50].

As we observe in our study, there is variations in the results among these four device types, which might limit their relevance to other IoT device types. We account for these

variations in the model by treating the device types as random effects while studying the fixed effects of the other factors. Moreover, although the factors we included were based on prior literature, we acknowledge that there might be other confounding variables that influence consumer purchase decisions which we have not considered. Future work can evaluate the influence of other factors and deepen our understanding of the underlying causal mechanisms at play.

7.2 Research Ethics

We got approval for the study from the Ethics Review Board in our institution. We assessed our methodology against the ethical guidelines outlined in the Menlo Report for ethical practices in computing studies [25]. We only scraped publicly available information from Amazon and Winkel, and did not collect the associated usernames. Moreover, to ease the load on the servers, rather than use web crawlers, we fed specific pages to the scraping scripts. We also added delays and distributed the scraping over a longer duration to minimise server strain.

8 Conclusion

In this work, we analysed consumer purchase decisions and signals for S&P in the market context within which these decisions are taken. Our results showed that despite lack of information about S&P for a majority of the devices, a one standard deviation increase in the S&P rating of a device is associated with a 56% increase in sales. However, the relationship is moderated by the price of the device. The effect is stronger at lower prices and decreases corresponding to an increase in price. In addition, we find that availability of complete update support information on online stores reflects the update practices of manufacturers and can therefore act as a signal for S&P. Further, we also find that on one of the online stores, devices with complete update support information correspond to a 69% increase in sales. This suggests that there are positive incentives at play that will reward manufacturers and sellers who adopt S&P transparency initiatives like security labels with higher sales. Our results also highlight the crucial role of sellers in ensuring the success of such initiatives since they are responsible to update the relevant information on online stores.

Acknowledgments

This publication is part of the RAPID project (Grant No. CS.007), financed by the Dutch Research Council (NWO), and has also been partially supported by the INTERSCT project (Grant No. NWA.1160.18.301), also funded by NWO. The authors would like to thank the Consumentenbond and Winkel for generously providing the datasets for the analysis.

The Unpatchables: Why Municipalities Persist in Running Vulnerable Hosts

Aksel Ethembabaoglu, Rolf van Wegberg, Yury Zhauniarovich, and Michel van Eeten

Delft University of Technology

Abstract

Many organizations continue to expose vulnerable systems for which patches exist, opening themselves up for cyberattacks. Local governments are found to be especially affected by this problem. Why are these systems not patched? Prior work relied on vulnerability scanning to observe unpatched systems, notification studies on remediating them, and on user studies of sysadmins to describe self-reported patching behavior, but they are rarely used together as we do in this study. We analyze scan data following standard industry practices and detect unpatched hosts across the set of 322 Dutch municipalities. Our first question is: Are these detections false positives? We engage with 29 security professionals working for 54 municipalities to collect ground truth.

All detections were accurate. Our approach also uncovers a major misalignment between systems that the responsible CERT attributes to the municipalities and the systems the practitioners at municipalities believe they are responsible for. We then interviewed the professionals as to why these vulnerable systems were still exposed. We identify four explanations for non-patching: *unaware*, *unable*, *retired* and *shut down*. The institutional framework to mitigate cyber threats assumes that vulnerable systems are first correctly identified, then correctly attributed and notified, and finally correctly mitigated. Our findings illustrate that the first assumption is correct, the second one is not and the third one is more complicated in practice. We end with reflections on how to better remediate vulnerable hosts.

1 Introduction

Exploiting known vulnerabilities for which a patch exists remains a dominant attack vector, even after years of warnings [11]. Local governments are seen as especially susceptible [26, 37]. The U.S. Cybersecurity and Infrastructure Security Agency (CISA) referred to them as the "cyber poor", offering vulnerability scanning services as support [31]. These concerns are not exclusive to the U.S. In the Netherlands, the Dutch Safety Board investigated the incidents following the 2020 Citrix vulnerabilities and concluded that municipalities struggle with patching because of a lack of resources [17].

The threat of exploitation of local governments, or any other organization, is not hypothetical. Municipalities worldwide have been hit with ransomware attacks paralyzing organizations and losing sensitive and personal information of citizens [10, 24, 43, 45]. These attacks had destabilizing societal effects, with governmental services being unavailable and data of citizens being lost. In the US alone, more than a hundred local government organizations reported cyberattacks in 2019 and 2020 [42].

To mitigate such threats, governments established Computer Emergency Response Teams (CERTs) or Computer Security Incident Response Teams (CSIRTs) [19]. These organizations receive security incident data and network scan information from various sources. This data is forwarded to the organization responsible for the vulnerable systems. The notified organization is then expected to mitigate the vulnerability. Prior research shows that such security notifications can expedite vulnerability remediation [32, 52]. CERTs around the world operate on a similar model of monitoring networks and notifying constituents. In Brazil, the CERT provides incident analysis and coordination services for any network that uses IP addresses or Autonomous Systems allocated to Brazil, and domains under the .br ccTLD. It alerts Brazilian networks involved in malicious activities [8]. The CERT-Bund in Germany supports handling IT security incidents; it provides active alerts for the federal administration in the event of acute threats [21]. In Africa, the non-profit organization AfricaCERT, with several African countries as its members, states in its objectives that it "encourages information sharing in ICT security, which includes findings from reported incidents and case studies, so that vulnerabilities can be rapidly identified, and its risks mitigated" [2]. In the UK, the NCSCS introduced the Early Warning service, offering its members to notify them of vulnerabilities in their networks [38]. These CERTs monitor threats and attribute IP networks to organizations for alerting and notifications.

Yet, despite these measures, governmental systems, as well as other organizations, are still frequently found to be vulnerable [49]. Therefore, in this study, we first ask the question: how accurate are the measurements of unpatched systems? Next, we consider the question: why are those systems not patched? Prior work has shed light on the presence of unpatched systems via three strands of research, (*i*) studying the self-reported patching practices of system administrators [13, 33], (*ii*) network scans that detected where vulnerable systems are located [27, 56], and (*iii*) the effectiveness of notifications about detected vulnerable systems [32, 52]. However, no prior work has integrated these three strands as we do in this study.

We combine passive network scans (relying on banner-grabbing to infer software versions) to link versioned software to known vulnerabilities from the National Vulnerability Database (NVD) and to detect vulnerable systems in local governments in the Netherlands that receive notifications from their CERT and then use these detections in interviews with security practitioners responsible for those systems. We gather ground truth on the detections to answer our first research question. Next, to answer our second question, we explore the non-patching behavior of practitioners in a way less sensitive to the biases that come with self-reporting, which previous studies have relied on, e.g., [33].

We collaborated with IBD-CERT, the CERT organization for all municipalities in the Netherlands. The municipalities have registered their IP network ranges with the IBD-CERT. The CERT receives scan data from the national CERT and other sources about hosts with CVEs (Common Vulnerabilities and Exposures). It then notifies its members about detected hosts in their networks. We explore potential explanations for the detected vulnerable systems. First, the passive network scans might produce false positives: the host might not actually be running the vulnerable software. Scan data can contain artefacts and version information from hosts that are manipulated or simply wrong. Second, the systems are unpatched, but there is a reason the municipality has not patched it. It might be unaware of the vulnerability, it might be unable to patch it, or it might have decided that patching is not needed. In the process of conducting the interviews, a third explanation arose: the municipalities do not consider the vulnerable system to be their responsibility, even though they reside in the IP ranges that they registered with the CERT.

We analyzed 1,687 registered IP ranges covering 322 municipalities in the country. Using passive scanning data from Shodan [35] and Censys [14], we observed 154 vulnerable hosts running 17 different services with 643 unique CVEs in total. We conducted 16 semi-structured interviews with 29 security practitioners working for 54 municipalities (some IT departments support multiple municipalities), covering about 17% of the total population of Dutch municipalities. This sample includes municipalities with and without exposed vulnerabilities, so we can compare their answers and the features of their organizations. We transcribed, coded, and analyzed the interview data and conducted follow-up conversations.

First, we observed that the observation of vulnerable hosts seems reliable and not plagued by false positives. Next, we found that a significant portion of the vulnerable systems that get notified about fall into a gap, because there is a misalignment between the IPs of municipalities registered at the CERT, and the IPs the sysadmins see themselves as responsible for. At least some of these vulnerable systems appear to be "shadow IT". This might explain why many of these systems persist in a vulnerable state. It also explains that the municipalities see themselves as much less vulnerable than their CERT or central government does. For the systems that were administered by the municipality, we observed that respondents were (*i*) not aware of vulnerable hosts, (*ii*) unable to patch the system, or (*iii*) systems were in the process of being retired. We also learned that vulnerable systems are rarely shut down because of security reasons. We make the following contributions:

- We collect ground-truth evidence that the external detection of vulnerable services is accurate and not plagued by false positives. The observations we collected from Shodan and Censys appeared to be 100% correct.
- We demonstrate major misalignments between the systems the CERT attributes to a municipality and the systems a municipality believes it is responsible for. For our sample of municipalities, this misalignment translates to the CERT observing 18 vulnerable hosts that the IT departments do not consider their responsibility, pointing to the problem of "shadow IT". On the other hand, the municipal IT departments do see themselves as responsible for 6 vulnerable hosts that the CERT does not attribute to them and thus doesn't notify them about. Only 9 vulnerable hosts are seen and attributed consistently by both organizations. These observations raise concerns about the effectiveness of the incident response framework of CERTs for notifying victim organizations.
- We identify four categories for not patching vulnerable systems in practice: *unaware*, *unable*, *retired*, and *shutdown*. In most cases, security professionals were unaware of the vulnerable system. Additionally, we find that there are no CVE or application-specific mitigation strategies applied to vulnerable hosts unless explicitly provided in the security advisory of the CERT or from the vendor. We also observe a strong tension between business continuity and security in the vulnerability management process.

2 Related Work

Our study ties into three main strands of research: (*i*) user studies of security practitioners or IT professionals; (*ii*) studies

using network scans to collect observational data on vulnerable systems; and (*iii*) studies on security and vulnerability notifications. We discuss each in turn.

First, several studies examined the perspectives of security practitioners to gain an understanding of their considerations or the organizational processes in which they operate, not necessarily related to security [5, 55]. Li et al. [33] identified processes system administrators use to manage software updates but relied solely on self-reporting via surveys. The software updates that system administrators reported were not empirically measured, and therefore a picture may be painted that does not fully align with reality. Dietrich et al. [13] looked at how system administrators managed their systems and their configurations, specifically examining the perspectives of system administrators. Velasquez et al. [53] looked at the role of the system administrator within the organization and found that they often act as a broker between the end-users and the technical community. Krombholz et al. [28] found that the deployment process of security measures for system administrators is too complex and recommended that server configurations should opt for security by default. Alomar et al. [3] observed that practitioners struggle with vulnerability remediation and that vulnerability discovery efforts are hindered by significant trust, communication, funding, and staffing issues. Smale et al. [12] found that vulnerability information acquisition by practitioners is not comprehensive and that up to 95% of all CVE disclosures are not ingested. These studies examine the perspectives of practitioners, but they are all based on self-reported behaviors, which is potentially biased. By using actual network data linked to known vulnerabilities, we ground the responses of the interviewees by discussing with them the evidence of vulnerable hosts in their network.

Vulnerabilities can be found in the wild with passive scanning services. The work of O'Hare et al. [44] presents a method to discover vulnerabilities by combining the CPE from passive scanning services with data from the National Vulnerability Database (NVD). A vast area of research relates to the use of Internet-wide scans with Zmap [16] and similar tools to detect vulnerable hosts [18, 23]. Numerous studies used Censys and Shodan to measure vulnerable systems [6, 15]. The work by West et al. [56] found that the Internet-facing OpenSSH service might not be as vulnerable as initially suspected due to the use of backports. Kotzias et. al [27] observed that the patching of server applications is much slower than the patching of client-side applications.

Finally, as stated in the introduction, there exists a line of research related to incident response and victim notification [52]. Li et al. observed that vulnerability notifications addressed directly to the owners of the resources promoted faster remediation than those sent to national CERTs [32]. Cetin et al. showed that retrieving contact information at scale was problematic. But once contacted, entities were more likely to remediate [9].

Our work builds on previous studies by connecting and contextualizing different methods and data sources to provide a deeper understanding of patching behavior and the responsibilities of networks. The combination of scanning networks and using that data in interviews should mitigate the risk of self-reporting in patching behavior. Additionally, it allows us to verify external measurements of software versions of networks, to obtain ground-truth. We complement those external network measurements with qualitative data to record the considerations of practitioners as to why those vulnerable systems exist in their infrastructure. Lastly, by collaborating with the CERT and the municipalities we are able to correlate (assumed) responsibilities for specific IP addresses that are attributed the municipalities.

3 Ethics

We received approval from our Institutional Review Board for conducting this human-subjects research. Participants were explained in detail about the study, associated risks, and use of information for which they provided informed consent.

Research on the vulnerabilities of an organization is a sensitive topic. In our informed consent form, as well as in the recruitment emails for the interviews, we consistently assured the participating municipalities, as well as their CERT, that their data was handled confidentially and would only be presented in an aggregated and anonymized form. No identities or municipalities would be named. We also made sure that answers that referred to specific tooling that might reveal their identity were cleaned.

After the interviews, we reported IPs with vulnerable services to the CERT. During the interviews, we notified respondents of the observed vulnerable hosts.

To minimize the burden on the security staff, we choose to use passive rather than active scans in order to prevent the disruption of regular operations or unintentionally triggering alerts (false positives) in their Security Operation Centers (SOCs). Before publication, we presented a draft of this paper to the respondents, so that they had a chance to check and correct quotes attributed to them.

4 Measurement Approach

We used a mixed-methods approach that combines external network measurements of the municipalities with a qualitative user study among sysadmins and security practitioners. The aim of this approach is two-fold. First, we validate the passive network measurements for detecting software versions with the responsible operators. This allows us to estimate the false positive ratio for the detection of vulnerable systems when relying on banner information about software versions and linking those to known vulnerabilities. We did not carry out active measurements on the networks of municipalities to ver-

ify vulnerabilities. Second, we conducted interviews to learn from the practitioners why the vulnerable systems, assuming they were correctly detected, were present in their network. We collaborated with the IBD-CERT, which is responsible for all Dutch municipalities. The CERT provided us with the IP ranges that the municipalities have registered with it. It also facilitated the process of recruiting interviewees.

4.1 Scanning Municipal Networks

Network scans can be done actively or passively. Active scans directly connect to the target network. They grab banners and infer software versions (e.g., Nmap [34]) but they can also be more intrusive. Some tools such as Metasploit [47], Nessus [51] or Qualys [46] actually try to exploit a potential vulnerability to determine if it is present on the target system.

By contrast, passive scanners run their own Internet-wide banner-grabbing scans and present the results to its users, often as a service via a web portal. The scan data is (somewhat) outdated but the target network is not directly touched by the users of the service. Popular passive scanning services are Shodan [35] and Censys [14].

The CERT provided the research team with 1,687 IP ranges for 322 municipalities. In the Netherlands, there are 346 municipalities, giving us coverage of over 93% of the total population. To reduce the burden on the municipality networks, we relied solely on passive rather than active scans. In November 2022, we queried Censys and Shodan to identify hosts. This process resulted in 3402 detected hosts. Figure 1 depicts the 322 municipalities from the CERT and the number of responding hosts for each. The next step was to determine what services were running on the detected hosts. Censys and Shodan parse banners to determine the service and version that is running on a port. A portion of the service banners contained version information. The service and, if available, version are used to generate a Common Platform Enumeration (CPE) identifier. We collected CPE identifiers of the applications and their versions running on a host. For those CPEs, we retrieved the accompanying Common Vulnerability Disclosures (CVEs) from the National Vulnerability Database (NVD) [40]. For these CVEs, we also collected their Common Vulnerability Scoring System Version 3 (CVSS3) scores. CVSS3 is an open framework for communicating the characteristics and severity of software vulnerabilities [20]. We used the CVSS score to label vulnerabilities as Critical, High, and Medium/Low [41].

Our study primarily relies on the scan results from Censys. Contrary to Shodan, it does not perform any black-box post-processing, so we can more transparently infer CPEs. Furthermore, Censys runs its scanners on a daily basis for each IP address [7]. To corroborate its results, we compared the results to those we got from Shodan. We observed two minor discrepancies. First, we found that for some IP ranges, each service returned a different number of hosts. (Both services did return the same number of hosts that were running a versioned service.) We asked respondents if they actively blocked either Censys or Shodan, which none did. However, several respondents did mention that their firewall blocks consecutive requests from a scanner and that it might explain the difference in resulting hosts. Second, we found minor discrepancies in how Shodan and Censys parse the banner for the CPE. For example, Shodan detects unversioned Apache2 instances conveying the following CPE for them: *cpe:2.3:a:apache:http_server:2*, while Censys returned the *cpe:2.3:a:apache:http_server:*:*:*:*:*:*:*:*:** CPE. Also, for Nginx 1.18.0, Shodan returns the CPE *cpe:2.3:a:igor_sysoev:nginx:1.18.0* while Censys returns *cpe:2.3:a:nginx:nginx:1.18.0:*:*:*:*:*:*:*:*. For neither CPE did it have an effect on the associated vulnerabilities.

4.2 User Study

Selection of municipalities. We compiled a list of versioned and (vulnerable) services per municipality. For the interviews, we selected municipalities on three criteria. First, we preferred municipalities with the highest number of hosts running versioned services, to maximize the number of external measurements of systems. We interviewed 10 municipalities with vulnerable hosts. Second, we interviewed municipalities without vulnerable systems. We wanted to learn if they approached vulnerability management differently, or if their organizational structure may have an effect. We interviewed 6 municipalities without vulnerable hosts. Third, we wanted a diverse set of municipalities in terms of size and geographical location. We aimed for a diverse sample measured in the number of inhabitants and Internet-facing hosts. Depicted in Figure 1, we plotted in red the participating municipalities among the total set of municipalities.

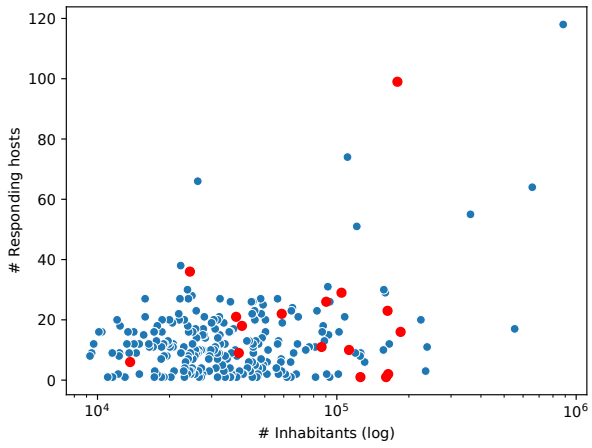

Figure 1: **Responding hosts versus the number of inhabitants (log scale) for the IPs of all municipalities. Red dots are the municipal IT organizations (16) we interviewed.**

Based on these criteria, we selected 34 municipalities and, in collaboration with the CERT, reached out to them in November 2022 until April 2023 via e-mail, inviting them to join a one-hour semi-structured interview. In case of no reply, we sent out a reminder after several weeks. We asked for respondents who were involved in the operational process of detecting and mitigating vulnerabilities, often system administrators. In total, we were able to set up interviews (4 declined to participate, and 12 did not respond). In several cases, municipalities maintained a shared ICT infrastructure with neighboring municipalities. In total, we interviewed 29 practitioners occupying 4 kinds of roles (Table 1) belonging to 16 organizations providing IT services to 54 municipalities (about 17% of the total population of Dutch municipalities). See Appendix A for more information on respondents.

Table 1: **Respondent roles**

Roles	**Respondents** ($n = 29$)

Pre-interview engagement. Our interviews were one part of a multi-step engagement with the responding municipalities. We first reached out to municipalities via the CERT contact points. We explained the purpose and design of the study and asked them to participate in an interview. The interview had two main purposes: to verify the validity of the detected vulnerable hosts and to understand the reasons for those hosts being present in the network. Discussing and validating specific hosts meant we needed to enable the municipalities to prepare for the interviews. First, we updated our scan results shortly before the engagement. Then we sent a list of hosts, services, and versions that we had detected to our main contact point at each municipality. The contact points then had to identify within their organizations which IT practitioners were responsible for the specific hosts that we wanted to discuss. The practitioners, in turn, would then be able to prepare for the interview, e.g., by checking the exact versions of the services running on the hosts.

Adapting the Research Design. A surprise emerged during the first few interview preparations. Some respondents told us that the hosts we had sent them were not known to them or were not their responsibility, even though they were located in the IP ranges that the municipality had registered with the CERT. They are responsible for updating the data about the corresponding IP ranges if changes happen, yet we consistently ran into discrepancies. We see these discrepancies as outcomes of our research and will discuss this issue in depth in Section 5. That being said, it also meant we had to adapt our research design.

Our first adaptation was to ask respondents to share with us the IP ranges that they were responsible for. This brought another surprise: some of these ranges were completely outside of the ranges that were registered with the CERT. This led to a second adaption: we asked all respondents to share with us, well before the interviews, the IP ranges they were responsible for. We would then scan these ranges, in addition to the ranges that the CERT had on record, for hosts and services in Censys and Shodan. We would also identify vulnerable hosts in these ranges. In this way, we could share up-to-date scan results in preparation for the interview, as well as ensure that we could discuss vulnerable systems. These additional scans brought into focus potentially vulnerable systems that were not attributed by the CERT to the municipality.

Interview protocol. The combination of conducting interviews about actual scanned vulnerable hosts provides an empirical basis for determining how practitioners manage vulnerable systems and reduces the risk of social-desirability bias that may occur with self-reporting. Previous works [13, 33] used qualitative data but did not relate that data to actual systems.

The interviews consisted of three parts. First, we would ask the interviewee to confirm or reject the version information we had inferred about the selected hosts and services. In other words, it acted as a ground-truth validation protocol for the vulnerable services and determined if the external measurements were indeed correct. Second, it seeks to understand practitioner perspectives on the responsibility of IP addresses for monitoring and mitigating vulnerable systems of an organization. Third, it determines how practitioners assess and mitigate vulnerable systems in practice. These discussions centered around the vulnerable systems that we measured, not hypothetical cases. For the latter part, we chose a semi-structured protocol because we wanted the interviewees to freely express their thoughts on the reasons for the presence of vulnerable hosts [25, 29]. The full interview protocol is included in Appendix B.

The interviews were conducted in person or using video conferencing applications and typically took about an hour. There were 6 interviews done with a single respondent, 5 with two, and 4 with three respondents. In those cases, respondents stated that several people were involved in administering the infrastructure and to improve our understanding, all should provide input. One municipality answered interview questions via e-mail because the infrastructure administration required too many people for one interview. In the pre-interview communication, the respondents were informed about the goals of the interview and received an Informed Consent form. At the start of the interview, we reiterated the research goals, gathered consent statements, and asked permission to record the interview for transcription. Respondents participated voluntarily and did not receive compensation for the interview.

Coding. Interviews were transcribed and coded using the ATLAS.ti software [4]. Initial codes were iteratively developed by the lead researcher and two other researchers. The codes clustered topics that described the various kinds of answers of participants. First, 4 interviews were coded by the lead researcher for the initial codes. The research team then refined the initial codes. These codes were then shared with another researcher to independently code a subset of interviews and discuss the results. We refined the codes with the research team with those results, leading to the final codebook. The process of meeting with authors and discussing and independently refining the codebook is a suitable way to ensure the reliability of findings, according to McDonald et al. [36]. The final codebook is available in Appendix C.

5 Validating Observed Vulnerable Systems

The first potential explanation for the presence of vulnerable hosts is that their detection might contain false positives. That is, the network scan data received and disseminated by CERTs might not be fully accurate. Our approach, extracting CPEs from version information in banners, is a normal industry practice, so our data is similar to the data CERTs receive. There is a second type of scanning that does not rely on version information alone and instead uses benign exploit code to test the presence of a vulnerability. Because of the intrusive nature of such scans, we did not adopt this approach. Clearly, the second approach offers greater reliability for estimating vulnerabilities but the approach has a direct impact on the target network, which was unfeasible for our collaborations.

There are two caveats to the approach we used. First, administrators may hide the version in the banners they expose. Second, a service may run a backport, i.e., an older version that includes security patches from a new version but still shows the old banner. A banner rarely shows the presence of a backport of a service. Therefore we asked respondents if they used them. None of our 29 respondents indicated that they (knowingly) ran backports. In two interviews, respondents stated they use a security product that hides version information.

Our scans resulted in 3,402 records from Censys, i.e., that is the number of responding hosts. Within this dataset, 578 hosts were found with at least one versioned service application (17%). A host can run multiple (vulnerable) services on different ports. We, therefore, examine all unique vulnerable CPEs on all hosts. From the 578 hosts, we derived 101 unique CPEs. Of these 101 unique services, 70 contained 1 or more CVEs, with a total of 643 unique CVEs. The 70 vulnerable services were observed in 154 unique hosts in 94 different municipalities. In our population, vulnerable hosts most frequently ran vulnerable versions of OpenSSH and Apache Httpd.

To verify the services and versions at vulnerable hosts, we prepared a list of detected systems for each of the 54 municipalities, based on the IP ranges registered with the CERT. In total, this set contained 24 vulnerable hosts for the 16 IT organizations servicing 54 municipalities.

However, as explained in Section 4.2, the pre-interview communication revealed that the municipalities did not consider some of the CERT-registered IP ranges as falling under their responsibility. So some of the detected vulnerable systems were not under their control or even unknown to our interviewees. This meant that in 9 of the 16 interviews, there were no vulnerable hosts at the municipality in the IP ranges reported by the practitioners. This misalignment is explored further in Section 6. In the remaining 7 interviews, we were able to validate 15 vulnerable hosts. We supplemented this set by validating the 27 non-vulnerable hosts since that inference (vulnerable or not) is based on the exact same data and analysis. This allowed us to test whether using version information from banners is reliable or plagued by a substantial false positive rate. The 15 vulnerable hosts ran 4 different vulnerable services: Apache, OpenSSH, PowerDNS, and Nginx (see Table 2). We confirmed the service and the version with the respondents. We agreed with respondents not to share the versions of the software so as not to facilitate attackers. For all the vulnerable services that we observed with the passive scan data, the actual running service and version were the same, according to the respondents. We also confirmed 27 Microsoft services: 1 MS Internet Information Services 8.0 service, 5 MS Internet Information Services 8.5 services, 9 MS Internet Information Services 10 services, and 12 MS HTTPAPI 2.0 services. Again, all versions were confirmed by the respondents. In total, all 42 observations were correct. While the measurements of the versions of the Microsoft systems are correct, the measurements do not provide insights into their actual vulnerability. First, we cannot determine CPEs that can be linked to specific CVEs. Second, we cannot actively verify vulnerabilities by exploiting them, as described in Section 4.1. During the interviews, we verified the versions but we did not discuss specific security updates. Table 2 provides an overview.

Table 2: **Validation of CPEs identified by Censys**

Service	# Correct	# Incorrect
Apache	6	0
OpenSSH	4	0
PowerDNS	3	0
Nginx	2	0
IIS 8	1	0
IIS 8.5	5	0
IIS 10.0	9	0
HTTPAPI 2.0	12	0
Total	**42**	**0**

Table 3: **The number of hosts, number of versioned hosts and number of vulnerable hosts that the CERT attributes to a municipality, and the practitioners at the municipality themselves.**

Muni Id	Hosts Muni	Hosts CERT	Versioned Hosts Muni	Versioned Hosts CERT	Vulnerable Hosts Muni Only	Vulnerable Hosts CERT Only	Vulnerable Hosts Shared	Total Vulnerable Hosts	Total Unique CVEs

6 Attribution and Unclear Responsiblities

As discussed in Section 4.2, our research approach led us to discover a new explanation for the presence of the vulnerable systems: the misalignment between the IP ranges that the municipalities registered with the CERT and the IP ranges that the respondents thought they were responsible for. Perhaps some vulnerable systems persist because the municipalities do not see them as their responsibility, even though they might be notified about their vulnerable status.

In this section, we further explore this misalignment. First, we briefly describe the role of the CERT and the crucial role that the registered IP ranges have in the institutional incident response system. Next, we analyze the relationship between the IPs registered with the CERT and the IPs that the practitioners provided. Then, we quantify the misalignment of the IPs between the CERT and the municipalities. Finally, we examine perspectives on responsibilities.

6.1 Role of CERT and Municipal IPs

The IBD-CERT supports municipalities with security advice and liaises between municipalities and the national CERT. On behalf of municipalities, it contributes to the Baseline Informatiebeveiliging Overheid (BIO) – the Dutch compliance framework for information security within government. One of the goals of the CERT is the detection of incidents and crisis situations and the sharing of knowledge between municipalities and suppliers. While municipalities are ultimately responsible for monitoring their own systems, in pursuing its goals, the CERT also monitors the Internet-facing infrastructure of municipalities. In doing so, it also receives information about vulnerable systems from other parties, such as the national CERT, their own scans, ethical hackers, Shodan, and the Dutch Insititute for Vulnerability Disclosures (DIVD).

6.2 Misaligned Threat Landscape

The misalignment in monitored IP addresses translates to misalignment in the perceived threat landscape by the CERT and the practitioners at the municipality. We find that the CERT generally observes more versioned and vulnerable hosts than the practitioners at the municipality itself. Table 3 describes the number of hosts, number of versioned hosts, and number of vulnerable hosts that the CERT attributes to a municipality, and the practitioners at the municipality themselves. It shows that respondents observed 6 vulnerable hosts that the CERT did not observe. The CERT observes 18 vulnerable hosts that the respondents do not. The respondents and CERT both observe 9 vulnerable hosts. In total, there are 33 vulnerable hosts for the municipalities.

The data in Table 3 shows that neither organization observes the full set of vulnerable hosts. The CERT observes more vulnerable hosts than the practitioners at the municipalities themselves. This would lead the CERT to send notifications to the respective municipalities, who, in turn, would not recognize the system. But the CERT also has a blind spot, the vulnerable systems in the public IP range of the municipality that the CERT does not monitor. In those cases, the CERT

could not exercise its supportive function, and would not send any notifications at all.

The differences in vulnerable hosts between the organizations impact the CVEs associated with a municipality. We find that the 15 vulnerable hosts at municipalities result in 62 unique CVEs within IP addresses for which they consider themselves responsible. The vulnerable systems observed by the CERT for those municipalities result in a much larger set: 481 unique CVEs. It is not just the sheer number of vulnerable hosts that is larger. We also see a remarkable difference when we look at the CVSS rating of the vulnerabilities (a score between 1 and 6.9 is considered "low/medium", between 7.0 and 8.9 is "high" and between 9.0 and 10.0 is "critical") [41]. We find that there are 15 critical CVEs in the IP space identified by the respondents versus 107 critical CVEs in the IP space that are registered with the CERT. Similarly, we find that there are 27 high CVEs in the municipality IP space and 191 highs in the CERT IP space. Table 4 depicts the CVEs by severity per organization. The key consequence of the misalignment of the IP ranges is this: the CERT observes much greater risks for the municipalities, compared to the municipalities themselves.

Table 4: **Number of vulnerabilities by CVSS3 severity, as observed by each organization. In parentheses are the number of unique IPs with a vulnerability. Note that most IPs run a service with multiple CVEs of different severity levels, skewing the individual and total IP count.**

Org.	Critical	High	Medium/Low	Total
Muni	15 (7)	27 (14)	20 (9)	62 (15)
CERT	107 (18)	191 (27)	183 (22)	481 (27)

This finding can explain two things. First, it means that the CERT – and in its wake, the national CERT and central government agencies – see the municipalities as much more vulnerable than the municipalities' security practitioners see themselves. That can translate into the perception of the CERT and other government entities that municipalities show a lack of urgency about these issues. Second, it means that the vulnerable hosts persist because the vulnerability notification system is broken. The municipality receives the notifications, but the bulk of these are deemed to fall outside their scope of responsibility. Conversely, there are vulnerable hosts in the self-reported IP ranges that are not registered with the CERT. The municipalities will not be notified about those. Both scenarios lead to vulnerable hosts persisting over time.

During the interviews, most respondents stated that they do not have a complete or up-to-date overview of all the systems that the organization is running externally, so outside the ranges they feel responsible for, but inside the ranges registered with the CERT. Some respondents stated that the internal processes at the municipality for departments to report external systems that they use to the IT or security team were unclear. One respondent (#12) stated "we have a view on those systems that are reported. But not on the ones that are not reported".

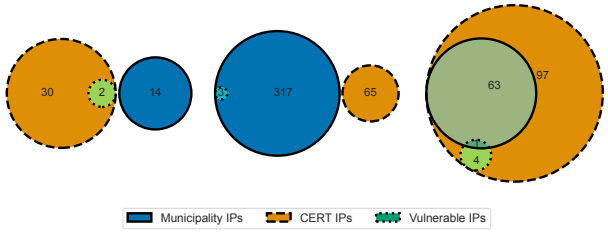

Figure 2: **Three examples of IP sets registered with the CERT and the IPs used by a municipality.**

6.3 Quantifying the Misalignment

To quantify this misalignment, we compare the *sets* of IPs that the CERT associates with a municipality and the IP addresses that the respondents reported as being responsible for. To measure the similarity of those two sets, we use the Jaccard similarity coefficient and the Szymkiewicz-Simpson coefficient, also known as the Overlap coefficient. Both scores range from 0 to 1. The Jaccard score tells us how similar two sets are, where 1 means that all the items appear in both sets. However, the score does not capture when one set is much bigger than the other. Therefore, we also include the Overlap coefficient, which is 1 if one set is fully subsumed in the other set. We find that, on average, the Jaccard coefficient is 0.21 and the Overlap coefficient is 0.56. This means that most municipality IP ranges and CERT IP ranges for that municipality are of a very different size, and also have only partial overlap – meaning, they monitor different addresses. More importantly, the incident response and vulnerability notification infrastructure assume they are 1.

We can also visualize the misalignment using a Venn diagram. Figure 2, shows three examples of sets of IP ranges with vulnerable IPs from the CERT and the municipality itself. The remaining diagrams are in Appendix D. Clearly, the IP ranges registered with the CERT, and the IP ranges used by our respondents are very different.

6.4 Perspectives on Responsibilities

We tried to understand what explains the differences in the attribution of vulnerable hosts. Respondents made a distinction between systems they administer and systems that are used by the organization but are not administered by the respondents, such as SaaS services.

Administering Systems Themselves. Most respondents stated that their responsibility was primarily the systems

they administer themselves, and exposing them through their public IP range – i.e., the IPs used for routing Internet traffic in and out of their internal network. They minimize their Internet-facing footprint because it provides the administrators with two clear advantages. First, the "front door" is small and easier to manage for "administrator"-type duties – it gives them a better overview. As one respondent (#2)stated, "the more external points you have, the harder it becomes and you quickly lose oversight". Second, the security tools only need to monitor a small set of addresses which reduces the capacity needed for monitoring those systems. One respondent (#5) stated, "Monitoring simply takes a lot of time, and then we are not even taking into account any type of response". Similar to [3], we found that many municipalities faced staffing issues and limited resources. Consequently, a lot of decision-making prioritized optimized use of (human) resources.

Not Administering Systems. The challenge of overseeing systems is exacerbated when external parties provide a service for the municipality. Most respondents observed a trend in the growing number of Software-as-a-Service (SaaS) platforms. They applaud this trend as it reduces the number of applications and servers they need to manage on-premise. This allows practitioners to handle more work with fewer people. However, the downside is that practitioners are not always aware of those systems, and they no longer administer or control the systems on which their data now resides.

Administering systems is difficult for respondents because of the sheer number of business services a municipality offers, each with its own software application. It is this wide array of services that distinguishes it from a regular enterprise according to one respondent: "A municipality has so many types of connections, partners, and disciplines that it's not comparable to a business. There, they want a single solution but that doesn't exist in municipalities. It's very complex. For example, you could get a notification that the tile of a curb is positioned wrong. The team responsible for that has its own application. We have many demands and wishes and we have a great number of running tenders. Unfortunately."

A majority of respondents stated that there was no clear overview of the platforms that the municipality uses, as those platforms were not always reported to the IT team. For some respondents, a clear process to register newly connected platforms or a mandate to enforce the registration obligation at the IT team was lacking. This is the well-known problem of "shadow IT", which has been plaguing IT managers for decades now [48]. In only two cases did the respondents know the vulnerable host at the IP address that we shared with them, even though they were not responsible for administering it and it wasn't in their public IP range. They knew it was running at a third party. Respondents also brought up the issue of control. They indicated that while procedures are in place to demand security measures during the tender, they do not have the power to exert control. For example, a respondent stated that monitoring – i.e., scanning – external systems was frequently not allowed by the external vendor. Another respondent mentioned that the municipality wanted to ingest logs from the vendor into their SIEM, but the vendor did not want to share its logs, one of the voiced concerns was the privacy of (non-municipality) user information. In all of those cases, the practitioners could not exercise control over how their data was managed at the partner organization, yet they feared that the (political) fallout in case of an incident would be their responsibility.

Administering Shared Resources. Some municipalities collaborate in a governance structure to share ICT resources. This governance structure streamlines resources to reduce costs and optimize the capacity of scarce IT personnel. However, it is not without problems. Respondents in such a governance structure stated that it is hard to draw the line between responsibilities. For example, in two interviews, we spoke to respondents about where the line was drawn between the hardware layer and the application layer. The idea behind this distinction is that the municipalities themselves can manage much of the application layer to accommodate their specific business needs. However, in practice, these layers are often intertwined, and it becomes unclear who is responsible for mitigating a vulnerable system. We observed one case where the organization that runs the infrastructure knows about vulnerable systems in the application layer but is unable to patch the system, mainly because they cannot oversee the impact of an update on the systems that provide the business services.

7 Managing Vulnerable Systems

The last explanation for exposed municipal hosts looks at the reasons that organizations might not patch a system they are responsible for. Practitioners may be unaware of vulnerable systems, or they might be unable to patch them, or they might have decided that patching is not needed, e.g., because they have specific mitigation strategies in place, such as firewall rules or monitoring.

We identified 15 vulnerable systems for which the practitioners we interviewed considered themselves responsible. We asked these respondents how they dealt with those systems. We asked for their rationale on patching, why the systems were not patched, and what if any, other actions had been taken. Due to the nature of our collaboration, we did not learn of the specifics of the business service that a vulnerable system provided. That said, in general, practitioners mentioned that most of their systems contain valuable data, such as personally identifiable information, albeit frequently fragmented. Every bit of valuable data or provided service is considered important, and compromise would have privacy implications even if it applied to only a handful of citizens.

Table 5: **Features of the municipalities, the number of total vulnerable hosts, and the Jaccard and Overlap indexes with CERT. Most municipalities collaborate and provide IT services for several municipalities and auxiliary organizations.**

Muni ID	Vulnerable Hosts	Inhabitants	IT team	Security Team	Servers	Muni's	Aux orgs	Jaccard	Overlap
1	3	10-100k	10-20	yes	100-200	1-2	0	0	0
2	2	10-100k	1-10	yes	0-100	1-2	0	0	0
3	2	100-200k	20-30	no	100-200	5-10	1-2	0.36	0.56
4	1	10-100k	1-10	yes	100-200	2-5	>3	0.038	1
5	4	10-100k	1-10	no	100-200	1-2	0	0.77	1
6	5	200-300k	30-40	yes	>1,000	>10	1-2	0.38	1
7	6	100-200k	20-30	yes	500-1,000	1-2	0	0.16	0.46
8	7	100-200k	10-20	yes	100-200	1-2	0	0	0
9	2	300-400k	30-40	yes	>1,000	5-10	1-2	0.98	0.99
10	0	200-300k	30-40	yes	200-500	1-2	0	0.17	0.79
11	0	100-200k	30-40	no	500-1,000	1-2	0	0.27	1
12	1	10-100k	1-10	yes	100-200	3-5	0	0.47	1
13	0	200-300k	40-50	no	>1,000	3-5	0	0.10	0.18
14	1	100-200k	20-30	yes	200-500	1-2	0	0.02	0.96
15	0	200-300k	40-50	yes	>1,000	5-10	1-2	0	0
16	0	100-200k	40-50	yes	>1,000	1-2	1-2	0	0

7.1 Identifying Vulnerable Systems

We asked respondents how they identified vulnerable systems in their daily work. All respondents stated that they use vulnerability scanners to do so. In addition, they stated that yearly penetration tests are conducted. To stay up to date on the latest vulnerabilities (that might not be incorporated in the vulnerability scanner), they receive security advisories from the CERT, vendors, and popular security news sources. Our findings on the ingress of vulnerability information are in line with earlier work [12], in that practitioners relied on curated vulnerability information from authoritative sources to consider vulnerability information. As we will discuss below, for some vulnerable systems, sysadmins did not know the version of the software they were running. So, they relied on external triggers to become aware of vulnerabilities.

There is a compliance framework in place to act on security advisories. As stated in Section 6.1, the Dutch government uses a compliance framework, BIO, to improve and measure security practices. It contains a chapter on vulnerability management which states that if the severity level of security advisory of the national CERT is marked with probability as "High" and impact as "High", (also known as a "High/High"), the vulnerability should be resolved or mitigated as soon as possible and at the latest within a week. All respondents noted that if they received a "High/High" advisory, they would move to action almost instantaneously.

7.2 Vulnerable vs. No Vulnerable Systems

We analyzed the interviews to determine if municipalities that did not have vulnerable hosts did anything differently than those with vulnerable hosts. We included 5 municipal IT organizations where we detected no vulnerable hosts. Remember that our measurement approach relies on obtaining versions from banner data. If administrators hide the version information, our method will not determine vulnerable hosts. We learned that 2 of the 5 municipal organizations indeed ran security products that obscured versions.

At 11 municipal organizations, we did observe vulnerable hosts, either in the IPs registered at the CERT or administered by the municipality. We tried to find a common denominator for organizations with vulnerable hosts versus those without. We looked at security tools, the capacity of IT staff, the size of the municipality, the size of the IT team, the presence of a security team, and the act of vulnerability scanning.

All the respondents we interviewed, with and without vulnerable hosts, had basic generic security tools in place, like firewalls, NAT, EDR, logging, and network segmentation. Similarly, all respondents noted that they did not have sufficient capacity, in terms of qualified IT staff, for their security duties. Next, we checked if the size of the municipality, measured by the number of inhabitants, had a relation to the number of vulnerable hosts. We observed that both the smallest and largest municipalities had vulnerable hosts, as did several in between. We then compared the size of the IT team but also found that vulnerable hosts occurred in small and bigger IT teams. Finally, we looked at organizations in terms of the number of servers they ran. These servers are not all exposed to the Internet, but the number of app servers acts as a proxy for the size of their infrastructure. The idea is that a larger infrastructure might contain more vulnerable machines. However, here too we see no clear distinction. Next, we observed that all respondents, except one, engaged in vulnerability scanning, discounting this as an explanation for the presence or absence of vulnerable hosts. The one respondent who did not actively

use it was not part of the security team. Finally, we wondered if the presence of a security team might have an effect. From the 16 interviews, 12 organizations ran a security team, and 4 did not. We observed that 9 municipalities with a security team have vulnerable hosts. Of the 4 municipalities without a security team, 2 municipalities exposed vulnerable hosts.

In sum, we do not observe a link between specific features of an organization and the number of vulnerable hosts. We also do not find substantially different security practices among respondents in the interview data.

7.3 No Patch

We hypothesized that observed vulnerable systems are indeed vulnerable, but administrators may have their reasons for not patching. We first examined if they had put specific mitigation strategies in place for the vulnerable hosts. All the respondents stated that they had generic mitigation strategies in place (such as network segmentation, logging, firewalls, and Intrusion Detection Systems). Some respondents stated that they also use a managed SIEM. However, only in one case was a specific mitigation strategy in place for an observed vulnerable system. That system was run on an isolated network. Without specific mitigation strategies in place, we asked administrators what other actions, if any, were taken for the vulnerable hosts. We analyzed the interviews for the 15 vulnerable hosts and synthesized the responses into various explanations that we condensed into four categories: *unaware* of the vulnerable system, *unable* to patch it, the system was (in the process of being) *retired*, or the system was *shut down*. We describe each in more detail below, and tabulate an overview of these explanations in Table 6.

Table 6: **Explanations for vulnerable systems**

Explanation	# Systems
Unaware	9
Unable	3
Retired	3
Shut down	N/A
Total	**15**

Unaware. We observed during the interviews that respondents were not always aware of the vulnerable system. We encountered three types of unawareness. First, an administrator retired the system and assumed it was no longer online. This, however, was not the case. One respondent (#6) said: "this is a system that is phased out. I'm actually surprised about this. Thanks, I've got some homework to do." Second, there was a case where a vulnerable system was not on the radar at the organization. When presented with the system, the security team could not find the system in their asset inventory but acknowledged it was running in their IP range. There was no direct explanation for that situation. Third, the system was not directly identified as a vulnerable system. The respondent (#1) stated: "These servers run directly from the Debian repos. We did not patch these systems because we assume the repo provides a decent package". For this particular case, the administrator was not part of the security team, so it may have been flagged as vulnerable elsewhere in the organization. However, the actual administrator of the system initially did not consider it vulnerable.

We investigated this type of unawareness further by checking if respondents knew about the versions of the software they run and if they were vulnerable. None of the respondents during the interview explicitly had the versions of the software they were running at the top of their minds. Similarly, none of the 29 respondents directly knew the latest version of the software they were running. All had to look up the service and version from their asset inventory system, most often a vulnerability scanning report.

We tried to gauge if respondents knew ex-ante if they set up a vulnerable system in their infrastructure. Most respondents stated that the software that is run is installed to the latest version when set up, regardless of potential vulnerabilities, because that is the best they can do. Potential vulnerabilities will be found when the vulnerability scanner is run. One respondent indicated that when installing the latest version, he checked the latest packages for information and vulnerabilities from the distributor's repository to make sure a newer version would not be released in the very near future.

Unable. In two cases, practitioners reported that they were unable to patch a vulnerable system. This happened either because of a lack of mandate from the organization or because the vulnerable software was a dependency in a product that was used to provide a business service.

At one organization, the security team was aware of the vulnerable system but was unable to undertake mitigating actions. This particular situation derived from a governance structure where the respondents were part of an organization that was responsible for the majority ICT infrastructure of the municipalities but not the last application layer. The application layer was managed by a small IT team at the municipality itself. The security team at the organization managing the infrastructure is somewhat involved in the management of the application layer due to their expertise, but they did not have the mandate to intervene themselves. Another consideration was that a patch could break the services offered by the vulnerable system. A respondent (#13) stated "fixing vulnerabilities in the application layer is outside the scope of our mandate. That said, it isn't entirely that black and white. But in this case, we cannot functionally oversee the consequences for the underlying application and business processes."

At another organization, the vulnerable host ran a product with a dependency that was vulnerable. The vulnerable software could only be patched by updates from the product.

The risks of that system were mitigated by the monitoring of an endpoint security product – that ran on all managed devices – and by running the system on an isolated segmented network. For that host, the security team did not directly intervene in mitigating the risk but had to engage other teams to act on the vulnerable system. The respondent (#12) stated: "that's why I'm pushing these people to act on this system". But sometimes such a system could not be removed. The respondent (#12) said: "this particular system, it is provided by a supplier and someone in our organization opted for that product. How do you deal with it? Retiring the system is the only way". The system was not actually retired because of business reasons.

Retired. In various cases, the observed vulnerable hosts were in the process of being retired. A retired system should not be online, but there is some time between deciding to retire the machine and it actually being offline.

Retiring a system could have various reasons but, most often, respondents stated that it was a (legacy) system that is outdated. For example, some systems ran outdated software, and the service it provided can now be done better with a new product. Consequently, the system was phased out and didn't get much attention anymore. The legacy system was marked for retirement and lingered around for a while before it actually went offline. A respondent (#6) said "this was a great product at the time but these days it's outdated. We are now in the phase of retiring this system". In another case, we found a vulnerable system before the interview, and during the interview, the system was no longer online, the respondent (#23) stated that: "by now that system is turned off". This happened only once.

Shut down. One of the most drastic mitigation strategies for vulnerable systems is simply "pulling the plug". This was not done for any of the vulnerable systems we observed, but many respondents stated that shutting a system down was part of their toolbox of mitigation strategies – albeit one very few actually want to use. When asked if this was actually done in practice, only a few respondents stated that this was within their power to actually execute. The majority of respondents stated that, while it is an option, in practice, shutting down is hardly done because business continuity takes priority. For most respondents, the only situation where they actually shut down systems was during the Log4J vulnerability. The severity of the vulnerability and the fact that it was not clear which software was vulnerable allowed for enough organizational pressure to trump business continuity. As one respondent stated: "once a vulnerability hits the news, people start taking it seriously. Sometimes we need an incident like that to make strides in security".

But without that sense of urgency, business overpowers security. One respondent (#22) stated, "business and security sometimes have opposing interests. Contrary to a commercial organization, a municipality has certain societal obligations, therefore we simply can't shut a system down like that because we are required to offer those services. Considerations are complex and discussions are quickly taken out of context. Then it doesn't matter what actually happened, but how it is perceived because something is in the newspaper".

7.4 Patching Systems: Prioritizing

Respondents stated that patching is the preferred strategy to deal with a vulnerable system. Sometimes, a patch is not directly available, as was the case with a Citrix vulnerability in 2020 [1], then they rely on the mitigation strategies provided by the vendor or the security advisory. However, the capacity, in terms of people, for rolling out patches is limited. The vast majority of respondents stated capacity as an obstacle to security. As practitioners face vulnerabilities in their Internet-facing systems as well as their internal networks, this forces them to prioritize what systems to patch first. In doing so, there are two main criteria: a) whether the system is Internet-facing and b) the severity level of the vulnerability.

First, several respondents stated that all vulnerabilities should be dealt with. This self-reporting, however, is contradicted by the fact that we did find vulnerable hosts, illustrating the limitations of self-reporting on patching behavior. To be fair, many respondents also appeared to accept that there will always be vulnerabilities somewhere in their infrastructure. Vulnerabilities in Internet-facing systems should be dealt with first – as they consider it the front door to their internal network. One respondent (#26) stated: "Internet-facing systems have priority because the chance of abuse is higher than systems inside our network." If this is true, then there should be more vulnerabilities in internal systems versus the Internet-facing systems. We could not measure this directly, but when asked, several respondents admitted that there were indeed (many) more vulnerabilities in their internal network.

While many respondents stated that their Internet-facing systems should not contain vulnerabilities, it was also mentioned that they do not consider it likely that a real attack would happen there. Instead, they feared an attack via an unsuspecting user clicking a link in a phishing mail.

Second, respondents indicated that systems with a high-severity vulnerability are prioritized. The severity metric is most often determined by either the severity level of the security advisory or the severity score of the vulnerability scanner. The Common Vulnerability Scoring System (CVSS) cite [20] is a popular scoring system to determine the severity of a vulnerability. The CVSS score is popular but has its limitations. For example, it does not take into account the ease of exploitability of a vulnerability, the availability of an exploit, or details on the number of exploitations of the vulnerability in the wild. Many security companies expand on CVSS with their own data and ranking to improve the assessment of the severity of a vulnerability. In doing so, (proprietary) vulner-

ability scanners often report the CVSS as well as their own scoring system. For example, the vulnerability scanner Nessus – popular among respondents – provides its own Vulnerability Priority Rating (VPR). The VPR takes additional factors into account, such as the CVSSV3 Impact score, the age of the vulnerability, the exploit code maturity, and more [50]. If vulnerabilities have a High or above classification (in any kind of scoring methodology), they are quickly prioritized according to the respondents.

To verify this claim for high-severity security advisories, we examined the national CERT security advisories for "High Impact/High Probability" vulnerabilities and referenced them with the systems we scanned. The security advisories contain vulnerabilities for open-source software but also proprietary software. We could not validate the claim that respondents patched "High/High" advisories for proprietary software quickly because the associated software services could not be fingerprinted by us for a version. However, in one case, security company Fox-IT wrote in their blog that they could fingerprint Citrix software for two specific CVEs [22]. In the CERT dataset with IP addresses, we reproduced their method and observed that the systems with CVEs were applicable for 7 hosts. Looking historically, in the two weeks after the advisory was sent and the update became available, these systems were patched, giving credibility to the respondents' claims.

8 Discussion

Explanations for persisting vulnerable systems. We consider three explanations for the 154 vulnerable systems we observed in the IP ranges registered with the CERT: incorrect measurements, misalignment in the responsibility of IPs, and vulnerable machines unpatched for some other reason. We interviewed 16 municipal IT organizations that had 33 of the vulnerable systems.

We learn that the first explanation doesn't explain any of the vulnerable systems. We find that the external measurements of hosts using banner information are not plagued by false positives. The second explanation, the misalignment of IPs – i.e., IPs registered at the CERT and those used by practitioners – is observed at all the 16 municipal IT organizations we spoke, and this most likely happens at many more, if not all, municipalities. Of the 33 vulnerable machines for the municipalities, 18 vulnerable hosts were seen only by the CERT, 6 by the municipalities alone, and 9 were seen by both organizations. This brings us to the third explanation: vulnerable machines that are unpatched for other reasons. Of the 15 vulnerable hosts observed by the municipalities, 9 are explained by administrators being unaware of those systems.

In short, the main explanation is the misalignment in the attribution of IP ranges, where administrators do not consider the systems their responsibility. This explanation is followed at some distance by the explanation that the IT organization was unaware of the presence of the vulnerable systems.

What is causing the misalignment problem? As Vermeer et al. [54] noted, organizations consistently struggle to keep a complete inventory of their assets. The assets are constantly changing, with many changes unplanned or unrecorded. This is closely related to the problem of "shadow IT" – systems and services that are "not known, accepted and supported" by an organization's official IT department [48]. Indeed, when respondents were speculating what the vulnerable hosts were, they frequently mentioned SaaS solutions and specific services contracted by some department of the municipality, but outside their purview, the purview of the IT department. This is classic "shadow IT". This explains why they did not consider it their responsibility to safeguard these systems. It also suggests that this is most likely not a problem exclusively to municipalities, and we might expect this also to occur in other enterprise environments. Not only does it mean there is no clear responsibility to keep those systems secure, but it also gravely undermines the CERT-based notification mechanism. Those notifications reach the IT department, but cannot find their way to the actual entity managing the host, because IT does not know. The fact that the IT teams see themselves as powerless towards "shadow IT" does not reduce the actual risk for the organizations. The vulnerable systems continue to run, exposing 183 "Low/Medium", 191 "High", and 107 "Critical" CVEs, according to IPs from the CERT data.

Finally, our findings also highlight a discrepancy between the widely-held view that local governments are very vulnerable, as mentioned in the Introduction, and the perspective of the local IT departments, as the latter observe far fewer problems in their own systems. This discrepancy might explain why the current situation persists, even though CERTs and higher levels of government keep warning local governments.

The municipal IT departments do their work under serious resource constraints. The lack of capacity and staff frequently came up. We observed that vulnerable hosts, with the exception of one, did not have specific mitigation strategies in place. Instead, respondents rely on generic mitigation measures. Respondents frequently mention the lack of capacity for IT security tasks. This aligns with our finding that organizations have only generic security measures in place – a rational choice to maximize defenses with limited resources. Coincidently, in December 2022, the Association of Dutch Municipalities (VNG) requested additional resources from the central government to increase its IT capacity in support of the Dutch National Cybersecurity Strategy, but those resources were denied [30]. Simply put, cybersecurity requirements increase, yet resources to comply lag behind.

Recommendations. So, what can municipalities do to tackle the attribution issue? After all, they themselves registered the IP addresses with the CERT. Clearly, they would benefit from keeping the IP ranges registered with the CERT up-to-date. At a minimum, this allows notifications to reach the correct

entity. If they are unaware of vulnerable systems, the notifications should help address that. What appears needed is some guidance or support on how to handle the responsibility gap that exists around "shadow IT". Who is responsible for what system? The owner of the system? The owner of the data in the system? Respondents occasionally stated that they feel somewhat responsible for systems running elsewhere since they handle municipal data. At the same time, another respondent stated that they are not allowed to scan the systems of their partners, so they are unaware that their data resides in a vulnerable system. Until a clear delineation of responsibilities exists, organizations remain at risk for cyber threats. The new NIST 2.0 framework may guide practitioners in this respect. It emphasizes a new Govern function to gain a better "understanding of cybersecurity roles and responsibilities" [39].

For CERTs, our findings suggest two points. First, the institutional framework to mitigate cyber threats assumes that vulnerable systems are correctly attributed. This assumption turns out to be problematic. The national CERT detects a vulnerable system and notifies the relevant sectoral CERT. In turn, the sectoral CERT notifies the appropriate constituent about the vulnerable system. The constituent is then expected to take action. But in practice, we observe that the last, crucial step of this notification process is flawed – as the owner of the vulnerable system is often not the recipient of the notification. As a result, we find that those systems remain vulnerable, with the data of the organization at risk. This finding contests the effectiveness of the institutional framework for notifying vulnerable entities and highlights the need for a better reporting process between the CERT and its constituents.

Second, for CERTs, like for municipalities, there seems to be a need for a clear delineation of responsibilities for external systems. Currently, what constitutes the network of an organization appears to be diffuse, but counting only on-premise infrastructure seems archaic. Perhaps a recommendation could be to build a feedback loop for the notifications, a bit like a ticketing system. This way, if a notification is not picked up by the entity to whom it is assigned, because that entity sees it as outside its responsibility, then the ticket gets returned to the CERT. Both the CERT and the municipal IT leadership, e.g., the CISO, can then observe what systems are vulnerable, yet not acted upon. This is then a starting point for identifying who is managing those systems. Currently, neither the CERT nor the municipalities seems aware of the scale problem we have uncovered. If notifications function like tickets, then the scale and location of the problem become very clear to see for all parties involved.

Limitations. Our research design introduces several limitations: external validity, internal validity, scope, and desirability bias. First, we focused exclusively on Dutch municipalities. This risks that our findings might not be generalizable. We believe, though, that CERTs worldwide face similar challenges in delineating responsibilities and correctly attributing vulnerable hosts to their constituents for effective notifications and subsequent remediation. Our findings point to the problem of "shadow IT": the challenges of managing asset inventory, including IPs and externally run services, which is a problem that many other organizations deal with. Also, a sample size of 16 interviews is limited. This sample, however, does cover 17% of the total population of municipalities. Second, our respondents were directly involved with managing vulnerable systems. Yet, they are only part of the (security) IT teams within the organizations, and their knowledge might be incomplete. We allowed additional respondents during the interviews to mitigate this risk. Yet, the limited knowledge is not just a barrier to measurement, but also an operational reality with consequences: respondents did not know who was responsible for large portions of the IP ranges that were registered with the CERT. Hence, they cannot delegate vulnerability notifications, let alone ensure mitigation.

Third, we could only discuss Internet-facing systems that ran a service with a version. Most proprietary (security) products run a service that does not include (backported) version information in the banner. Thus, the number of exposed vulnerable hosts is likely to be higher. That said, our methodology is limited as we could not perform active measurements of observed vulnerabilities. Therefore, the measured vulnerability of systems does not directly map to an equal amount of risk.

Lastly, the interviews risk desirability bias. When asked why systems were vulnerable, participants might give answers to paint them in a favorable light. We tried to mitigate this risk by a) talking about actual systems, b) interviewing respondents without their superiors, c) keeping the interviews confidential for the municipality and the CERT, and d) stating in the interview that we were scientists and were not there to pass judgment. We also believe that our methodology, interviewing respondents about actual systems, led us to a new discovery of the misalignment in responsibilities for vulnerable systems. Without our approach, practitioners would have reported very few, if any, vulnerable systems in their networks.

9 Conclusion

We asked what explains unpatched vulnerable systems that are detected and notified about, but not patched. We found that the detections are correct. It turned out that most of the vulnerable systems fell into a responsibility gap around "shadow IT" and other systems outside the reach of the IT organizations. Sysadmins did not consider these systems their responsibility. The CERT was not aware. We further identified that for most systems that did fall under the sysadmin's responsibility, they were unaware of the presence of the vulnerabilities. Our findings highlight the need to re-evaluate and improve the critical institutional structures of incident response and vulnerability notifications.

Acknowledgments

We are grateful for our collaboration with IDB-CERT, which allowed us to connect with Dutch municipal IT-teams. We thank the anonymous reviewers for their constructive feedback that improved the paper. This work was supported by the Ministry of the Interior and Kingdom Relations of the Netherlands and Delft University of Technology under Grant M75B07 and partially by NWO-project "THESEUS" (NWA.1215.18.006).

B Interview Protocol

Introduction and background

- Can you tell me about yourself?
- What does a typical day look like?
- How many devices and servers are you managing, and how big is the team?
- How is security organized in your organization?
- What do you consider the biggest obstacles in security?
- What are the Internet-facing systems of the municipality?
- How do you monitor those systems?
- How do you stay up to date on vulnerabilities? Is that an active process?

Advisories and CERT

- Who receives advisories and notifications from the CERT?
- Who manages the IP ranges, an individual or a team?
- Who is responsible for following up after a notification from the CERT?
- How do you determine if a notification is relevant?
- Do you report changes in your infrastructure to the CERT?

Specific Vulnerable Systems

- For system X, we detected service Y and version Z. Is that correct? Did you run a backport? Is it vulnerable? If so, which CVEs? How did you obtain that information?
- Are you aware of the latest version of service X? How do you obtain that information?
- How do you deal with those CVEs?
- Did you apply mitigation strategies? Why?
- Do you have other mitigation strategies that were not used? Do you have examples?
- How does the location or function of the system influence the choice of a mitigation strategy?

C Codes

Determining Vulnerable Systems

Subcodes Active Search; Asset Inventory; Notifications; Not determined; Vulnerability Scanning.

Mitigation Strategies

Subcodes Strategies Notifier; Security Tools; Isolating systems; Managed Services; Non-internet facing.

Prioritization and Patch Practices

Subcodes Critical versus non-critical score; Internet-facing vs non-Internet-facing; Latest version on install.

Responsibilities

Subcodes Compliance; Dependencies in products; External, Cloud and Saas services; Public IPs and internal network; Security role in organization; Users and awareness.

Undermining Security

Subcodes Capacity for security tasks; Budget; People and skills; Priorities, partners and collaborations; Legacy systems.

D Venn Diagrams Total IP Sets

Abstract

IoT devices have significantly impacted our daily lives, and detecting vulnerabilities in embedded systems early on is critical for ensuring their security. Among the existing vulnerability detection techniques for embedded systems, static taint analysis has been proven effective in detecting severe vulnerabilities, such as command injection vulnerabilities, which can cause remote code execution. Nevertheless, static taint analysis is faced with the problem of identifying sources comprehensively and accurately.

This paper presents LARA, a novel static taint analysis technique to detect vulnerabilities in embedded systems. The design of LARA is inspired by an observation that pertains to semantic relations within and between the code and data of embedded software: user input entries can be categorized as URIs or keys (*data*), and identifying their handling code (*code*) and relations can help systematically and comprehensively identify the sources for taint analysis. Transforming the observation into a practical methodology poses challenges. To address these challenges, LARA employs a combination of pattern-based static analysis and large language model(LLM)-aided analysis, aiming to replicate how human experts would utilize the findings during analysis and enhance it. The pattern-based static analysis simulates human experience, while the LLM-aided analysis captures the way human experts perceive code semantics. We implemented LARA and evaluated it on 203 IoT devices from 21 vendors. In general, LARA detects 556 and 602 more known vulnerabilities than SATC and KARONTE while reducing false positives by 57.0% and 54.3%. Meanwhile, with more sources and sinks from LARA, EMTAINT can detect 245 more vulnerabilities. To date, LARA has found 245 0-day vulnerabilities in 57 devices, all of which were confirmed or fixed with 162 CVE IDs assigned.

✉Corresponding Authors.

1 Introduction

The Internet of Things (IoT) has become an indispensable part of our daily lives, and the number of devices in use is expected to reach 27.1 billion by 2025 [2]. However, this growth has also resulted in an increase in vulnerabilities in embedded systems. According to recent statistics [6], weekly attacks on IoT devices have increased by 41% per organization in the first two months of 2023 compared to 2022. The threat of IoT vulnerabilities includes numerous vulnerabilities, some [4, 5, 47] of which are easily exploited and impact an average of 14% to 49% of organizations worldwide on a weekly basis. Hence, early detecting vulnerabilities in embedded systems has become crucial. IoT devices with web services are more susceptible to attacks compared to other IoT devices [10]. This is because while web services provide a convenient interface for device control and configuration, they also create opportunities for remote attacks if the underlying backend contains vulnerabilities. Thus, detecting vulnerabilities in IoT devices relying on web services is crucial.

Most existing techniques [7,8,55,59] have limited effectiveness in detecting vulnerabilities in the backend programs of the web services in IoT devices. The testing techniques suffer from low code coverage and only focus on memory-related vulnerabilities. In comparison, static taint analysis is more suitable for detecting a wider variety of vulnerabilities. Taint analysis tracks and analyzes the flow of tainted information in a program, using source, sink, and taint propagation [49]. The source is where user inputs are introduced, the sink is where potentially risky operations occur, and taint propagation analysis examines how tainted markers propagate along variable dependencies in the program. Currently, most researches focus on taint propagation analysis, which employs techniques such as multi-binary tracking or pointer analysis to obtain more efficient and accurate analysis results [12, 38]. However, their effectiveness on embedded systems is not significant. This is because traditional sources such as recv function are not effective in revealing the characteristics of user input entry identification and processing in embedded systems, thereby

missing many potential vulnerabilities.

To address the source identification challenge, a recent advancement in static taint analysis called SATC [10] proposes to leverage common input keywords between the frontend and backend to identify the user input handling code in the backend as sources. It can improve static taint analysis by providing more sources. Nevertheless, SATC misses certain sources (at least 82.5% according to our investigation) because some hidden user input handling code in the backend does not have frontend counterparts and some non-hidden user input entries are ignored due to the incomplete rules used for extracting the keywords. Additionally, SATC still suffers from high false positives (52.7%) for the detected sources due to a lack of awareness of dangling keywords with no/unreachable handling code. The falsely identified sources could affect the result of final vulnerability detection (missing over 87.3% with 75.2% false positives). In conclusion, static taint analysis shows promise in detecting vulnerabilities in IoT web services, but extracting sources systematically remains an open problem.

To mitigate false negatives and false positives in source identification, we conducted a comprehensive analysis of the web services in mainstream devices and made an observation relates to the characteristics of the user input entries. User inputs for the web services are typically encoded as key-value pairs organized by forms or form-like data [22]. Rather than treating all user input entries equally, separating them into URIs and keys enables better utilization of their mapping to identify corresponding backend handling codes and more sources effectively. Maintaining a mapping between them can facilitate the identification of their corresponding backend handling codes. These code of the functions, in turn, can reveal hidden URIs and keys, leading to the discovery of additional sources. However, how to identify sources based on the complex relations among URIs and keys and the corresponding pattern between them and the backend code remains a challenge. Additionally, the semantic information in the backend code can facilitate more precise pattern-based static analysis, such as inferring the purpose of a function. Effectively perform semantic-based analysis and combine it with pattern-based analysis is another challenge.

In this paper, we propose LARA[2], a novel static taint analysis technique for detecting vulnerabilities in embedded systems. LARA utilizes URIs and keys extracted from the frontend to determine their corresponding handling code in the backend. This process is achieved through a combination of pattern-based static analysis and large language model (LLM)-aided analysis, aiming to replicate how human experts perform the identification based on previous experience and code semantics. The pattern-based static analysis leverages predefined rules and pattern matching, which simulates human experience, to address the first challenge. Meanwhile, the LLM-aided analysis performs the identification from the code semantics aspect to address the second challenge, as LLMs have been shown effective for summarizing the semantics of functions [16, 25, 37]. LARA then combines the results obtained from both analyses to generate two sets of codes that handle URIs and keys, respectively. By analyzing the URI and key handling codes, LARA can also identify the other URIs and keys that are handled by the same functions. In this manner, LARA can systematically and precisely identify the key handling functions and use them to extract sources. Regarding sinks, LARA analyzes the primary program and its related shared libraries to identify calls to dangerous operations as sinks. Finally, using the identified sources and sinks, LARA performs the static taint analysis that supports inter-process analysis to detect potential vulnerabilities.

We implemented LARA as a static taint analysis framework and evaluated it on the dataset used by SATC, which includes 203 devices from 21 vendors such as DLink, Tenda, NetGear and others. The evaluation results indicate that LARA can detect significantly more vulnerabilities with fewer false positives than both SATC and KARONTE. Specifically, LARA can detect 556 and 602 more known vulnerabilities than SATC and KARONTE, respectively, while reducing false positives by 57.0% and 54.3%. Additionally, EMTAINT could detect 245 more vulnerabilities with the assistance of LARA. To comprehensively understand the capability of each component in LARA, we also conducted an ablation study and the results showed that the pattern-based static analysis, LLM-aided analysis, and sink extraction can all improve the overall performance. Last but not least, we applied LARA to the firmware dataset for vulnerability detection. In total, we have found 245 0-day vulnerabilities in 57 devices, with all confirmed or fixed by the developers and 162 CVE IDs assigned.

In summary, we make the following contributions:

- We tackle the technical challenges and transform the observation into a novel static taint analysis technique called LARA. LARA can capture sources with low false positive and false negative rates and thus is capable of detecting more vulnerabilities.
- We implemented LARA and comprehensively evaluated its performance in vulnerability detection, source identification and sink identification. The results show that LARA can significantly outperform the state-of-the-art IoT static taint analysis techniques by detecting more vulnerabilities with fewer false positives.
- We discovered 245 0-day vulnerabilities in 57 devices from 13 vendors. To date, all have been confirmed or fixed and 162 CVE IDs have been assigned.

We make the raw data, detailed information and source code of LARA available on the LARA-Site: https://sites.google.com/view/lara-data.

[2]Lara Croft is a fictional archaeologist and adventurer who can use her intuition and perception to spot hidden objects and secrets in tombs and ruins.

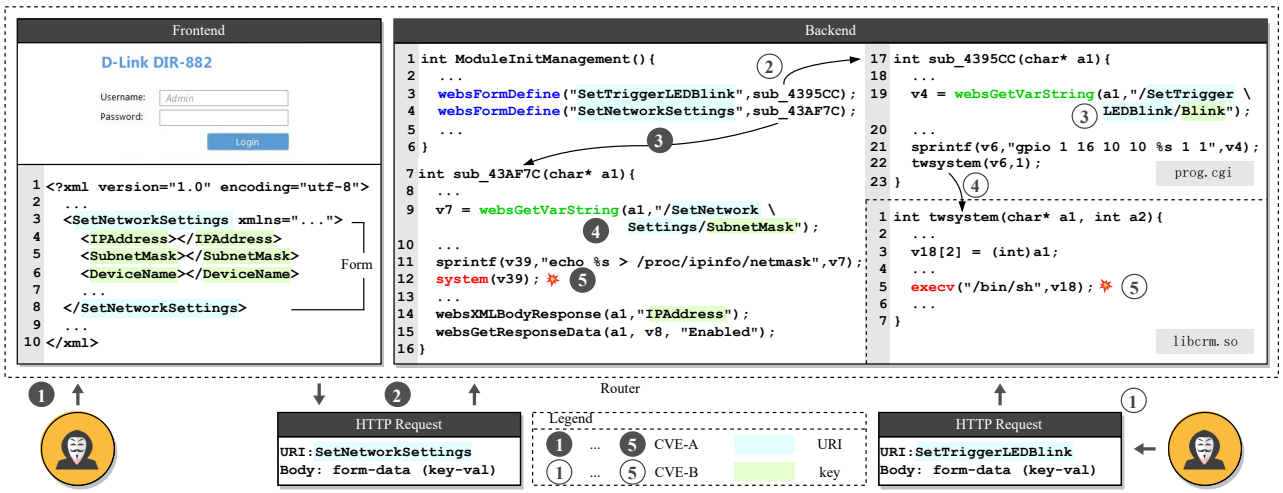

Figure 1: Motivating Example

2 Motivating Example

2.1 Threat Model

In this paper, we focus on attacks against WEB services in embedded systems. The threat model assumes that the attacker can obtain the corresponding firmware from the vendor website and access the target over a local (LAN) or wide area (WAN) network and send malicious HTTP requests to the services. On the service side, the backend programs, including middleware, CGI programs, and related shared libraries, handle these malicious data. Usually, the data in the HTTP request has corresponding labels in the frontend, but there are hidden data without frontend labels in the backend programs. The vulnerability CVE-B shown in Figure 1 is caused by such hidden data. By analyzing the backend program, attackers can obtain these non-hidden and hidden data and then send crafted HTTP requests that inject payloads to the vulnerable backend handling code, leading to consequences like denial-of-service (DoS) and remote-code-execution (RCE).

2.2 Observation

Figure 1 illustrates a motivating example that includes two vulnerabilities detected by LARA in the firmware of the D-Link DIR-882 router. The first vulnerability CVE-A [3] is triggered through the following steps: ❶ The attacker interacts with the web interface (frontend) of the router DIR-882 to configure the *networksettings*. Inside the SubnetMask field, the attacker inputs an injection payload such as ";rm –rf /;". ❷ The frontend generates an HTTP request using the form SetNetworkSettings and the *key-value* pairs encoding the form data. In this case, SetNetworkSettings is filled into the URI [52] field of the HTTP packet, while SubnetMask and the payload are filled into the body field as one of the *key-value* pairs ("SubnetMask=';rm –rf /;'") encoded as form–data [22]. ❸ When receiving the HTTP request, the backend of the router finds the corresponding function to handle it according to the URI value of the form. In this case, the function is sub_43AF7C. ❹ After sub_43AF7C receives the content of the HTTP request, it extracts the values of the keys with specific functions. In this case, the function is websGetVarString. ❺ The backend processes the extracted values as a command and invokes the function system to execute the command, allowing the attacker to execute arbitrary code on the router.

The second vulnerability, CVE-B, can be triggered with the following process: ① The form for this vulnerability is *hidden*, which means there is no corresponding frontend code. Hence, the attacker needs to generate the HTTP request and send it to the backend directly. In this case, the form used by the HTTP request is SetTriggerLEDBlink. ② According to the URI value of the form, the backend invokes the function sub_4395CC to handle the HTTP request. ③ After sub_4395CC receives the HTTP request, it extracts the value for the key Blink. ④ The extracted value is processed to form a command with sprintf and send to the function twsystem. It is worth noting that the function twsystem is not in the main binary of the router (prog.cgi), but instead resides in the shared library libcrm.so. ⑤ Inside the function twsystem, the user-controlled value is executed by execv and the vulnerability is triggered.

Existing techniques have difficulty in identifying vulnerabilities similar to both CVE-A and CVE-B due to omitted sources. To this end, we make an observation of why certain sources are omitted from the examples in Figure 1.

The ***observation*** relates to the characteristics of the user input entries. As shown in Figure 1, some user input entries are *non-hidden* as they have corresponding frontend handling logic (e.g., SubnetMask). In contrast, some user input entries are *hidden* as they do not have corresponding frontend han-

[3] CVE-A is CVE-2022-28896 and CVE-B is CVE-2022-28901.

dling logic (e.g., Blink). The backend handling codes of all the hidden and non-hidden user input entries can be used to extract sources for taint analysis. A state-of-the-art technique, namely SATC [10], suggests using the common keywords extracted from the frontend and backend to identify the sources precisely. Although using the common keywords can help with source identification to some extent, SATC fails to find the sources for both CVE-A and CVE-B. For CVE-A, since SATC uses predefined rules to capture the common keywords and the proposed rules are incomplete, SATC fails to locate the user input entry related to SubnetMask [4]. For CVE-B, since the user input entry lacks corresponding frontend handling code and is not related to a common keyword, SATC cannot detect it. To conclude, a systematic approach is needed to identify the sources, regardless of whether they are related to the hidden or non-hidden user input entries.

2.3 Findings based on the Observation

Based on the observation, we have uncovered two key findings that inspire the design of LARA to enhance taint-based vulnerability detection by identifying more accurate sources.

Finding 1. User input entries can be categorized as URIs or keys. Identifying their corresponding handling codes and relationships can help to identify both hidden and non-hidden user input entries and locate the taint sources.

The first finding pertains to identifying more sources. User inputs are often encoded as key-value pairs that are grouped by forms or form-like data [22]. URIs serve as unique identifiers for these forms, while the keys represent the names of the user input parameters under each form. Figure 2 illustrates the relationships between the URIs and keys in both frontend and backend. In the figure, u and k represent the URIs and keys in the frontend, while U and K represent those in the backend. Though the backend always contains the URIs and keys in the frontend, the inverse is not always true. There are four possible types of relationships between URIs and keys: ❶ both the keys and their corresponding URI are in both frontend and backend; ❷ the URI is in both frontend and backend, but some of the keys related to this URI are only in the backend; ❸ the URI and its related keys are only in the backend; and ❹ the keys do not have any related URIs.

Separating URIs and keys provides two advantages over treating all user input entries the same. Firstly, separating and recombining URIs and keys allows us to avoid counting keys in unreachable functions as sources leading to false postives. These keys are not reachable because they are not linked to any URIs (relation ❹ in Figure 2). Secondly, we can utilize the backend functions that handle URIs to identify the functions that handle keys. By identifying these functions, we

[4]Detailed analysis of why SATC fails to detect CVE-A is in the case study I on the LARA-Site

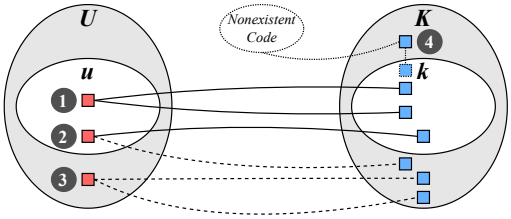

Figure 2: The relationships between the URIs and keys on the frontend and backend.

can uncover both more non-hidden URIs and keys (relation ❶) and more hidden URIs and keys (relation ❷ and ❸).

Although URIs and keys can be categorized as hidden and non-hidden according to whether they are labeled in the frontend, they share similar/same backend handling codes. In the example in Figure 1, we can get the URI SetNetworkSettings from the frontend. In the backend, we can infer that the function websFormDefine maps the URIs to their corresponding handling functions. Through websFormDefine, we can then identify SetTriggerLEDBlink as another URI even though it has no corresponding frontend form. Moreover, from the frontend, we can also see that SubnetMask is a key under the URI SetNetworkSettings. From the code of the function sub_43AF7C, we can see that webGetVarString handles the key SubnetMask, and identify it as a key handling function. Following this, inside sub_4395CC, we can identify Blink as a key under the URI SetTriggerLEDBlink. Therefore, we can use the backend functions and their relations to systematically extract the URIs and keys no matter whether they are hidden or not.

To this end, the rationale for how Finding 1 contributes to improved source identification is clarified, but the key problem in converting it into methodology is how to identify the backend URI and key handling codes. Intuitively, following the analysis of the rationale for Finding 1, we can conclude some patterns to identify these codes to address this challenge. The identification of non-hidden URIs and keys can help identify other hidden and non-hidden URIs and keys by revealing the corresponding handling codes. In the example in Figure 1, the pattern-based static analysis can help to identify websGetVarString (line 9 in prog.cgi) as a key handling function because it takes SubnetMask as a argument. Further, the hidden key Blink will be identified.

Finding 2. Due to the better understanding of code semantics provided by LLM and the differences in false positive sources between LLM-aided analysis and pattern-based static analysis, LLM-aided analysis effectively enhances the identification of more accurate sources.

The second finding pertains to identifying sources with fewer false positives. The results of only using the patterns are still worse than manual analysis because, besides previous experience (pattern), human experts can also understand the semantics of the functions according to the

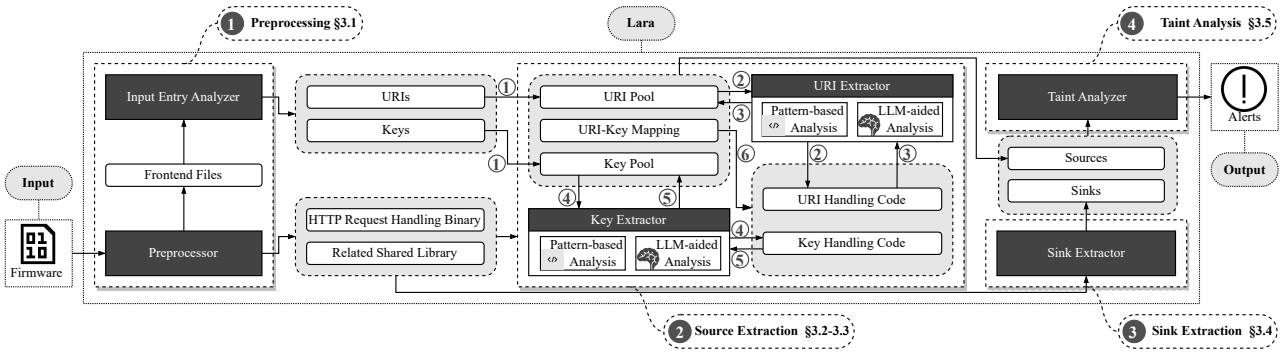

Figure 3: The Overview of LARA

decompiled code with meaningful symbols. For example, in Figure 1, the pattern-based analysis will falsely report websXMLBodyResponse (line 14 in prog.cgi) as a key handling function due to the appearance of IPAddress as a argument. However, through the name of the function, a human expert can easily grasp the semantic of it and realize that it is not a key handling function but a response generation function. Therefore, semantic analyses are necessary. In recent years, deep learning techniques have demonstrated great performance in understanding code semantics [26, 31, 45]. Specifically, the emerging LLMs are superior choices for this task [15, 17, 37, 44]. Therefore, combining the pattern-based static analysis and LLM-aided analysis to mimic how human experts work becomes the design choice of LARA.

Our preliminary analysis of code semantics with LLM reveals a noteworthy finding: Although false positives were present in the results, the sources of false positives in LLM-aided analysis results were distinct from those in pattern-based static analysis results. False positives in pattern-based static analysis are caused by code patterns, while false positives in LLM-aided analysis are due to misleading code semantics, such as symbolic data. For example, in Figure 1, the LLM-aided analysis will falsely report websGetResponseData (line 15 in prog.cgi) as a key handling function due to the function name and the arguments. However, both methods produce accurate results. By taking the intersection of their results, false positives can be eliminated. But effectively combining these two methods remains a challenge. To address this challenge, we designed LLM automatic interaction models and algorithms that combines pattern-based static analysis with LLM-aided analysis to identify more accurate sources.

3 Methodology

Figure 3 depicts the overview of LARA. The input for LARA is the firmware image, and the outputs are alerts for potential vulnerabilities. LARA works in four steps: ❶ ***Preprocessing.*** The preprocessor is in charge of extracting the frontend files and backend files. Mainly, backend files include the binary handling HTTP requests and the related shared libraries. The input entry analyzer extracts the URIs and keys from the frontend. ❷ ***Source Extraction.*** This step involves extracting the URIs from the backend and using the URI information to identify the keys and their handling code. The key handling code is then used to extract the source. For URI extraction, LARA first uses the URIs extracted from the frontend to identify the URI handling code (substeps ① – ② in Figure 3) and then enriches the URI pool (substep ③). Similarly, for key extraction, LARA first uses the keys extracted from the frontend to identify the key handling code (substeps ①,④) and then enriches the key pool (substep ⑤). In addition, LARA also uses the mapping between URIs and keys to filter out unreachable key handling code (substep ⑥). ❸ ***Sink Extraction.*** With a predefined dangerous functions list from system libraries, LARA detects their appearances in the main binary and the shared libraries. The caller functions of the dangerous functions are called the wrapper functions. LARA recursively finds all the wrapper functions, their callers, callers of the callers, and so on, and uses them as the sinks. It is worth noting that taint analysis is utilized to ensure that the parameters of the wrapper functions can affect the danger function calls. ❹ ***Taint Analysis.*** With the sources and sinks, LARA performs static taint analysis and reports alerts for vulnerabilities whenever it encounters connections between sources and sinks.

3.1 Preprocessing

Extraction of Files to be Analyzed. The files are mainly frontend files, backend programs, and related shared libraries. There are three types of frontend files in IoT devices: HTML files, XML files, and JavaScript files. The preprocessor traverses the file system of the firmware and matches file types to extract these frontend files. As for backend files, the preprocessor uses path matching, file type matching, and keyword matching to extract.

Extraction of Input Entries from the Frontend files. The input entry analyzer of LARA uses regular expressions to extract the input entries. Additionally, in LARA URIs and keys are categorized according to the tags or node labels. For

Algorithm 1: Extract URI from Backend Binary

Input: u, the set of URIs extracted form frontend
$\mathcal{B}$, the set of binaries handling HTTP requests
Output: UF, the corresponding set of URI and URI handling function

```
1  BindingTypeI, BindingTypeII, BindingTypeIII ← ∅;
2  UF ← ∅;
3  foreach u_i ∈ u do
4      if {b ∈ B | b.name = u_i.value} ≠ ∅ then
5          BindingTypeIII ←+ u_i;
6      else
7          address ← get_xref(u_i);
8          if address ∈ Segment(".data") then
9              BindingTypeII ←+ address;
10         if address ∈ Segment(".text") then
11             AST ← Decompiler(address);
12             r1 ← LLM_URIAnalysis(address);
13             r2 ← ∅;
14             while visit(AST) do
15                 if is_call(expr) ∧ u_i ∈ expr.arg then
16                     r2 ←+ expr.name;
17                 BindingTypeI ←+ Merge(r1, r2);
18 foreach F_i ∈ BindingTypeI do
19     foreach f_i ∈ get_xref_func(F_i) do
20         AST ← Decompiler(f_i);
21         while visit(AST) do
22             if is_call(expr) ∧ expr.name = f_i then
23                 [u, f] ← get_arg(expr);
24                 UF ←+ [u, f];
25 foreach add_i ∈ BindingTypeII do
26     if [add_i, add_i+offset] ∉ UF then
27         while [add_i, add_i+offset] match [String, Func] do
28             UF ←+ [add_i, add_i+offset];
29             add_i ← next_ins(add_i);
30 foreach b_i ∈ BindingTypeIII do
31     f ← ∅;
32     foreach f_i in b_i.func do
33         if no_xref(f_i) ∨ f_i = "Main" then
34             f ←+ f_i
35     UF ←+ [b_i, f];
36 return UF
```

example, in HTML files, URIs are identified by the action tag, and keys are identified by tags such as input.

3.2 Pattern-based Static Analysis

3.2.1 Extraction of the URI Set

Starting with the URIs extracted from the frontend, LARA extracts URIs from the backend program that handles HTTP requests. This involves two steps: identifying the functions that handle URIs in the program (substep ② in Figure 3) and using these functions to identify more URIs (substep ③). We studied the backend programs of mainstream firmware and found that the code to bind URIs with URI handling functions can be categorized into three types.

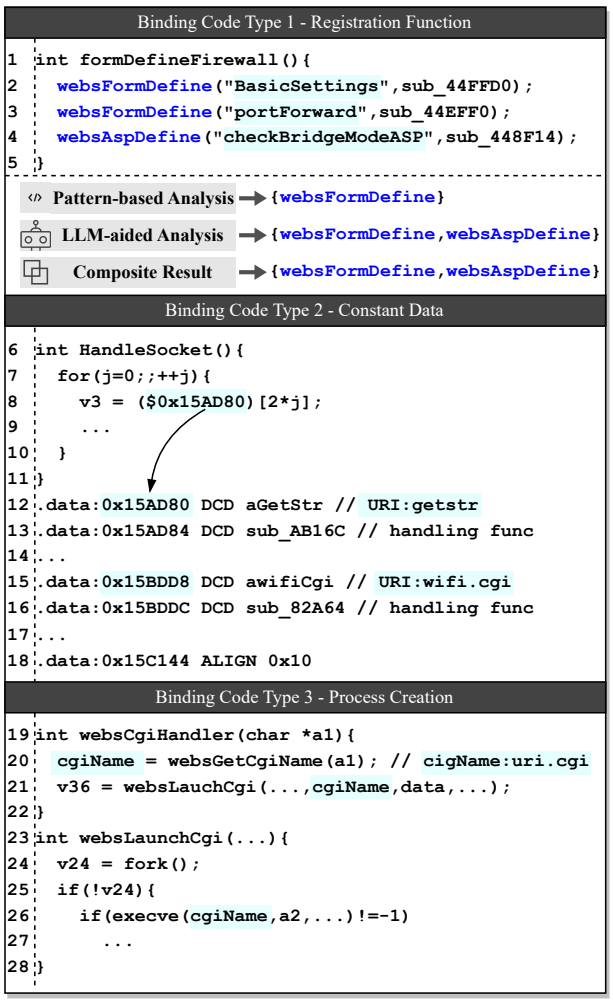

Figure 4: Examples of URI binding code types. The URIs and URI registration functions are marked with blue color.

Binding Code Type I — Registration Function. In line 2 of Figure 4, BasicSettings is an URI, which is an argument for the function websFormDefine, while the other argument is the entry address of the function sub_44FFD0. It means that the request body in the HTTP packet with the URI BasicSettings will be processed in function sub_44FFD0. We refer to functions such as websFormDefine and websAspDefine as *registration functions*, which are mainly used to bind the URIs with their corresponding handling functions.

Binding Code Type II — Constant Data. The Define Constant Data (DCD) instruction in lines 12 to 13 of Figure 4 allocates a continuous memory initialized with the address of the string getstr and the function sub_AB16C to handle the URI getstr. The URI and corresponding URI handling function are stored in pairs in the .data segment memory addresses range of the binary. When receiving an HTTP packet, the program matches the URI by traversing the address range and uses the content of next instruction as the corresponding URI handling function entry address to invoke (lines 6 to 11).

Binding Code Type III — Process Creation. As shown in lines 19 to 28 of Figure 4, the function websGetCgiName extracts the URI from HTTP requests and passes it to the function websLauchCgi as an argument. The function websLauchCgi launches a new process using fork and passes HTTP requests to the new process through an environment variable. This newly launched process handles the user input in HTTP requests, and the launched program is uri.cgi. The corresponding URI handling function resides in the launched program.

Algorithm 1 describes how LARA extracts URIs in detail. LARA utilizes the URIs extracted from the frontend to analyse URI handling code in the program. If an URI value matches a program name that handles HTTP requests, it is classified as the type III (line 5). If the instruction calling the URI is located in the .data segment, it is considered type II. However, as multiple *Address Ranges* may exist, each instruction that operates on the URI string must be recorded (line 9). If the instruction is in the .text segment, it is classified as type I. LARA decompiles the function containing the instruction to generate an abstract syntax tree (AST) (line 11). It then records the function with URI as an argument in AST traversal (lines 14 to 16). Simultaneously, LLM analyzes this code segment (line 12) and merges its results with the results obtained from pattern-based static analysis (line 17).

For type I, LARA decompiles each function containing call registration function instructions and then traverses the AST to resolve the parameters of the registration functions (lines 19 to 24). For type II, LARA traverses upwards and downwards from the instruction calling the URI string address (lines 27 to 29). For type III, the main function and functions without callers are considered URI handling functions empirically (lines 32 to 35). For the main function, the reason is that it's often the handler of the base URI (e.g., upgrade.cgi). For functions without callers, the reason is that some caller-callee relations are lost during the decompilation and we aggressively count functions without callers to avoid FNs.

3.2.2 Extraction of the Key Set

LARA uses a method similar to URI extraction to extract key. When the program parses the HTTP request body, the function that handles these data extracts the value corresponding to the key. For example, in Figure 5, the key time is extracted form the frontend. The function websGetVar extracts the value corresponding to the key time from the HTTP request represented by the wp variable in the URI handling function formSetSchedLed and assigns it to the local variable time_interval. LARA can also extract the hidden key ledCloseType, which cannot be found in the frontend file, through the same key handling function websGetVar.

LARA also needs to make sure that the extracted key is associated with the HTTP request. That is, the function takes the request packet as input and extracts the value matching the key from it, rather than simply comparing or concatenating the key string or extracting the *Key-Value* from other sources such as environment variables or configuration files. In Figure 5, string time is passed as an argument not only to websGetVar but also to strncmp. If whether the key time is relevant to the HTTP request is not checked, strncmp will also be treated as a function that handles keys, which will cause the string close to be incorrectly extracted as a key, maybe leading to a large number of false positives. The solution is straightforward as LARA needs to check if the parameters of the key handling function and the URI handling function have an intersection.

Algorithm 2 describes how LARA extracts keys in detail. At first, LARA decompiles the function which the instruction

Key Handling Code

```
1  int formSetSchedLed(wp,path,query){
2    time_interval = websGetVar(wp,"time","00:00-06:30"); // non-hidden
3    close_type = websGetVar(wp,"ledCloseType","allclose"); // hidden
4    if(!strncmp(old_sched_led_type,"time",4)&&!strncmp(sched_led_type,
5       "close",5)){
6      ResponseResultString = GetResponseResultString(v6);
7      ...
8      respCgiSendResp(v6,v7,"PWD_password",query);
9    }
10   get_mib_2cJSONString(root,"config","w15g.bss.wps.basic_have_config"
11                        ,&wifi_buf_entry);
12   ...
13   return sub_1BB34("PWD_password",query);
14 }
```

Pattern-based Analysis → {websGetVar,respCgiSendResp,strncmp,sub_1BB34}

LLM-aided Analysis → {websGetVar,get_mib_2cJSONString,GetResponseResultString}

Composite Result → {websGetVar}

Figure 5: An example of key handling code.The keys and key handling functions are marked with green color.

Algorithm 2: Extract Key from Backend Binary

Input: k for the key set extracted from frontend
UF for the corresponding set of URI and URI handling function
Output: $KFunc$ for the key handling function set
UK for the URI, key corresponding set

1 $KFunc \leftarrow \emptyset$;
2 $UK \leftarrow \emptyset$;
3 **foreach** $k_i \in k$ **do**
4 **foreach** $f \in get\_xref\_func(k_i)$ **do**
5 $r1, r2 \leftarrow \emptyset$;
6 $AST \leftarrow$ Decompiler(f);
7 $r2 \leftarrow$ LLM_KeyAnalysis(f);
8 **while** *visit(AST)* **do**
9 **if** *is_call(expr)* **then**
10 **if** $k_i \in expr.arg \wedge f.arg \cap expr.arg \neq \emptyset$ **then**
11 $r1 \xleftarrow{+} expr.name$;
12 $KFunc \xleftarrow{+} r1 \cap r2$;
13 **foreach** $[u_i, f_i] \in UF$ **do**
14 $AST \leftarrow$ Decompiler(f_i);
15 $\mathcal{K} \leftarrow \emptyset$;
16 **while** *visit(AST)* **do**
17 **if** *is_call(expr)* $\wedge$ $expr.name \in KFunc$ **then**
18 $\mathcal{K} \xleftarrow{+}$ getStringArg($expr$);
19 UK $\xleftarrow{+} [u_i, \mathcal{K}]$;
20 **return** $KFunc, UK$

calling the key and generates the AST for the function (line 6). LARA records the function that handles HTTP requests and takes the key as an argument by traversing the *AST* (lines 8 to 11). Simultaneously, LLM analyzes this code segment (line 7) and the intersection of its results with pattern-based static analysis is taken as key handling functions (line 12). Then, LARA extracts the key set using the key handling functions. The key set is extracted separately in each URI handling function and associated with its corresponding URI record. To extract the key, LARA traverses the AST generated by decompiling the URI handling function and analyzes the parameters called by the key handling function (lines 16 to 18).

3.3 LLM-aided Analysis

Large language model can effectively enhance the effectiveness of pattern-based static analysis through code semantics comprehension. It can help reduce false positives(FPs) and false negatives(FNs) in the extraction results of URI and key.

LLM-aided analysis can identify more URI registration functions for URI binding code type I with clear code structures. As shown in Figure 4, due to the limited URI extracted from the frontend (substeps ① in Figure 3), pattern-based static analysis can only identify websFormDefine. But LLM-aided analysis can effectively identify all registration functions, namely websFormDefine and websAspDefine.

LLM contributes more on reducing FPs when extracting keys. In Figure 5, function formSetSchedLed handles key time and ledCloseType, and the real key handling function is websGetVar. Pattern-based static analysis and LLM-aided analysis generate FPs in their respective results. Due to the presence of two strings password and PWD_password extracted in the frontend, so when functions respCgiSendResp, strncmp and sub_1BB34 conform to the code patterns, they will be mistaken for key handling functions by pattern-based static analysis. For LLM-aided analysis, some misleading symbols lead to false positives. Arguments wl5g.bss.wps.basic_have_config and wifi_buf_enty misled the judgment of LLM, leading the function get_mib_2cJSONString to be misidentified as key handling function. Additionally, the function GetResponseResultString was mistaken due to the function name. However, despite the misleading arguments PWD_password and query, the function sub_1BB34 is not considered as a key handling function. This is because LLM also takes into account the code structure and contextual information of the function. It is worth noting that FPs in both cases have inconsistent reasons, so intersecting the results can effectively eliminate them. As shown in §2.2 on the LARA-Site, the pattern-based static analysis extracted 1,032 key handling functions, the LLM-aided analysis extracted 1,206, but only 388 were in both sets.

We designed corresponding LLM interaction models for extracting URIs and keys based on the LMQL [3], enabling LLM-aided analysis to produce valid results without manual interactions. The model consists of three parts three components: the **query** clause, the **from** clause and the **where** clause. The Figure 6 shows the model for automatically identifying URI registration functions. The **query** clause serves as the core and models the process of interaction with LLM. In the query clause, the text [CoT Prompts] [51] marked with blue color serves as specific few-shot examples that can be referred to when LLM runs. The text marked with green color indicates the parsed answers retrieved from LLM or the calls on them. For unmarked text, the content within quotation marks serves as prompts for interacting with LLM, which prompts can be a combination of strings and previous results, while the rest consists of Python programming statements, which also makes use of control-flow and branching behavior. The **from** clause denotes which LMQL backend to use, like GPT-3 model available via the OpenAI API [35]. The **where** clause directly operates on tokens, constraining the LLM in what it can generate. Constraints can be an arbitrary conjunction or disjunction of condition expressions which allow comparison and membership checks between standard python expressions [3]. For the example on line 16 in Figure 6, STOPS_AT(A2, "YES") expresses when the answer A2 is decoded, the decoding should stop as the specified phrase "YES" is encountered. In summary, the process of LLM-aided analysis is controlled by the Python programming statements in the **query** clause. When sending the prompt, the LMQL backend specified by the **from** clause is selected, and the answer of LLM is parsed according to the constraint defined in the **where** clause. Figure 7 shows the model for automatically identifying key handling functions, with the same underlying concept but a different design.

LLM interaction model for extracting URI Registration Function

```
1  query:
2    [CoT Prompts]
3    f = Locate_function(URI_reference_address)
4    "Analyze the function f pseudocode and identify each called function"
5    funcs = []
6    "[FUNCs]"
7    funcs += (FUNCs.list())
8    result = []
9    for func in funcs:
10     "Whether the function func is with registration functionality?"
11     "[A2]"
12     if A2 == "YES":
13       result.append(func)
14 from "GPT-3"
15 where
16   FUNCs over OPTIONS.split(",") and
17   STOPS_AT(A2, "YES")OR STOPS_AT(A2, "NO")
```

Figure 6: The Model for extracting URI Registration Function.

Prompt Design. For URI registration function, prompts check if the code fragment referencing a URI includes a function with registration functionality. For key handling function, prompts first check if the function arguments originate from HTTP requests, then infers from the code implementation whether the primary purpose of the function is to retrieve some information and assign a value.

Merge Operation. For URI binding code type I, LARA first

```
int save_encrypted_data(char *a1, char *a2){
    memset(s, 0, 0x200);
    snprintf(s, 0x200, "echo -n %s | openssl ... -out %s",
    ↪ a1, a2);
    return popen(s, "r");
}
```

Listing 1: An Example of the Wrapper Function

takes the intersection of the results of pattern-based static analysis and LLM-aided analysis to identify potential URI registration functions. Any additional results identified by LLM-aided analysis are then evaluated to determine if they conform to the code patterns, i.e., having one string and one function as parameters. For type II and III, pattern-based static analysis is sufficient on its own, as LLM involvement offers minimal benefits. For key handling function, the intersection of LLM-aided analysis and pattern-based static analysis results is taken. While LLM-aided analysis provides additional results compared to pattern-based analysis, these additional results cannot be verified using valid code patterns and are therefore discarded. This approach leads to a small and acceptable number of FNs (explained in §C).

3.4 Sink Extraction

The sinks are operations that may violate security rules leading to vulnerabilities when supplied with distrusted inputs. We categorize these sinks into function-call sinks, which include dangerous functions from standard library and their wrapper functions, and non-function-call sinks.

Some dangerous functions may not be invoked directly. Instead, they are wrapped up by some wrapper functions in either the main binary or shared libraries. Wrapper functions may pertain to a straightforward but easily overlooked scenario where the dangerous function that triggers the vulnerability is not in the same binary as the code that handles user inputs. It is worth noting that this scenario differs from the multi-binary scenario that KARONTE [38] addresses, as there is no inter-process communication involved. Listing 1 illustrates a wrapper function, save_encrypted_data, defined in a shared library and used to save encrypted data by dangerous function popen, which poses a command injection risk. In the case of CVE-B in Figure 1, the absence of the corresponding sink twsystem is also one of the reasons why SATC cannot detect this vulnerability. To date, all existing techniques have overlooked this type of sinks, resulting in the failure to detect many vulnerabilities. Therefore, the program and its shared library should be analyzed when extracting sinks. The dangerous function calls can be detected via function name matching, while for wrapper functions, we can collect all related programs and shared libraries, then recursively extract the wrapper functions of the dangerous functions. When analyzing wrapper functions, there may be multiple layers wrapper functions. Therefore, we have designed two strategies to improve accuracy of extracting wrapper functions in the backend programs and its shared libraries recursively. ❶ Using taint analysis ensures that the input to the dangerous function is user-control. ❷ Filtering out the wrapper functions which do not include any URI or key handling code.

It is worth noting that directly analyzing shared libraries during taint analysis and extracting wrapper functions from the shared libraries as sinks have the same effect. However, pre-analyzing shared libraries to extract wrapper functions can reduce the overhead caused by repetitive propagation and locating functions within the shared library.

For non-function-call sinks, vulnerabilities are caused by direct variable operations, which may affect the contents of variable values, the positions of array reads, the number of controlled loop iterations, and so on. Non-function-call sink can also exist within shared libraries, and it can be identified simultaneously during the process of extracting wrapper functions through taint analysis.

3.5 Taint Analysis

LARA uses a key-sensitive taint analysis engine to analyze the backend program that handles HTTP requests and tracks the data flow of the user input entries to detect potential vulnerabilities. The engine can decompile program binaries to produce AST and traverses the AST to propagate the taint information and detect security issues.

The Taint Source. During the analysis process, a taint source is considered to be the variable to which the value corresponding to the key is assigned. This variable can be an argument or a return value of the function.

Taint Tracking. Taint analysis begins at the URI handling function where the processing of the HTTP request body begins. Based on the AST, LARA can quickly obtain the type of each data and operation during the taint propagation process. We have defined a variable triplet consisting of the *taint property*, *allocated memory or value*, and *maximum allocatable memory* to record the state of each data. The taint property is categorized as *uninitialized*, *tainted*, and *not_tainted*. LARA leverages this triplet to record the memory size and taint property changes of each affected array, pointer, writable global variable, and data in classes and structures.

Taint Analysis. Taint propagation rules involve intra-function and inter-function propagation. Intra-function propagation is path-sensitive and utilizes ASTs and forward analysis to track data flow. It performs separate taint propagation for different branches and summarizes the results at branch convergence points. Taint status is assigned as tainted if a variable is tainted within a branch. Inter-function propagation follows the rules of analyzing only function calls with taint property parameters and categorizing functions into dangerous, imported, and general types for separate analysis. Dangerous functions, including standard library functions and their wrapper functions, are used as sinks and analyzed based on predefined rules. For

imported functions, LARA forcefully sets taint properties of return values and parameters to tainted. Although this may lead to errors in taint propagation, it also reduces the overhead caused by analyzing those functions in detail. For general functions, LARA decompiles them based on their entry addresses and performs taint analysis on the ASTs, propagating taint to variables corresponding to function parameters with taint attributes. And LARA determines the presence of vulnerabilities in the function based on contextual information before and after function calls and records whether other function parameters and return values are tainted.

Vulnerability Detection. LARA checks variable triplet and determines if a vulnerability can be triggered based on the sink models. Non-function-call sink models and dangerous standard library function sink models are predefined. Wrapper function models are extended based on the results of wrapper function extraction. LARA checks constraints when tainted data reaches a sink. For example, it assesses buffer overflow risks at strcpy by evaluating buffer constraints from functions like memset and stack length. Constraints from strncpy-like functions are also considered. Additionally, LARA evaluates other constraints, such as the impact of %s and %d on string formatting result, and only the first parameter of execv can lead to command injection vulnerability.

4 Evaluation

Implementation. We implemented the LARA prototype with over 10,200 non-comment lines of Python code. LARA leverages several other existing libraries or tools. The keyword analyzer is based on the standard XML processing library and JavaScript parsing library Js2Py [14]. All data flow analysis, including pattern-based static analysis, sink extractor and taint analyzer, is implemented using the disassembly engine of IDA Pro [20], which supports the analysis of programs across different architectures and the IDAPython [21] plugin. We implemented LLM-aided analysis using the LMQL model written in Python [42] and by invoking the GPT-3 model through the OpenAI library [35]. LARA focus on detecting memory-corruption vulnerabilities and command injection vulnerabilities, but also supports format string vulnerabilities, path traversal and other taint-style vulnerability detection.

Evaluation Questions. We evaluated LARA on real-world embedded systems to answer the following research questions (RQs):

- **RQ1.** How is the performance of LARA comparing with the state-of-the-art tools? (§4.2)
- **RQ2.** How effective each part of LARA is for discovering vulnerabilities? (§4.3)

4.1 Evaluation Setup

Dataset. To evaluate LARA, we collected samples from SATC [10], KARONTE [38], EMTAINT [12], FIRMAE [27] and other real-world devices as firmware dataset. The dataset comprises 203 firmware samples from 21 vendors, including 10 different device types, covering 80 Routers, 37 APs, 20 Switches, 19 IPCameras, 17 Firewalls, 11 Range Extenders, 6 VPNs, 6 Modems, 4 Bridges, 3 NAS. The selection process was guided by several crucial criteria, including popularity, frequency of being tested, development activeness, and functionality diversity. To have a fair ground truth, we collected all known buffer overflow vulnerabilities and command injection vulnerabilities that exist in these firmware samples from CVE records [13], while filtering out vulnerabilities without detailed information. For example, AXIS have no relevant vulnerabilities, whereas most of the vulnerability information for NetGear and Zyxel is not publicly available. In the end, we totally collected 646 known vulnerabilities, as illustrated in the fourth column in TABLE 2. Furthermore, we manually determined the URI binding code type for each vulnerability and checked whether the source was from hidden data. Our findings indicate that the dataset comprehensively covers all types of URI binding code, and that 84 of 645 vulnerabilities were attributable to hidden data.

Baselines. We compared LARA with three SOTA tools and various variants of LARA presented in TABLE 1. KARONTE [38], SATC [10] and EMTAINT [12] are the most relevant tools, while the variants of LARA are used to demonstrate the benefits of each technique in the paper.

- KARONTE, which focuses on vulnerabilities caused by interactions between multiple binaries. Its idea was integrated by SATC and LARA.
- SATC, which uses sources extracted from the frontend, and sinks are predefined functions.
- EMTAINT, which utilizes on-demand alias analysis to enhance taint tracking. Its sources and sinks are predefined.
- LARA-Sink, which uses the same sources with SATC and the sinks provided by sink extraction. Comparing LARA with this variant helps to evaluate the effectiveness of the sink extraction module (§3.4).
- LARA-Key, which considers key pattern to extract sources and uses the same sinks with SATC. Comparing LARA with this variant helps to evaluate the effectiveness of the key-pattern analysis module (§3.2.2).
- LARA-Pattern, which combines URI and key patterns to

Table 2: Vulnerability Detection Result of LARA and SOTAs on the Dataset. (x(y) means #All(#Hidden). "Prec." and "Reca."Indicate Precision and Recall, respectively. Time is overall analysis time which unitIs min.)

extract sources and uses the same sinks with SATC. Comparing LARA with this variant helps to evaluate the effectiveness of the pattern-based static analysis module (§3.2).

- LARA-LLM, which only adopts LLM-aided analysis to extract sources and uses the same sinks with SATC. Comparing LARA with this variant helps to evaluate the effectiveness of the LLM-aided analysis module (§3.3).
- LARA-Combined, which combines pattern-based static analysis with LLM-aided analysis to extract sources and uses the same sinks with SATC. Comparing LARA with this variant helps to evaluate the effectiveness of the entire source extraction module.

Configurations. LARA and its various variants were executed on a host machine with an 8-core Intel Xeon Processor and 128GB of RAM running the Ubuntu 18.04 operating system. Firmware analysis was conducted and any analysis exceeding 8 hours was recorded as 8 hours.

4.2 RQ1: Comparison with the SOTA tools

We conducted a comparative analysis between LARA, SATC and KARONTE, focusing on their capabilities in finding known vulnerabilities, extracting source and sink information, and incurring time overhead.

Overall Results. TABLE 2 presents the results of LARA, SATC and KARONTE on firmware samples. LARA identified 780 potential vulnerabilities, with a precision of 81.8%. It missed 8 vulnerabilities, having a recall of 98.8%. On the other hand, SATC reported 331 potential vulnerabilities with a precision of 24.8%. Moreover, SATC achieved a low recall of 12.7%. KARONTE reported 131 potential vulnerabilities with a precision of 27.5% and a recall of 5.6%. In particular, all vulnerabilities detected by SATC and KARONTE are covered by LARA. In summary, LARA significantly outperformed SATC and KARONTE concerning precision and recall in detecting vulnerabilities in firmware samples; i.e., it improved the precision of SATC by 57.0% and KARONTE by 54.3%, while improving recall by 86.1% and 93.2%.

Regarding detecting of vulnerabilities triggered by hidden data, LARA successfully identified 83 of 84 vulnerabilities, while SATC only caught one. Upon further manual analysis, we discovered that SATC only coincidentally identified the vulnerability. This is because the key which caused the vulnerability was also in the frontend file, but with a different corresponding URI. SATC only analyzed the key, resulting in the detection of the hidden vulnerability.

FP Analysis for LARA. We analyzed all false positives in LARA, and summarized two reasons. 105 false positives occurred due to LARA disregarding critical key operations between the source and sink, like filtering or format-checking functions. For example, a string check on user input filters out certain special characters to avoid command injection vulnerabilities. However, incomplete filtering can be bypassed leading to command injection vulnerabilities. Vulnerability CVE-2022-45996 that found on Tenda W20E by LARA allows for command injection using the character $, despite the code checking for characters ; \ &. Additionally, incorrect identification of sinks leads to 37 false positives. This includes cases where conditional checks are used in wrappers functions to prevent data from reaching dangerous functions.

FN Analysis for LARA. 8 vulnerabilities were not detected by LARA due to either the complex inter-process communication (IPC) method or problems with the disassembly engines itself. Some embedded systems use complex IPC communication methods without keywords, leading to untraceable inter-process data flows and resulting in 3 false negatives. In addition, some functions cannot generate pseudo-code due to the disassembly engine itself, specifically missing function parameters, which prevents regular data flow analysis. After manual intervention and testing, the pseudo-code was

Table 3: Overall Comparison Results of LARA with Baselines.

	EnhanceII	47	231	599	16.9%	7.3%

fixed, and LARA could detect these five previously missed vulnerabilities. An in-depth investigation of the URIs and keys responsible for these vulnerabilities revealed that LARA had identified them already.

FP and FN Analysis for SATC. The false positive is caused by imprecise identification of key in the backend binary and harmless processing operations. First, the key extracted by SATC is called at multiple locations, where only one represents a controllable user input while the others are uncontrollable strings. A path from an uncontrolled string to a dangerous function may lead to a false positive. Second, some keys are in unreachable functions. However, for LARA, these false positives can be avoided by separating and recombining URIs and keys and extracting the key through key handling code. Additionally, Our manual analysis of false negatives for SATC found two primary reasons: SATC failed to extract some non-hidden or hidden keys and lacked certain sinks. Out of 563 vulnerabilities not found compared with LARA, 441 were caused by failure to extract corresponding keys, 105 were due to the lack of sinks, and 17 were attributed to the absence of both keys and sinks.

FP and FN Analysis for KARONTE. KARONTE focuses on the shared data between binaries but ignores on the entry points of the user input. Thus uncontrolled sources (such as fgets) lead to most false positives. The dataset contained a total of 58 IPC vulnerabilities, out of which KARONTE failed to detect 22. Among these, 13 were attributed to unrecognized IPC paradigms (such as apmib_set and apmib_get), while the remaining 9 were due to a lack of sources.

Time Overhead. The analysis time overhead of KARONTE, SATC and LARA is presented in TABLE 2. It shows that LARA requires less time than SATC and KARONTE. Overall, the total analysis time was reduced by 65.5% and 63.1%.

Source Extraction. TABLE 3 presents an overview of the URI and key extraction results obtained by LARA in the dataset. LARA extracted a total of 27,781 URIs and 102,905 keys from the dataset with a precision of 99.8% and 99.7%,

Table 5: Results of Sink Extraction in the Dataset by LARA.

Sample	Type	#Sink Func.	Max Wrap Times	FP
DLink DIR816	Router	9	2	1
Tenda AC9	Router	12	3	0
TOTOLink A7100RU	Router	31	3	2

H3C H100	AP	23	3	1
TRENDnet TV-IP110WN	IPCamera	2	2	0
Cisco RV110W	FireWall	18	2	0
Draytek G1282	Switch	21	3	2
Total	—	**158**	—	**10**

including 9,299 hidden URIs and 15,411 hidden keys. In contrast, SATC identified 5,201 URIs and 34,081 keys with a precision of 83.2% and 52.7%. Additionally, LARA detected 23,385 more URIs and 84,638 more keys than SATC, representing an increase of 5.4 times and 4.7 times. This indicates that some non-hidden data is not being detected by SATC, due to the incomplete keyword matching rules employed.

Sink Extraction. TABLE 5 presents the Sink extraction results of 8 firmware samples. The samples were selected based on the number of known vulnerabilities collected make sure that they come from different vendors or device types. LARA identified 158 such functions in 8 firmware samples, with 10 false positives identified with manual analysis, indicating a precision rate of 93.7%. These false positives are caused by ignoring data checks, i.e., the wrapper functions may check the data, leading to the user-controlled data not reaching the dangerous operations. The maximum number of wrapper function calls for these dangerous functions was 3, highlighting the significance of identifying them.

Enhanced EMTAINT Evaluation. To better assess the impact of additional sources and sinks, we conducted an analysis of EMTAINT that utilizes SSE-based on-demand alias analysis technique to enhance the analysis in embedded systems. As shown in TABLE 4, EMTAINT could find 14 known vulnerabilities. The uncontrolled sources, disregarding sanitizer operations cause false positives, while incomplete recognition of indirect calls and IPC methods lead to false negatives. With more sources from LARA and SATC, EMTAINT-EnhanceI could detect 212 and 45 vulnerabilities. Meanwhile with more sources and sinks from LARA and SATC, EMTAINT-EnhanceII could detect 259 and 47 vulnerabilities. Note that EMTAINT only used the provided sources and sinks in the enhanced evaluation. The results proves that our source and sink extraction methods are more effective than SATC, which leads to higher precision and higher recall.

Summary to RQ1: The performance superiority of LARA is evident. Compared with SATC, LARA detected 556 more vulnerabilities, extracted 5.4 times more URIs and 4.7 times more keys, and incurred 65.5% less time overhead. Compared with KARONTE, LARA detected 602 more vulnerabilities and incurred 63.1% less time overhead. With more sources and sinks from LARA, EMTAINT could detect 245 more vulnerabilities.

4.3 RQ2: Ablation Study

Contribution of Source Extraction. To evaluate the contribution of source extraction, we compared variants of LARA with SATC. The detailed results are represented in TABLE 3. Specifically, compared with SATC, LARA-Combined (with the same sink) detected an additional 422 vulnerabilities, thus achieving a 58.8% and 65.3% improvement in precision and recall, respectively. This can be attributed to the fact that LARA-Combined extracted 23,385 more URIs and 84,638 more keys than SATC while maintaining a higher precision rate. The detection of additional vulnerabilities was facilitated by both pattern-based static analysis and LLM-aided analysis, which contributed to an increase in precision. Specifically, with pattern-based static analysis enabled, LARA-Pattern identified 498 true vulnerabilities, achieving a precision rate of 72.7%. Similarly, with LLM-aided analysis enabled, LARA-LLM detected 504 true vulnerabilities, albeit with a precision rate of 73.0%. However, by combining these two methods, the precision rate improved significantly to 83.6%. Meanwhile, extracting key based on URI has been shown to enhance the precision of vulnerability detection, as evidenced by the data presented in the third and fourth row in TABLE 3. Specifically, compared to LARA-Key, LARA-Pattern improved the precision by 9.0% with regards to vulnerability detection and 5.1% in terms of key identification.

Contribution of LLM-aided Analysis. LLM-aided analysis contributes more on reducing the FPs than reducing the FNs. TABLE 3 shows that compared with LARA-Pattern, LARA-Combined reduces the FPR of vulnerability detection by 10.9%, the FPR of URI registration function identification by 57.9%, the FPR of key handling function identification by 61.6%, and the FPR of keys by 33.9%. Meanwhile, LARA-Combined reduces the FNs by detecting 6 more vulnerabilities, 52 more URI registration functions, 2,745 more URIs, and 164 more keys. Detailed data as show in §2.2 at LARA-Site, LLM-aided analysis detects more registration functions, leading to more URIs extracted in 44 firmware samples. Combining pattern-based static analysis and LLM-aided analysis, the key handling functions of 196 firmware samples were manually confirmed to be completely accurate.

FP Analysis for Source Extraction. There are 5 FPs in the combined results of key handling functions, which leads to 308 FPs of keys. Further analysis of the misstated keys showed that they lead to no FPs in vulnerability detection.

Table 6: 0-Day Vulnerabilities Discovered by LARA.

Vendor	#Series	#0-Day Vuln			#Hidden	#Wrapper Func.
		LARA	SATC	KARONTE		
Tenda	8	81	26	1	5	3
TOTOLInk	16	48	0	0	6	23

ASUS	3	3	0	1	0	0
Cisco	2	3	0	0	0	0
Zavio	1	2	0	0	0	0
NetGear	1	1	0	0	0	0
Total	**57**	**245**	**36**	**11**	**32**	**52**

Contribution of Sink Extraction. Each sink has the potential to lead to a vulnerability with user-controllable data . The results presented in TABLE 3 indicate that LARA-Sink has identified 86 additional vulnerabilities in comparison to SATC. Moreover, LARA has identified 134 more vulnerabilities compared to LARA-Combined. This proves that sink extraction can effectively improve the ability to discover vulnerabilities. Despite a slight decrease in precision of 1.8%, it's an acceptable trade-off due to improved vulnerability detection.

Summary to RQ2: The evaluation proves the effectiveness of every component of LARA. Source extraction and sink extraction significantly contributes to detecting 556 additional vulnerabilities. Furthermore, the utilization of LLM-aided analysis and URI-pattern analysis helps to minimize FPs and FNs in the extraction of URI and key, resulting in a notable improvement in precision by 57.0%.

4.4 RQ3: Real-world Vulnerabilities

We also applied LARA to detect unknown vulnerabilities of the firmware dataset in the wild. Each vulnerability was verified on the latest version of the firmware sample. As illustrated in TABLE 6, LARA uncovered a total of 245 previously unknown vulnerabilities. So far, all 245 vulnerabilities have been confirmed by the corresponding vendors, and 162 of them have been assigned CVE IDs following responsible disclosure. Among these confirmed vulnerabilities, 32 (13.1%) were due to hidden data, and 52 (21.2%) were caused by dangerous wrapper functions.

Meanwhile, SATC and KARONTE were applied to analyze these firmware samples. The results were disappointing, with 36 and 11 vulnerabilities detected. Furthermore, after analysis of the vulnerabilities that not detected by SATC, LARA detected 32 more vulnerabilities caused by hidden data, at least 125 more vulnerabilities caused by non-hidden data and 52 more vulnerabilities caused by wrapper functions.

Summary to RQ3: LARA identified 245 vulnerabilities on different devices, including vulnerabilities caused by hidden or non-hidden data and multi-layer wrapper functions.

5 Discussion and Limitation

Adaptation for Other Protocols. Our evaluation focuses on detecting vulnerabilities caused by the HTTP protocol in the embedded systems. We also analyzed vulnerabilities caused by other key-value pairs-based protocols. LARA can detect vulnerability CVE-2021-27239 caused by the SSDP protocol and vulnerabilities [28] caused by the DHCP options field using methods similar to pattern-based static analysis.

Sanitizer for Taint Analysis. Some false alarms are often caused by incomplete consideration of user input legitimacy checks. Some operations, such as type conversion and length check, have been considered. However, some checks can be bypassed, such as CVE-2022-45996 mentioned in §4.2.

Unique Advantages of Taint Analysis. For fuzzing, black-box testing targeting real devices faces challenges in code coverage and crash monitoring. The web program of some devices restarts quickly after crashing, making it difficult to judge the crash through response packets. Additionally, some devices cannot be accessed by shell, which also brings difficulties to monitoring. Meanwhile, emulation-based fuzzing is limited by the success rate of emulation [53]. FIRMAE [27] successfully emulated 892 out of 1,124 firmwares. Out of 102 randomly selected firmwares from 1,124, FIRMAE determined that 80 were successfully emulated, but after manually confirmation, only 45 met the fuzzing requirement. Furthermore, the setup of specific complex functions is necessary before they can be tested. For symbolic execution, it requires a lot of time to solve constraints and explore paths. However, Time overhead is also an important criterion for evaluating the efficiency of static analysis. TABLE 2 shows that SATC still has significant time costs even when analysis paths are provided for the symbolic execution engine. Taint analysis is more efficient for complex data flows and diverse data structures, and IDA pro [20] provides a well-structured AST to support pseudocode analysing.

Threat to Validation. First, LARA only supports backend programs developed with C and C++. Second, the precision of the disassembly engine may impact the outcomes of data flow analysis for intricate program. Third, there may be potential errors in the labeling/ground truth manually confirmed.

Responsible Disclosure. We have responsibly disclosed all vulnerabilities we found. We provided detailed information and PoC to the vendors for each vulnerability, facilitating them to confirm and reproduce the vulnerability.

6 Releated Work

Static Analysis. Various static analysis techniques [30, 32, 57] have been developed to detect IoT vulnerabilities. Karonte [38] tracks interactions between multiple binaries, but overlooks user input resulting in many false positives. SATC [10] extends Karonte [38] by focusing on the frontend user input, but it is not enough. DTaint [11] detects taint-style vulnerabilities in firmware using pointer aliases, inter-procedural data flow, and data structure layout similarities, but also overlooks the backend logic. EmTaint [12] comes up with indirect call resolution and accurate taint analysis scheme based on a structured symbolic expression-based on-demand alias analysis technique. However, EmTaint only strengthens the analysis of function pointers and cannot pinpoint precise source in the program to guide the discovery of more vulnerabilities. Firmalice [41] uses concolic execution and program slicing to detect authentication bypass vulnerabilities in firmware, but the constraint solver limits its effectiveness. NeuTaint [40] tracks information flow using neural program embeddings and performs better than other taint analysis tools. They all miss many sources and sinks, which leads to numerous undetectable vulnerabilities.

Dynamic Analysis. Many works are based on fuzzing techniques [50, 55, 58] to detect vulnerabilities in IoT devices. SRFuzzer [59] and IoTFuzzer [8] employ black-box fuzzing to detect vulnerabilities. Simulation-based fuzzing has also become a research trend to reduce costs, with FirmAFL [60] and Fuzzware [39] improving on the simulation method of Firmadyne [7]. Static analysis techniques have been combined with fuzzing to improve testing efficiency [9, 33, 43]. Other works [18, 23, 54, 56] focus on firmware rehosting or verifying specific vulnerabilities. However, they suffer from low code coverage and only focus on memory-related vulnerabilities.

LLM for Program Analysis. With the popularity of LLMs, many researchers have begun to focus on their applications in program analysis, particularly in vulnerability detection [1, 34, 46, 48], program repair [24, 36], software testing [16, 17, 29] and program comprehension [19]. In addition, the work [37] has surveyed the assistance of GPT models in reverse engineering and reports promising results.

7 Conclusion

In this paper, we proposed LARA, a novel static taint analysis technique for detecting vulnerabilities in embedded systems by leveraging semantic relations in code and data, which is motivated by two key findings. First, user input entries can be classified into URIs or keys. Analyzing their relations and correspondence between the frontend and backend can systematically locate more sources. Second, due to the distinct sources of false positives between LLM-aided analysis and pattern-based static analysis results, LLM-aided analysis based on code semantic comprehension can effectively help to identify more accurate sources. The evaluation indicates that, in comparison to other state-of-the-art tools, LARA has a clear advantage in detecting more vulnerabilities with fewer false positives. Moreover, LARA identified 245 vulnerabilities in popular real-world embedded system firmwares, including 162 CVE IDs.

A Case Study

LARA-Site provides a detailed analysis of previously undisclosed vulnerabilities from various sources, including non-hidden data, hidden data, and multi-layer wrapper functions.

B Rules Adopted by SATC and LARA

The URI and key identification rules adopted by LARA and SATC are specifically listed to illustrate their differences and clarify the gaps.

- **URI identification rules**: For URI binding code I, SATC introduces a URI-like concept but doesn't link URIs and keys for vulnerability detection or analyze backend code for them. LARA take this into account. For identification rules defined in URI binding code II and III, they are unique to LARA.
- **Key identification rules**: SATC only uses the backend location of the shared keywords extracted from the frontend as the source. LARA first identifies the key handling function and then extracts the key in the backend, taking into account the corresponding pattern of URIs and keys.
- **LLM-aided analysis rules**: LLM-aided analysis identifies registration functions as URI handling functions and identifies functions that retrieve information from HTTP requests as potential source functions. This feature is unique to LARA.
- **Handle unreachable keywords through URIs**: This rule is adopted both by LARA and SATC, but the difference is that SATC only applies to certain URIs of URI binding code I.
- **Exclude key handling functions that share no arguments with URI handling functions**: This rule is unique to LARA.

C Detail in Compare URI and Key Extraction

The detailed data is presented in §2.2 on the LARA-Site, showing the results of URI and key extraction in each firmware sample by LARA and SATC in the dataset.

And since LLM-aided are not used for URI binding code type II and III, so URI extracted by LLM-aided and Combined are used from P.A. It means *27,823 = 17,138 + 10,685*.

In two firmware samples (G0 and G0-POE), there were 2 key handling functions missed , namely cJSON_GetDouble and cJSON_GetObjectItem. While LLM-aided analysis was able to extract these two functions (total four functions for two samples), they were not extracted by key-pattern analysis. However, since we took the intersection of the analysis results, we missed these two functions, resulting in 14 fewer keys being extracted. Further analysis of the missed key showed that they did not lead to any vulnerability.

In two firmware samples (BS228FX and BS252FX), IDA Pro does not support analysis of the eh_frame section, which makes it impossible to extract URIs.

Abstract

The extensive integration of embedded devices within the Internet of Things (IoT) has given rise to significant security concerns. Various initiatives have been undertaken to bolster the security of these devices at the software level, involving the analysis of MCU firmware and the implementation of automatic MCU rehosting methods. However, existing hardware-oriented rehosting techniques often face scalability challenges, while firmware-oriented approaches may have limited universality and fidelity. To address these limitations, we propose PERRY, a system that synthesizes faithful and extendable peripheral models for MCUs. By extracting peripheral models from hardware drivers, PERRY ensures compatibility and accurate emulation of targeted MCUs. The process involves gathering hardware metadata, analyzing driver code, capturing traces of peripheral accesses, and converting software beliefs into hardware behaviors. PERRY is implemented with approximately 19,000 lines of code. A comprehensive evaluation of 75 firmware samples has showcased its effectiveness, consistency, universality, and scalability in generating hardware models for MCUs. PERRY can efficiently synthesize hardware models consistent with the actual hardware and achieve a 74.24% unit test passing rate, outperforming the state-of-the-art techniques. The hardware models produced by PERRY can faithfully emulate diverse firmware and can be readily expanded with minimal manual intervention. Through case studies, we show that PERRY can help reproduce firmware vulnerabilities, discover specification-violation bugs in drivers, and fuzz RTOS for vulnerabilities. These case studies have led to the identification of two specification-violating bugs and the discovery of seven new vulnerabilities, underscoring PERRY's potential to enhance various security-focused tasks.

1 Introduction

The advent of the Internet of Things (IoT) has led to the extensive integration of embedded devices in various domains such as smart homes and industrial IoT, enabling enhanced connectivity and functionality. These embedded devices predominantly utilize microcontroller units (MCUs) to strike a balance between power efficiency and computational capabilities. However, in the context of extensive deployment of MCU-based IoT devices, ensuring their security is of utmost importance. These interconnected devices are susceptible to numerous vulnerabilities and security threats (e.g., unauthorized access, data breaches, and malicious attacks), which jeopardize the confidentiality, integrity and availability of sensitive information, presenting substantial risks to individuals and organizations [23, 30, 36].

Efforts have been made to bolster the software-level security of embedded devices, primarily through MCU firmware analysis [5, 9, 15, 31, 40, 44, 56, 61]. Among various analysis techniques, automatic MCU rehosting has emerged as a popular method. It involves running firmware in a virtual environment separate from the original hardware platform, allowing analysts to employ advanced dynamic analysis techniques and attain MCU platform independence. However, hardware-oriented rehosting techniques [9, 31, 56] rely on the actual hardware platform, employing hardware-in-the-loop emulation or record-and-replay mechanisms, which pose scalability challenges. Conversely, firmware-oriented rehosting techniques [5, 15, 44, 61], such as register-level approaches, infer peripheral responses based on register accesses but have limited universality and fidelity. Given these inherent limitations in the current state of research, there is an urgent demand for further advancements in this domain.

However, the task of creating accurate and adaptable peripheral models for MCUs is an exceedingly complex undertaking. It necessitates seamless integration, compatibility, and precise emulation of specific MCUs, all while grappling with the intricacies of hardware intricacies. Fortunately, we have observed that hardware is consistently accompanied by corresponding hardware drivers, which enable firmware to effectively access and utilize the hardware. These hardware drivers explicitly express expectations on corresponding hardware behaviors (i.e., software beliefs), which encompass crucial information about the behavior of the underlying hardware. This approach brings forth significant advantages since the drivers inherently conform to the underlying hardware for normal operation, ensuring that the inferred hardware models are universally applicable and accurate.

Building upon this observation, we introduce PERRY, a comprehensive methodology comprised of four essential

[*]Corresponding author: Prof. Zhen Ling of Southeast University, China.

steps. First, we collect hardware metadata, acquire the driver source code, compile it into LLVM bitcode, and extract supplementary information using Clang/LLVM. Second, we analyze the driver bitcode, establish a symbolic execution environment, and capture traces of peripheral accesses through symbolic execution. Third, from these traces, we extract software beliefs about the underlying hardware and convert them into hardware behaviors. Finally, by using the inferred hardware behaviors and user inputs, we fill in the gaps within the hardware model template, resulting in a complete and valid hardware model. This synthesized hardware model can be seamlessly integrated into an emulator such as QEMU, enabling the emulation of diverse firmware on the target MCU.

During the design of PERRY, we face several challenges, all of which are successfully addressed. For instance, we introduce a set of rules to identify software beliefs within drivers and convert these beliefs into hardware behaviors. Additionally, we tackle the challenge of efficiently analyzing driver libraries through symbolic execution by breaking loops and eliminating scoped constraints.

We implement PERRY by leveraging Clang/LLVM [33], KLEE [4], and Z3 [11], incorporating approximately 19,000 lines of our own code. We conduct a comprehensive evaluation of PERRY using 75 firmware samples, assessing its efficiency, consistency, universality, and scalability. Evaluation results on 10 driver libraries show that PERRY can infer hardware behaviors efficiently for over 30 MCUs. These behaviors are consistent with actual hardware, yielding a 74.24% unit test passing rate and surpassing the state-of-the-art. Hardware models generated by PERRY can be directly used to emulate various firmware with high fidelity, and can be easily extended to support more non-trivial hardware functionalities with minimum manual efforts.

We conduct three case studies to illustrate the potential security applications of PERRY. In the first study, we demonstrate that hardware models generated by PERRY could rehost BLE host firmware, facilitating the replication of BLE protocol stack vulnerabilities. In the second case study, we demonstrate how hardware models inferred from drivers could be cross-referenced with corresponding hardware specifications, allowing us to identify deviations or violations within the drivers. Finally, in the third case study, we fuzz real-time operating systems (RTOS) and uncover vulnerabilities by emulating RTOS with PERRY-generated hardware models. Consequently, we discover two specification-violation bugs in drivers and seven new vulnerabilities in RTOS, underscoring the versatility and practicality of PERRY in the realm of security.

Our major contributions are summarized as follows.

- **Novel Insights.** We demonstrate that drivers expose information about the behaviors and characteristics of the underlying hardware, which can be effectively extracted and processed to infer actual hardware behaviors.
- **Practical Tool.** We introduce PERRY, which collects hardware metadata and driver source code, analyzes the driver's LLVM bitcode to capture traces of peripheral access, extracts hardware behaviors from these traces for symbolic execution, and subsequently completes the hardware model template with the inferred behaviors.
- **Extensive Evaluations.** We perform a thorough evaluation of PERRY with 75 firmware samples to demonstrate its efficiency, consistency, universality, and scalability. PERRY can efficiently synthesize faithful hardware models and achieve a 74.24% unit tests passing rate, outperforming the state-of-the-art. PERRY-generated hardware models can be used to emulate diverse firmware with minimum manual efforts.
- **Security Implications.** Our security case studies demonstrate the capability of PERRY in replicating BLE protocol stack vulnerabilities, detecting specification-violation bugs, and fuzzing RTOS for new vulnerabilities.

Availability. PERRY is open source at https://github.com/VoodooChild99/perry.

2 Background

2.1 MCU-based Embedded Systems

Architecture of MCU-based Embedded Systems. MCU-based embedded systems refer to resource-constrained devices built for specific purposes, utilizing MCUs as the core processing units. As shown in Figure 1, these systems run firmware, which contains the control logic and interacts with various peripherals through peripheral drivers. The firmware can be executed on top of an MCU with a lightweight RTOS or directly on the hardware (bare-metal). In these systems, the peripherals expose interfaces through registers that can be accessed by the CPUs using memory-mapped I/O (MMIO). By accessing these MMIO registers, the firmware configures working modes, acquires the working status of peripherals, and performs data exchanges with external environment, enabling a wide range of hardware-related functionalities.

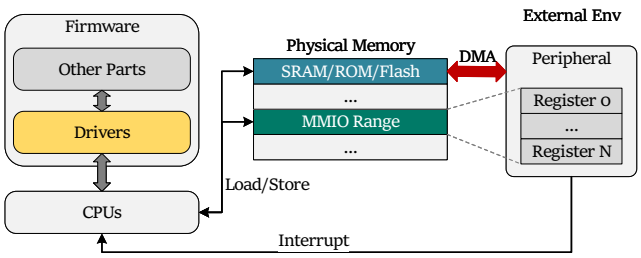

Figure 1: MCU-based embedded systems architecture.

At a high level, MCU drivers are the proxy between the

software world and the hardware world. As such, they must translate software requests into hardware interactions, read hardware responses, and provide them back to the software. Software will then perform various tasks (e.g., processing protocol packets) utilizing these results.

MCU Peripherals. MCU peripherals, in addition to passive CPU access, utilize interrupts to notify the CPU of specific hardware events. For example, a UART triggers an interrupt to alert the firmware to read incoming data. Peripherals that support interrupts have distinct interrupt sources connected to the interrupt controller. When certain conditions in the registers are met, the corresponding interrupt is activated, and the signal is sent to the CPU if enabled. The CPU then pauses the ongoing code execution and jumps to the appropriate interrupt service routines (ISRs) based on the interrupt number. Since there is a finite number of interrupt numbers, multiple hardware events may share the same number, resulting in the same interrupt for different events. To specify the actual event, peripherals configure diverse register values to assist ISRs in demultiplexing interrupts. It's worth noting that peripherals can also interact directly with memory through direct memory access (DMA), thereby enhancing firmware throughput without requiring CPU involvement.

2.2 Automatic MCU Rehosting

Rehosting techniques are designed to execute firmware in a virtual execution environment, independent of the original hardware platform. This enables the examination of MCU firmware through sophisticated dynamic analysis techniques. Rehosting necessitates emulating CPUs and peripherals [14]. Emulating CPUs is labor-intensive but a one-time effort (e.g., QEMU [2]), given the relatively small amount of CPU models, this is acceptable in general. However, the number of peripherals is much larger than that of CPU models (e.g., over 30 peripherals per SoC) [14]. Although it takes relatively less manual efforts to model a peripheral, the huge amount of peripherals makes it impractical to emulate all of them. As a result, emulators often have few hardware models [14], and analysts have to implement missing models on their own. This makes automatic MCU peripheral emulation the key challenge in rehosting. In this section, we review the literature on rehosting techniques, which can be grouped into two categories based on their implementation.

- **Hardware-Oriented Rehosting.** Some techniques leverage the inherent capabilities of the hardware platform to accomplish MCU rehosting, and these approaches can be categorized into two groups. The first kind of rehosting technique is called hardware-in-the-loop [9, 31, 56], where only CPUs are emulated, and peripheral accesses are forwarded to real devices. In the second category of techniques [20, 49], peripheral interactions during firmware executions are recorded, peripheral outputs are analyzed and then replayed during firmware emulation. However, these techniques face scalability challenges due to their reliance on physical hardware.
- **Frimware-Oriented Rehosting.** Other techniques aim to provide different virtual execution environments for different firmware and can be divided into register-level approaches and function-level approaches. Function-level techniques [8, 34, 39] involve summarizing peripheral driver functions to remove hardware interactions and only retain semantics, but they are limited by the manual effort required and the lack of practicality due to the absence of debugging information in MCU firmware binaries. Register-level techniques [5, 15, 44, 61] infer how peripherals respond to register accesses to explore more firmware paths instead of faithfully emulating hardware, but they suffer from low universality (e.g., these models are firmware-specific and limited in emulating complex hardware functionalities), making them specific to analyzed firmware, and low fidelity, as they cannot accurately replicate actual hardware behaviors.

An concurrent effort [62] seeks to address the aforementioned limitations by creating highly accurate hardware models based on hardware specifications. However, this approach entails a significant amount of manual work, such as manually identifying expected hardware descriptions in manuals, converting these descriptions from PDF format to plain text, and diagnosing the generated rules. These manual tasks restrict its practicality.

3 Problem and Motivating Example

3.1 Threat Model and Problem Statement

Possible Threats. Malicious data can be injected into the firmware of a MCU through its peripherals. Vulnerabilities in the driver code of a peripheral may then be exploited [35]. The malicious data can propagate into other parts of the firmware such as upper-layer applications, whose vulnerabilities may also be exploited [23, 43].

Conducting security analysis on MCU firmware presents challenges due to significant influences of the hardware on both control flow (e.g., interrupts) and data flow. Emulating hardware often requires huge manual efforts, and emulators typically have few hardware models (see §2.2). Therefore, automating hardware emulation is essential.

Problem Objectives. Our objective is to autonomously generate extensible and accurate peripheral models for a target MCU to facilitate security analysis. The generated peripheral model faithfully reflects actual hardware models and can be easily integrated into existing emulators. As a result, these models can be used to rehost various firmware, thus enabling security analysis of MCU firmware.

However, this can be challenging. The integration of these peripheral models into existing emulators is a complex task, as ensuring seamless integration and compatibility between the generated models and the emulator framework can be technically demanding. It requires careful consideration of the interface, timing, and synchronization aspects to ensure the accurate emulation of the targeted MCU. Additionally, firmware variations, different software versions, and compiler optimizations further complicate the task of developing firmware-independent rehosting techniques. Lastly, the lack of comprehensive documentation, proprietary components, and closed-source firmware can hinder the reverse-engineering and understanding of hardware behaviors.

Problem Assumptions. We have the following prerequisites and assumptions. First, we assume that we can access the source code for at least one implementation of the peripheral driver. We believe that requiring the source code for the driver is reasonable: (i) MCU vendors do make driver source code public for MCU peripherals. (ii) Any open-source driver even one by a third party for specific hardware is sufficient. We conduct a survey on 10 top MCU vendors as shown in Table 1 and find that all investigated MCU vendors provide public access to driver source code.

Table 1: The availability of MCU driver source code

Vendor	Region	Host*	Example	First Release (YYYY/MM)
STMicroelectronics	Switzerland	GH	[51]	2019/04
NXP Semiconductors	Netherland	GH	[47]	2021/01
Microchip Technology	USA	OW	[54]	2022/10
Texas Instruments	USA	GH	[26]	2022/12
Renesas Electronics	Japan	GH	[12]	2019/10
Infineon Technologies	Germany	GH	[53]	2019/08
Nuvoton Technology	Taiwan, China	GH	[55]	2021/12
Nordic Semiconductor	Norway	GH	[46]	2017/10
Espressif Systems	Mainland China	GH	[52]	2016/08
GigaDevice Semiconductor	Mainland China	OW	[45]	2023/08

* GH: GitHub, OW: Official Website

Second, we assume the MCU corresponding to the target firmware is known. Such information can be obtained from the product brochure or model number printed on the SoC. It is needed for acquiring corresponding drivers and building hardware models. For example, Giese [16] identified several MCU models combing both methods.

Third, like previous efforts [15, 44], we assume that the hardware metadata of the target MCU is available, including memory mapping information, CPU model and initial interrupt vector location. The information can be extracted from hardware manuals. Specifically, for ARM Cortex-M MCUs, such information can be obtained more easily by parsing the Common Micro-controller Software Interface Standard System View Description (CMSIS-SVD) file [1] of the target MCU.

3.2 Motivating Example

As discussed in §3.1, synthesizing faithful and extendable peripheral models for MCUs is a complex task. However, we have made an observation that allows us to achieve our goal without the need for additional documentation processing or component analysis.

Key Insight. We observe that hardware is always accompanied by corresponding hardware drivers so that the hardware can be accessed and used by firmware, and these hardware drivers contain information about the behaviors of the underlying hardware. Based on this observation, to achieve our goal, we propose to extract peripheral models from hardware drivers. As a benefit, because drivers must respect the underlying hardware to function normally, hardware models inferred from drivers are universal and faithful.

We would like to illustrate this observation with a motivating example. Specifically, peripheral drivers must effectively manage hardware states to ensure successful interaction with the hardware and the realization of expected functionalities. Typically, this is accomplished through the use of various conditional statements that check the values of specific hardware registers. Listing 1 shows the code snippet taken from the universal asynchronous receiver/transmitter (UART) driver for STM32F7 series MCUs. The code has been simplified for the ease of reader comprehension. The API `HAL_UART_Receive()` is exposed to upper-layer applications for receiving incoming data through UART. According to the specification of STM32F7 UART peripheral [50], the `RXNE` bit of the `ISR` register is set by hardware when incoming data is ready to be read from the `RDR` register. Therefore, in correspondence with the specification, the driver: 1) waits until the `RXNE` bit is set in the `ISR` register (line 5), and then 2) reads the data register `RDR` for the incoming data and stores it into a buffer (line 9).

```
1  // uart.c
2  HAL_StatusTypeDef HAL_UART_Receive(UART_HandleTypeDef *huart,
   ↪  uint8_t *pData, uint16_t Size, uint32_t Timeout) {
3    ...
4    while (Size > 0) {
5      /* wait until UART_FLAG_RXNE flag in the ISR register is
       ↪  set by the hardware */
6      if (UART_WaitOnFlagUntilTimeout(huart, UART_FLAG_RXNE,
       ↪  RESET, tickstart, Timeout) != HAL_OK) {
7        return HAL_TIMEOUT;
8      }
9      /* read incoming data from the TDR register */
10     *pData = (uint8_t)(huart->Instance->RDR & (uint8_t)uhMask);
11     ++pData;
12     --Size;
13   }
14   ...
15   return HAL_OK;
16 }
```

Listing 1: STM32F7xx UART driver code snippet.

Assuming we have no prior knowledge about UART behaviors when receiving data, we can still deduce this information from the driver code. First, by analyzing the code, we can know from the type (details will be elaborated upon in §4.1) that `huart->Instance` actually represents a peripheral, which means accessing its members will access MMIO registers. Second, by examining all the code paths, we observe that the data within the `RDR` register is written into a data buffer, implying that `RDR` serves as a data register. Third, after establishing this understanding, we can analyze the path constraints and observe that the `RDR` register is accessed only when the `UART_FLAG_RXNE` flag in the `ISR` register is set. This indicates that the flag should be set by the UART hardware when the incoming data in `RDR` is ready to be read – otherwise, the driver will never read the data. Finally, with the inferred UART behavior, we insert the following logic into our hardware model to mimic such hardware behavior: when the UART receives external inputs, we first move the data into the `RDR` register and then set the `UART_FLAG_RXNE` flag in the `ISR` register.

4 PERRY Design

Based on the example in §3.2, we can conclude that to synthesize peripheral models from drivers, we must process the driver source code to extract useful information (e.g., register accesses), observe how registers are accessed in drivers, infer hardware behaviors from the observed register accesses, and finally synthesize a hardware model using these inferred behaviors. As shown in Figure 2, we propose a system called PERRY[1] to synthesize MCU peripheral models from peripheral drivers, which can be divided into four phases:

① **Pre-Processing (§4.1).** We perform several steps to prepare the input required by the system. This includes gathering the hardware metadata and acquiring the driver source code (see §3.1). To facilitate further analysis, we compile the driver source code into LLVM bitcode and extract relevant auxiliary information using Clang/LLVM.

② **Trace Collection (§4.2).** With these inputs in hand, we proceed to analyze and instrument the driver bitcode to establish the symbolic execution environment correctly. Additionally, we employ symbolic execution to analyze the driver APIs and capture traces of peripheral accesses.

③ **Model Inference (§4.3)** Next, we extract software beliefs regarding the underlying hardware from the collected traces and convert these beliefs into hardware behaviors that support and justify them.

④ **Model Synthesis (§4.4).** Finally, we utilize the inferred hardware behaviors along with user inputs to complete the missing sections in the hardware model template, thereby synthesizing a valid hardware model. This generated hardware model can then be seamlessly integrated into the emulator, such as QEMU [2], enabling the emulation of various firmware running on the target MCU.

[1]The system is named PERRY because its pronunciation is reminiscent of the word "peri", which stands for "peripheral".

4.1 Pre-Processing

PERRY takes hardware metadata and the driver source code as inputs. It parses the names and memory ranges of peripherals to be analyzed and obtains the target hardware information from hardware metadata. When compiling the driver source code to LLVM bitcode, we collect three types of source-level information (**SI**): loop header location, success return values, and peripheral structure names.

(SI-I) Loop Header Location. Loop headers (e.g., line 3 in Listing 1) define loop iterations. Drivers typically employ a waiting strategy, repeatedly reading specific registers in loop headers, and anticipating hardware updates. These features greatly aid in inferring hardware models (See §4.3). "To facilitate model inference, we gather loop header locations from the driver source code during preprocessing in the format of "`(filename, beginLoc, endLoc)`". For example, in Listing 1, the loop header `(uart.c, {3, 3}, {3, 18})` at line 3 has `beginLoc` referring to "w" and `endLoc` referring to ")".

(SI-II) Success Return Values. Drivers often perform a preliminary check to ensure proper functionality of a peripheral before certain operations (e.g., reading the data register). If the check succeeds, normal operations are carried out (valid paths). If the check fails, the driver may immediately return an error status code and skip all subsequent operations (invalid paths). To accurately infer expected hardware behaviors and synthesize hardware models, focusing solely on valid paths and disregarding invalid paths is essential. To achieve this, we collect return values that indicate success, aiding PERRY in identifying valid paths. Drivers commonly utilize enums to denote execution status, which possess semantic features. For instance, the enum value `HAL_OK` (line 14 in Listing 1) signifies successful execution, while `HAL_TIMEOUT` (line 6 in Listing 1) indicates a timeout error. Based on this observation, we gather enum values returned by driver functions and identify success return values by their names. If a name contains typical words denoting success (e.g., `"ok"` or `"success"`), we consider the corresponding value as a success return value. We contend that this pattern sufficiently identifies success return values, as all drivers listed in §5 adhere to this convention.

(SI-III) Peripheral Structure Names. Peripheral registers are arranged in a compact and contiguous manner within the peripheral's address space. To abstract the layout of a peripheral, drivers commonly employ structures known as peripheral structures, where each structure member represents a register within the peripheral. Peripheral structure instances

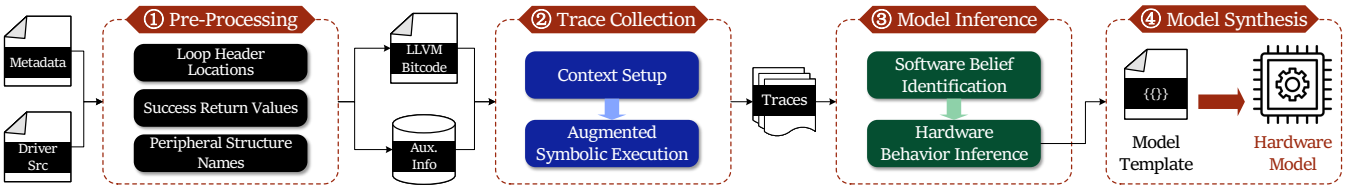

Figure 2: PERRY overview.

are typically hard coded and mapped to the actual peripheral address, and drivers directly use these instances to access peripherals. However, some peripherals, such as UART, may share the same peripheral structure. To ensure generality, drivers for such peripherals often avoid using hard-coded peripheral structure instances. Instead, they allow users to specify the instance through a parameter. In such cases, we need to identify these parameters and assign them to the corresponding peripheral structure instances. We have observed that structure instances are typically defined using macros that follow a common pattern, as shown below:

```
#define [INSTANCE] (([STRUCT]*) [ADDRESS])
```

where `[INSTANCE]` represents the instance name, `[STRUCT]` represents the structure name, and `[ADDRESS]` represents the peripheral address. For example, the macro below defines a peripheral instance `USART1` at the address `USART1_BASE` using the structure `USART_TypeDef`.

```
#define USART1 ((USART_TypeDef *) USART1_BASE)
```

By parsing macros in drivers, we can extract peripheral structure names accordingly.

4.2 Trace Collection

PERRY collects peripheral access traces during the symbolic execution of driver APIs. To this end, PERRY first analyzes and instruments the driver bitcode to properly setup the context for symbolic execution. After this, PERRY records essential peripheral access information through augmented symbolic execution.

4.2.1 Context Setup

Five tasks (**T**) must be performed to properly setup the symbolic execution context for drivers. First, we prepare MMIO regions to replicate the actual MCU memory layout. Second, we identify potential entry points for symbolic execution, as drivers are commonly found in library form. These identified entry points are then organized to establish their corresponding calling contexts. In the fourth task, we identify and taint input data buffers to aid in the recognition of data registers. Lastly, we identify and hook callbacks to aid the inference of interrupt conditions.

(T1) Prepare MMIO Regions. Peripheral drivers access peripheral registers by directly accessing specific memory addresses (i.e. MMIO regions). To enable the symbolic executor to handle register accesses, we pre-map these MMIO regions. Additionally, we need to track the usage of values obtained from registers to infer hardware models. To achieve this, we symbolize all mapped MMIO regions and allocate unique taint labels to different registers as taint sources.

(T2) Identify Entry Points. Driver code, unlike code with a pre-defined entry point like `main()`, is typically presented as a library. This means that multiple potential entry points (i.e., APIs) are exposed without being used. To pinpoint potential entry points for symbolic execution within drivers, we construct a call graph and identify top-level functions that are not invoked by other functions. We identify top-level functions as entry points for two reasons: firstly, top-level functions typically encapsulate complex peripheral functionalities and engage in extensive hardware interactions; secondly, interactions between different top-level functions with hardware are often non-interfering, ensuring comprehensive observation of hardware behavior.

(T3) Assemble Entry Points. We set up the program environment (i.e., parameters and global variables) for each API to enable symbolic execution as they are not directly used. The entry point assembly algorithm is shown in Algorithm 1. Parameters and global variables are analyzed and prepared following the principle of avoiding symbolic pointers. For pointer variables, we recursively allocate an array of objects of the underlying type and symbolize their content (line 21-26). The array length is typically set to 1, unless it is a data buffer (see **T4**) where a larger constant value is used (e.g., 8). Non-pointer variables are allocated as objects with their content symbolized (line 29-30). If the object is a structure, we repeat the above procedure for each field (line 31-35). Two exceptions are pointers to peripheral structures and constant global variables. Pointers to peripheral structures are assigned the corresponding concrete peripheral physical addresses (line 12). Constant global variables are not made symbolic as their values remain unchanged. The above method fails to handle function pointers. Inspired by MLTA [38], we adopt a light-weight yet effective type analysis to determine indirect call targets (line 14).

(T4) Taint Input Data Buffers. Driver APIs that send data to peripheral hardware typically use data buffers to store user

Algorithm 1: Entry Point Assembly Algorithm

Input : Set of identified entry points S_{API}
Output: Prepared program environment for symbolic execution

```
foreach API ∈ S_API do
    SetupProgramEnvironment(API);
end
Function SetupProgramEnvironment(API):
    S_para, S_glob ← AnalyzeParametersAndGlobals(API);
    foreach var ∈ S_para ∪ S_glob do
        SetupVariable(var);
    end
Function SetupVariable(var):
    if isPointer(var) then
        if isPeripheralStructPointer(var) then
            AssignConcreteAddress(var);
        else if isFuncPtr(var) then
            FillinFuncPtrByType(var);
        else
            AllocateAndSymbolizeArray(var);
        end
    else
        AllocateAndSymbolizeObject(var);
    end
Function AllocateAndSymbolizeArray(ptrVar):
    pointee ← getPointee(ptrVar);
    len ← isDataBuffer(ptrVar) ? CONSTANT : 1;
    for i = 1 to len do
        SetupVariable(pointee);
    end
Function AllocateAndSymbolizeObject(var):
    if ¬isConstant(var) then
        AllocateObject(var);
        SymbolizeContent(var);
        if isStruct(var) then
            for field ∈ getFields(var) do
                SetupVariable(field);
            end
        end
    end
```

inputs, which are directly written into data registers. Based on this observation, we adopt a taint-based mechanism to recognize data registers. We first identify data buffers based on API parameter types and names. If a parameter has a buffer type (e.g., `uint8_t *`) and its name matches common patterns (e.g., `"data"`), it is considered a data buffer. We then taint the content of each identified data buffer to track data flows from user data to peripheral registers. By analyzing the taints within registers, we can identify data registers where the taints come from data buffers.

(T5) Hook Callbacks. Interrupt handlers frequently trigger callbacks upon successfully managing interrupts. By intercepting the callbacks and collecting the associated path constraints (see §4.3.1), PERRY can infer interrupt conditions. Callbacks are recognized as unresolved function pointers or empty functions with weak linkage. For each identified callback, we reroute it to our built-in hook functions.

4.2.2 Symbolic Execution for Trace Collection

PERRY combines symbolic execution and taint analysis for hardware model inference. Similar to previous efforts [5, 44, 61], peripheral registers are set as non-volatile symbol/taint sources. However, two challenges arise due to the limitations of symbolic execution and unique characteristics of drivers. Firstly, symbolic execution can lead to state explosion due to extensive loop usage in drivers. Secondly, symbolic execution can be blocked due to conflicting constraints caused by hardware. Drivers initially assume a specific register value, which is then updated by hardware. Afterwards, drivers might assume a different value for the same register. However, the two constraints conflict with each other and symbolic execution is blocked. To address these challenges, we use two methods (**M**): actively breaking loops during symbolic execution to reduce complexity, and utilizing checkpoints to remove hardware-related constraints. These mechanisms efficiently achieve the goal (**G**) of collecting peripheral register access traces and execution results for further processing.

(M1) Break Loops for Path Pruning. To facilitate effective exploration of software-hardware interactions, we employ loop handling that imposes constraints on program states rather than terminating them. This approach enables continued program execution by detecting and exiting loops. When the symbolic executor encounters a conditional branch instruction, it checks for repeated execution of the branch target beyond a predefined threshold (e.g., twice). If exceeded, it negates the loop condition and jumps out of the loop, allowing uninterrupted execution.

```
1 while(__HAL_RCC_GET_FLAG(RCC_FLAG_PLLRDY) != RESET) { ... }
2 ...
3 while(__HAL_RCC_GET_FLAG(RCC_FLAG_PLLRDY) == RESET) { ... }
```

Listing 2: Conflicting constraints due to symbol reuse.

(M2) Remove Constraints using Check-Points. Listing 2 shows an example of conflicting hardware-related constraints caused by reusing the same symbol. If the constraint at line 1 evaluates to false, the constraint on line 3 will always evaluate to true, and the driver API will return an error because we cannot break such a loop – the negated loop condition will conflict with existing path constraints. While on a real device, both constraints can be satisfied since the accessed register is updated by the hardware before line 3. We

observe that such constraints (e.g., line 1) usually appear as scoped loop conditions, i.e., their impacts on program execution is restricted to be within the loop body. Based on this observation, we propose a check-point-based mechanism to detect and remove these scoped hardware-related constraints.

A check point is defined as a (PC, CS) pair, where CS denotes a hardware-related constraint, and PC denotes the code location where CS is introduced. The check point mechanism maintains a set of check points within the current function. When a hardware-related constraint evaluates to true, we check if the corresponding $(PC\prime, CS\prime)$ pair exists in the set. If so, we identify $CS\prime$ as a scoped hardware-related constraint, remove it from the current program state, and force the program to take the negated branch.

(G) Trace Collection. For each explored program state, we collect the following information.

- **Exit Status** (*ES*): Program states can terminate normally (i.e., reaching the end of an execution path) or abnormally (e.g., errors during symbolic execution). Traces from normally exited program states provide valuable information for hardware model inference, while traces from other program states are less useful.
- **API Return Value** (*RV*): Program states with success return values provide valuable insights into the expected hardware behavior.
- **Path Constraints** (*CS*): The path constraints until program state terminates. These constraints help PERRY infer hardware behaviors.
- **Register Accesses** (*RA*): During symbolic execution, the recorded information for each identified peripheral access includes: (*i*) access action A (read or write); (*ii*) accessed offset O within the peripheral; (*iii*) access width W (e.g., 4 bytes); (*iv*) symbolic expression S returned for a read or to be written for a write; (*v*) taint T of the value to be written (only for writes); (*vi*) path constraints C until the access; and (*vii*) code location L of the access.
- **Output Data Buffer Taints** (*OT*): Tainting input data buffers helps identify data registers (see §4.1). However, for peripherals with separate registers for receiving and transmitting data, the previous mechanism only identifies transmitting data registers. To address this, we additionally collect taints (*OT*) from data buffers after executing the API. If a taint from a register is found in *OT*, the register is recognized as a receiving data register.
- **Callback Hook Invocation Constraints** (*CC*): The path constraints when the callback hook is invoked. These constraints help PERRY infer interrupt conditions.

4.3 Model Inference

With the collected driver traces, we perform model inference, which involves identifying basic software beliefs and convert them into hardware behaviors (§4.3.1), and identifying complex software beliefs and transforming them into hardware behaviors using on-demand analysis (§4.3.2).

4.3.1 Basic Software Beliefs Identification and Hardware Behaviors Transformation

Software beliefs represent software's expectations on hardware, i.e., hardware is believed to perform certain functionalities after instructions issued by software. The most basic beliefs reside in conditional statements checking whether hardware has reached expected states. For example, checking status registers before accessing peripheral functionalities (e.g., read incoming data) to guarantee the success of subsequent operations, or after configuring peripherals (e.g., enable a clock) to indicates the success of previous configurations. These checks represent the software's assumptions regarding expected hardware behaviors and can be employed to infer actual hardware behavior. We categorized four distinct basic types of software beliefs (**SB**) related to anticipated hardware behaviors:

- **Reading data registers (RDR)**: These beliefs are derived from constraints related to data register reads.
- **Writing data registers (WDR)**: These beliefs stem from constraints related to data register writes. We observe three sub-kinds of WDR beliefs: the first write (FW), between two writes (BW) and after all writes (AW).
- **Handling interrupts (HINT)**: These beliefs are drawn from constraints associated with interrupt handling.
- **Updating non-data registers (UNDR)**: These beliefs are inferred from correlations among non-data registers (e.g., updating one register leads to the software waiting for another to be updated).

Software may also express beliefs using other statements. For example, drivers may store the variable representing source address into the source address register of a DMA peripheral, under the belief that the register holds DMA transmission source address. Unlike the above SBs that can be located by conditional statements, such beliefs are harder to locate as they also involve semantic information of drivers. We therefore equip PERRY with the on-demand analysis capability to handle such complex SBs (see §4.3.2). We demonstrate how to transform basic SBs into hardware behaviors below.

RDR Transformation. RDR beliefs capture the constraints that software should follow to successfully read incoming data from data registers. Speculatively, when the hardware receives incoming data and updates the corresponding data registers, it should satisfy the constraints specified in RDR beliefs. This enables the software to detect the signal and read the incoming data. To analyze the hardware behavior, we group RDR beliefs based on the accessed data register (using offset O). Then, we derive the hardware behavior for

receiving incoming data through the data register by combining all the constraints using disjunction. Formally, for a group of RDR beliefs $\{(C_i, Sym_O)\,|i = 1,...,N\}$, we derive a hardware behavior:

$$B_{RDR} := \bigvee_{i=1}^{N} C_i \tag{1}$$

WDR Transformation. WDR beliefs capture the constraints that software should follow to successfully send data through data registers. While there are three sub-kinds of WDR beliefs, it can be assumed that the constraints in WDR beliefs must evaluate to true after user data is written into a data register. Otherwise, the data transmission process in the software would fail. To analyze the hardware behavior, we group WDR beliefs for each sub-category by the accessed data register. This results in a triple of WDR belief groups (G_{FW}, G_{BW}, G_{AW}) for each data register corresponding to three sub-kinds. For each triple, we derive the hardware behavior when transmitting data through the data register by disjuncting constraints within each triple element, then conjuncting the results. Formally, assume $G_{FW} = \{(C^i_{FW}, Sym_O)\,|i = 1,...,N\}$, $G_{BW} = \{(C^i_{BW}, Sym_O)\,|i = 1,...,M\}$, and $G_{AW} = \{(C^i_{AW}, Sym_O)\,|i = 1,...,K\}$, we derive the following hardware behavior:

$$B_{WDR} := \left(\bigvee_{i=1}^{N} C^i_{FW}\right) \wedge \left(\bigvee_{i=1}^{M} C^i_{BW}\right) \wedge \left(\bigvee_{i=1}^{K} C^i_{AW}\right) \tag{2}$$

HINT Transformation. HINT beliefs consist of path constraints that exist before executing interrupt handling operations in ISRs. We regard data register reads/writes and callback hook invocations as interrupt handling operations. These constraints include triggering conditions for different hardware events. Since the interrupt condition is composed of these hardware event triggering conditions, we can infer the actual interrupt triggering condition by combining all the HINT belief constraints using disjunction. In other words, the interrupt will be triggered if at least one event is triggered. Formally, assuming $\{C_i | i = 1,...,N\}$ represents all the HINT beliefs, we derive the following hardware behavior:

$$B_{HINT} := \bigvee_{i=1}^{N} C_i \tag{3}$$

UNDR Transformation. UNDR beliefs describe the relationship between two non-data registers. If a register Reg_A is written in a specific way, it is expected that the hardware will update another register Reg_B accordingly. To translate UNDR beliefs into hardware behaviors, we need to consider the write semantics (how Reg_A's value is changed) and the update semantics (how Reg_B should be updated). In most cases, the value written into Reg_A is bounded and the expected value for Reg_B can be easily derived from the path constraints. We propose a bit value variation-based approach to infer write semantics under such cases. However, sometimes the value written into Reg_A is unbounded, making the above method fail to infer the write semantic. To handle such cases, we additionally propose a write-update dependency resolution method to synthesize a linear formula between the written value and the expected update value. The technical details of the proposed two methods can be found in Appendix A. With the inferred write semantic WS and update semantic US, the hardware behavior can be derived as:

$$B_{UNDR} := (WS, US) \tag{4}$$

4.3.2 On-Demand Complex Software Beliefs Identification and Hardware Behaviors Transformation

PERRY supports on-demand analysis to locate complex SBs and transform them into hardware behaviors. Analysts can use commands to instruct PERRY to identify complex SBs. PERRY will then transform these beliefs into hardware behaviors accordingly. PERRY recognizes three types of commands from analysts – `PARAM`, `CALLBACK` and `FUNCTION`.

- **PARAM:** `PARAM` commands describe the software belief where specific data is supposed to be stored into dedicated registers. A `PARAM` command contains parameters of a function. PERRY handles such commands by locating all registers where the specified parameters are written into, and outputs these registers as hardware behaviors.
- **CALLBACK:** `CALLBACK` commands describe the software belief where certain hardware events are supposed to happen. A `CALLBACK` command contains the name of a callback. PERRY handles `CALLBACK` commands by gathering path constraints when the specified callback is invoked, and generates a hardware behavior expressed as the disjunction of these constraints.
- **FUNCTION:** `FUNCTION` commands describe the software belief where certain hardware functionalities should be triggered by invoking the function. A `FUNCTION` commands contains the name of a function. PERRY handles `FUNCTION` commands by locating all register updates within the specified functions, and generates hardware behaviors based on their write semantics.

4.4 Model Synthesis

The last step of PERRY is to synthesize a hardware model that can be directly integrated into emulators using the inferred hardware behaviors. To this end, we adopt a template-based synthesis approach. PERRY first takes user-provided hardware metadata file and generate a basic hardware model template file, where only basic hardware behaviors are included – register reads return the current register value, and register writes will update corresponding registers. Other

hardware behaviors are left as holes, which are then synthesized and filled based on the inferred hardware behaviors. We demonstrate the synthesis procedure for behaviors inferred from basic SBs (basic behaviors) and complex SBs (complex behaviors) respectively.

Basic Behaviors. There are four kinds of holes corresponding to the four basic behaviors, we reuse the name of corresponding belief as introduced in §4.3.1 as the name of each kind of holes for simplicity. For RDR holes, we synthesize a function that takes inputs from the host, store inputs into the involved receiving data register, and update other registers to validate B_{RDR}. Whenever a receiving data register is read, we update relevant registers again to invalidate B_{RDR}, so that the software cannot read the data register when there is no data available. For WDR holes, we synthesize a function that sends the written data to the host, and update relavant registers to validate B_{WDR}. For HINT holes, we synthesize a function that evaluate and update the interrupt firing condition according to B_{HINT}. For each register involved in the condition, we insert a call to the introduced function after its value is updated to update the interrupt condition. For UNDR holes, we insert code after writes to related registers: if the written value meets the corresponding condition in B_{UNDR}, we update registers to reach the expected value as indicated in B_{UNDR}.

Complex Behaviors. The meanings of complex behaviors generated through on-demand analysis (see §4.3.2) are related with the semantics of the used commands, which are pre-defined by analysts according to the target peripheral. With such semantics, these behaviors can then be interpreted and utilized to complete the template. Note that for peripherals of the same kind, the involved commands as well as their semantics can be reused across different MCUs, and one only has to adapt the command contents for each different driver library family. Following this procedure, we successfully synthesized DMA models for STM32 MCUs with only 3 commands.

5 Evaluation

We implement PERRY for ARM Cortex-M MCUs using Clang/LLVM [33], KLEE [4] and Z3 [11], which consists of about 19,000 lines of C++ and Python code. In this section, we first present details of our testing environment (§5.1), then we organize the results of our study around four key research questions (RQ) we attempt to answer (§5.2). Those research questions are listed below:

(RQ 1): How effective is PERRY in inferring hardware behaviors from drivers, considering the adoption of symbolic execution (i.e., efficiency)?

(RQ 2): Are the inferred hardware behaviors consistent with actual hardware behaviors (i.e., consistency)?

(RQ 3): Can hardware models generated by PERRY be used to emulate various firmware (i.e., universality)?

(RQ 4): Can hardware models generated by PERRY be easily fixed or extended to support missing hardware functionalities (i.e., scalability)?

5.1 Experiment Setup and Methodology

Experiment Setup. We select 10 driver libraries from three top MCU vendors as shown in Table 2. A driver library may cover a series of MCUs, e.g., the STM32CubeF4 driver library can be used by all STM32F4xx MCUs such as STM32F469/479, STM32F407/417 and STM32F413/F423. Therefore, the selected driver libraries can cover over 30 MCUs. For each driver library, the corresponding SVD files are already contained within driver libraries, and we only need to provide RAM/ROM range information for the hardware metadata file before the evaluation, which requires a small amount of one-time effort (specifying CPU models, memory regions, etc.) and is a common procedure in existing methods [15,44]. Driver libraries for NXP MCUs are generated by the MCUXpresso SDK builder tool [41] provided by NXP and hence have different versions. The driver library from Microchip supports all MCUs, but we have to compile it for each MCU. All experiments are conducted on an Intel Xeon E5-2620 v2 @ 2.10GHz machine running Ubuntu 20.04 TLS, equipped with 64GB memory.

Methodology. We first evaluate time consumption of applying PERRY to synthesize hardware models from the selected driver libraries to answer **RQ 1**. Then, we evaluate the passing rate achieved by the generated models on P2IM unit tests [15] to answer **RQ 2**. To address **RQ 3**, we use the hardware models to emulate firmware samples, inspect whether they can perform expected functionalities, and evaluate the success rate. To answer **RQ 4**, we use the

Table 3: PERRY model consistency.

LoC to Fix		3 (1 for RCC, 2 for I2C)			1 (for I2C)	2 (for UART)		**49/66(74.24%)**

* All STM32F103/RIOT unit tests failed due to a single wrong behavior in the RCC peripheral. Unit tests marked with "-" do not exist. ✧ represents implicit assumptions on hardware and ▲ represents in-context register operations.

LoC required to fix/extend models as metric to evaluate the involved manual efforts.

5.2 Experiment Results

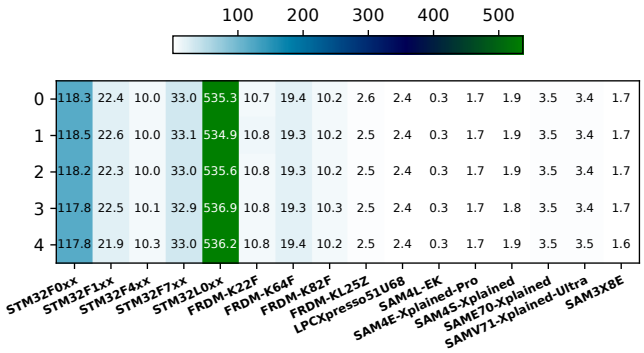

Figure 3: Model synthesis time consumption (# minutes).

Efficiency (*to Answer RQ1*). We use PERRY to synthesize peripheral models for all MCUs listed in Table 2. We conduct experiments for each MCU 5 times to eliminate the influence of random factors. We list the number of collected traces, the number of inferred hardware behaviors, and synthesized peripheral models in Table 4. We use time consumption to evaluate PERRY's efficiency in synthesizing hardware models, and the results are listed in Figure 3.

The results demonstrate that PERRY can effectively collect execution traces by symbolically exploring driver library paths and infer peripheral behaviors for most MCUs within reasonable time budget (i.e., less than 33 minutes). PERRY needs time (∼9 hours) when the target driver library is over complicated (e.g., 4,820,407 traces from the STM32CubeL0 driver library).

Consistency (*to Answer RQ2*). We validate the consistency of the synthesized models by PERRY using P2IM unit tests [15]. The authors of P2IM provide 48 firmware images consisting of 66 valid unit tests to validate the functionality of emulated hardware platforms. These unit tests cover eight categories of peripherals on different combinations of three MCUs (STM32F103, FRDM-K64F and SAM3X8E) and three OS libraries (Arduino, RIOT and NuttX). We now compare PERRY with SEmu [62] because SEmu also aims to synthesize universal hardware models. We do not compare PERRY with path exploration oriented methods including Laelaps, P2IM, uEmu, and Fuzzware, because they only generate firmware-specific models as discussed in §2.2.

Table 3 shows the evaluation results. Without manual intervention, PERRY passes 49 (74.24%) unit tests, while SEmu fails all of them. SEmu cannot infer hardware behaviors for clock configuration peripherals (RCC, MCG and PMC) and the involved firmware samples cannot boot. SEmu fails to infer such behaviors because they are not described in the hardware manual. However, the driver source code presents such behaviors and PERRY successfully captures them. PERRY fails to pass 17 unit tests due to 6 wrong or missing hardware behaviors. After fixing or adding these behaviors with 6 LoC, PERRY achieves a passing rate of 100%. In comparison, SEmu achieves the same goal by manually fixing and adding 16 rules.

Universality (*to Answer RQ3*). We demonstrate the universality of the hardware models by emulating various firmware. Note that we reuse the models from the consistency evaluation. The used firmware samples consist of two parts: 10 real-world firmware samples from P2IM [15], and 19 shell firmware from two popular RTOS (LiteOS [25] and Zephyr [58]). A piece of firmware is successfully emulated if it can perform expected tasks defined by its code logic.

We collect the number of missing and wrong behaviors for

Table 4: PERRY model synthesis efficiency.

* **"HB"** represents hardware behavior.

each hardware model during emulation and the number of LoC to fix these models. The evaluation results are shown in Table 5. Without manual intervention, PERRY successfully emulates 20 (%68.97) firmware. After manually fixing problematic models (see scalability evaluation), we successfully emulate all firmware.

To demonstrate that these models can actually help the emulated firmware to perform meaningful tasks, we conduct two case studies on the CNC and Drone firmware. Without the synthesized hardware models, both firmware cannot even boot. This demonstrates that hardware models generated by PERRY are necessary and sufficient for firmware to perform meaningful tasks.

The CNC firmware includes a G-Code interpreter that controls the movement of the underlying hardware. The firmware accepts G-Code inputs from USART. Our hardware model directly connects the emulated USART hardware to `stdin` of the host. Every time we enter G-Code into `stdin`, the emulated USART is notified, certain status register bits of the hardware are set, and the incoming data is stored in the data register. Hence, the firmware can bypass checks of these status bits, retrieve the data within the data register, parse it, and perform predefined functionalities.

The Drone firmware reads sensor data through I2C, control the position of the drone accordingly, and report drone state using USART. The emulated USART and I2C are connected to separate pipes for data injection, and set certain status register bits upon receiving incoming data. We inject random inputs to the I2C as sensor data, and monitor the output from the USART. As a result, the firmware can continuously read sensor data and perform position control, and we can inspect the running state of the drone through USART output.

Table 5: PERRY model universality.

Note ☆: Non-trivial hardware functionalities. ✧: Implicit assumptions on Hardware. ▲: In-context register operations.

Scalability (*to Answer RQ4*). For encountered missing or wrong behaviors, we manually extend or fix them according to corresponding hardware manuals. By thoroughly investigating these failing cases, we summarize main causes as listed below.

- **Implicit Assumptions on Hardware:** Drivers assume the hardware always functions as expected. Therefore, drivers may perform certain operations on the hardware without checking every related registers. For example, drivers can write a register and implicitly assume that another register is updated automatically by hardware without waiting for it. As a consequence, such implicit behaviors cannot be captured by PERRY.
- **In-Context Register Operations:** A register might get updated after a sequence of register operations, but the UNDR pattern makes PERRY to falsely believe that only the last register operation leads to the update.
- **Non-trivial Hardware Functionalities:** Some firmware samples utilize non-trivial hardware functionalities (e.g.,

interrupt table relocation), which PERRY fails to synthesize behaviors.

We use the number of LoC to measure the required manual efforts, and each line contains only one instruction. The results are shown in Table 3 and Table 5. In total, we add or modify 35 LoC to fix generated hardware models, and it only takes at most 4 LoC to fix one model. Note that fixing models for MCUs of the same family (e.g., STM32F4 and STM32F7) even requires less manual efforts because their peripherals are highly similar, resulting in similar fixes. Additionally, as a benefit of our method, fixed models can be used to emulate other firmware without further modification, e.g., for MCUs involved in P2IM unit tests, PERRY achieves a 100% success rate when emulating firmware samples running on them. Therefore, the scalability of PERRY is demonstrated by the minimum manual efforts it requires.

6 Security Applications

As discussed in §3.1, bugs within drivers and applications endanger the firmware. Therefore, we conduct three case studies (**CS**) to demonstrate PERRY's capability in catching driver bugs, as well as reproducing and finding vulnerabilities in firmware application code. Note that we reuse hardware models from §5 without additional refinements.

6.1 Security Application in Drivers

(CS-I) Mining Specification Violation Bugs. PERRY infers hardware behaviors from drivers when generating hardware models, and we can compare these inferred hardware behaviors with hardware manuals to see whether the driver implementation follows the specification. We manually check the hardware behaviors inferred from STM32Cube and MCUXpresso drivers and identify two inconsistent bugs. We reported the two bugs to corresponding vendors, and they have acknowledged and fixed them. We demonstrate this process using the bug found in the RCC driver for STM32F0 MCUs. The hardware behavior is inferred from Listing 3, where the hardware is supposed to set the `HSI48RDY` bit of the `CR2` register after the `HSI48ON` bit of `CR2` is set by the driver, which, if taken literally, is correct.

```
1 #define __HAL_RCC_HSI48_ENABLE()  \
2     SET_BIT(RCC->CR2, RCC_CR2_HSI48ON)
3 __HAL_RCC_HSI48_ENABLE();
4 tickstart = HAL_GetTick();
5 while(__HAL_RCC_GET_FLAG(RCC_FLAG_HSI48RDY) == RESET) { ... }
```

Listing 3: STM32F0 RCC driver code snippet.

However, the macro `RCC_FLAG_HSI48RDY` is falsely defined to check the `HSI48ON` bit. As a result, the inferred hardware behavior indicates that it is the `HSI48ON` bit, instead of the `HSI48RDY` bit, that should be set by the hardware after it is set by the software, which conflicts with the specification. This bug will cause the firmware to directly perform subsequent operations without waiting the HSI14 oscillator to stabilize (because the condition at line 5 is always evaluated to false), which may lead to unexpected errors.

6.2 Security Application in Firmware Applications

(CS-II) Reproducing Firmware Vulnerabilities. In this case study, we use PERRY to reproduce two vulnerabilities (CVE-2022-1041 and CVE-2022-1042) in Zephyr's Bluetooth protocol stack. The two vulnerabilities are located in the BLE host [59, 60], and can be triggered by malformed Host Controller Interface (HCI) packets during BLE mesh provisioning. HCI packets are exchanged between BLE host and controller over USB or UART.

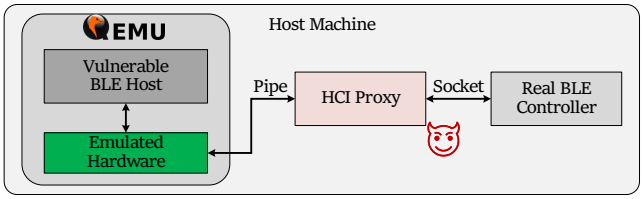

Figure 4: Reproducing BLE host vulnerabilities with PERRY.

Figure 4 depicts our vulnerability reproducing method. The vulnerable Zephyr BLE host firmware runs inside QEMU, using the STM32F4xx hardware model generated by PERRY. The emulated vulnerable BLE host exchanges HCI packets over the emulated UART peripheral with interrupt enabled, while the emulated UART is connected to a HCI packet proxy using pipes, and the proxy communicates with the BLE controller on the host machine though sockets. The proxy forwards HCI packets between the emulated BLE host and the real BLE controller as if they're directly communicating with each other. We inject malicious HCI packets into the emulated HCI host through the proxy to trigger the vulnerabilities. To validate the effectiveness of the payload, we place break points on bug triggering locations and inspect the program state using GDB. As a result, we successfully reproduce both vulnerabilities.

(CS-III) Fuzzing RTOS for Vulnerabilities. In this case study, we fuzz LiteOS by emulating it using PERRY-generated hardware models. The overall fuzzing approach is inspired by TriforceAFL [24]. We implement fuzz drivers for the MQTT and LWM2M protocol stack of LiteOS, and compile it against the STM32F769 Discovery MCU board. Additionally, we implement various sanitizers (UBSAN [7], KASAN [17], KMSAN [19] and KCSAN [18]) for LiteOS

Table 6: Results of a 6-hour fuzzing campaign on LiteOS.

Component	Target	Speed (#/sec)	# Exec.	# Path	# Vuln.
MQTT	Deserialize_ack	518.99	11,400,193	9	0
	Deserialize_connack	729.21	15,757,024	11	0
	Deserialize_connect	1233.25	26,547,383	35	1
	Deserialize_publish	634.81	13,632,707	14	1
	Deserialize_suback	517.32	11,380,177	13	1
	Deserialize_subscribe	969.45	20,505,021	12	1
	Deserialize_unsuback	469.20	10,261,209	10	0
	Deserialize_unsubscribe	537.79	11,910,801	11	1
LWM2M	coap_parse_message	331.79	7,331,274	4,112	3
	lwm2m_data_parse(TLV)	271.10	6,261,404	6,000	0
	lwm2m_data_parse(JSON)	10.84	1,638,116	3,160	2

to facilitate vulnerability detection. The target firmware is emulated using the STM32F7xx hardware model generated by PERRY. We also modify QEMU to collect coverage using dynamic binary instrumentation (DBI), such that a coverage-guided fuzzer (i.e., AFL [57]) can be integrated.

We develop 8 fuzz drivers for the MQTT protocol stack and 3 fuzz drivers for the LWM2M protocol stack. Fuzz drivers are compiled with KASAN and UBSAN enabled. We run each fuzz driver for 6 hours and the statistics are listed in Table 6. Through fuzzing, we totally uncover 10 vulnerabilities. 7 are new vulnerabilities and 3 have been reported by previous efforts [34], which were not fixed until we reported them again. The discovered vulnerabilities are all out-of-bound access vulnerabilities. We also reported newly discovered vulnerabilities to relevant parties. Three of them have been acknowledged and fixed with CVE-2021-41040 assigned. The remaining four vulnerabilities were directly fixed in LiteOS, as they were linked to a ported third-party library. Unfortunately, the developers of the library have not responded to us as of the time of writing.

7 Threats to Validity

In assessing the validity of our study, several potential threats emerge, particularly related to the limitations of PERRY in inferring hardware behaviors from drivers and the manual effort required to utilize PERRY effectively:

Limited Hardware Behaviors. Although PERRY enables on-demand analysis to infer complicated hardware behaviors, the categories of hardware behaviors that PERRY can infer from drivers are limited. For example, PERRY fails to infer non-trivial hardware behaviors like IVT relocation, due to their inconspicuous characteristics in drivers. However, these behaviors can be implemented based on the generated hardware models with little manual efforts.

Manual Efforts. Although PERRY substantially automates the process of synthesizing hardware models, it still demands manual involvement in three specific areas. Initially, an analyst must prepare the relevant hardware metadata for each driver library and utilize the provided compiler-wrapper to compile the library into LLVM bitcode. Secondly, the generated hardware models must be integrated into an emulator, which necessitates altering the emulator's build script. Lastly, despite these tasks being minimal, it is incumbent upon the analyst to manually correct any incorrect or missing hardware behaviors in the generated model.

8 Related Work

Firmware Rehosting and Analysis. Firmware can be analyzed statically to find bugs [10, 22, 42, 48], thus eliminating the requirement for firmware rehosting techniques. To take advantage of dynamic analysis techniques, efforts have been made to rehost firmware. Hardware-oriented approaches assume the presence of actual physical devices and can be divided into two categories: hardware-in-the-loop and record-and-replay. The first kind of approaches [9, 31, 56] only emulate CPUs and forward peripheral accesses to actual devices. The second kind of approaches [20, 49] record peripheral accesses during firmware executions and replay them when emulating firmware. The dependency on real devices has limited the scalability of these methods.

Table 7: Hardware-free MCU rehosting techniques.

Study	Input	Model Generation		RQ2. Model Consistency			
		Faithful Model		Firmware-independent	Exec. Low-Level Code	Full System	
HALucinator [8]		✗		✗	✗	✓	
BaseSAFE [39]		✗		✗	✗	✗	
Para-rehosting [34]		✗		✗	✗	✓	
P2IM [15]	Firmware	✓	✗	✗	✓	✓	
Laelaps [5]	Firmware	✓	✗	✗	✓	✓	
uEmu [61]	Firmware	✓	✗	✗	✓	✓	
Fuzzware [44]	Firmware	✓	✗	✗	✓	✓	
SEmu [62]	Manual	✓	✓	✗	✓	✓	✓
PERRY	Driver	✓	✓	✓	✓	✓	✓

Firmware-oriented approaches address this limitation by providing different virtual execution environments for different firmware, and can be performed at either register-level or function-level as listed in Table 7. Function-level approaches replace certain firmware functions to avoid hardware interactions [6, 8, 27, 29, 34, 39]. Register-level approaches infer how peripherals respond to register accesses, and are designed to explore firmware paths instead of faithfully emulating peripheral hardware [5, 15, 28, 37, 40, 44, 61]. These methods generate firmware-specific hardware models, which suffer from low universality and low fidelity. Function-level and register-level approaches can be combined [21, 23, 43] to emulate complex firmware like TrustZone OS.

A concurrent work [62] aims to mitigate the above limitations by generating hardware models with high fidelity under the guidance of hardware specifications. This method

involves a considerable amount of manual labor, while our work is more automated.

Belief-based Software Analysis. Belief analysis [13] is a technique to analyze a program's assumptions on certain program properties, and has been successfully applied to discover bugs [3, 13] and infer specifications for programs [32]. Unlike these approaches, our work extend belief analysis to infer hardware models instead of software properties.

9 Conclusion

In this paper, we propose PERRY, a system that synthesizes faithful and extendable MCU peripheral models from peripheral drivers. Through a comprehensive evaluation, we demonstrate the efficiency, consistency, universality, and scalability of PERRY in synthesizing hardware models. With a 74.24% unit test passing rate, PERRY efficiently infers hardware behaviors and enables high-fidelity emulation of various firmware, while also allowing for easy extension with minimal manual efforts. Through our case studies, we showcase the security applications of PERRY in reproducing firmware vulnerabilities, detecting specification-violation bugs in drivers and fuzzing RTOS for new vulnerabilities. These results highlight the potential of PERRY in enhancing security-oriented tasks of IoT firmware analysis.

A Write and Update Semantic Inference

A.1 Bit Value Variation-Based Write Semantic Inference

```
1 #define __HAL_RCC_HSI14_ENABLE() (RCC->CR2 |= RCC_CR2_HSI14ON)
2 /* Update CR2 to Enable HSI14 */
3 __HAL_RCC_HSI14_ENABLE();
4 ...
5 /* Wait till HSI14RDY is set in CR2 */
6 while(__HAL_RCC_GET_FLAG(RCC_FLAG_HSI14RDY) == RESET) {
7   if((HAL_GetTick() - tickstart) > HSI14_TIMEOUT_VALUE) {
8     return HAL_TIMEOUT;
9 }}
```

Listing 4: STM32F0xx RCC driver code snippet.

To infer write semantics in UNDR beliefs, considering all possible concrete values that can be written into Reg_A is impractical. However, we have observed that UNDR beliefs typically involve bit-level granularity, where only specific bits, known as critical bits, are intended to be toggled. For example, in Listing 4 at line 3, the critical bit is `HSI14ON`. Leveraging this observation, we propose a bit value variation-based method to identify critical bits and infer write semantics. The approach compares the values of each bit in the target register before and after the write operation. If a bit's value changes after the write, we consider the new value as the write semantic.

Formally, we define three states for bit values: `MUST_ONE`, `MUST_ZERO`, and `ANY`. These states indicate whether a bit must be 1, must be 0, or can have any value, respectively. To analyze the bit values, we utilize the bit-blasting technique to obtain symbolic expressions for each bit in both the original register value and the written value. Then, using an SMT solver, we determine the ranges of possible bit values for each bit. We formulate queries to the SMT solver based on the path constraints CS, asking whether a bit can be 1 (query Q_1) or 0 (query Q_0). The resulting bit state ST is determined as follows:

$$ST = \begin{cases} \texttt{MUST\_ONE}, if(Q_0, Q_1) = (unsat, sat) \\ \texttt{MUST\_ZERO}, if(Q_0, Q_1) = (sat, unsat) \\ \texttt{ANY}, else \end{cases} \quad (5)$$

By diffing bit states after and before the write, critical bits can be identified using the following function

$$f\left(ST_b^i, ST_a^i\right) = \left(ST_b^i \neq ST_a^i\right) \wedge \left(ST_a^i \neq \texttt{ANY}\right) \quad (6)$$

where ST_b^i and ST_a^i denotes the bit status of the i-th bit before and after the write. The concrete value v for each identified critical bit b can be calculated with the $eval$ function:

$$eval\left(\texttt{MUST\_ONE}\right) = 1, eval\left(\texttt{MUST\_ZERO}\right) = 0 \quad (7)$$

For each identified critical bit b and its concrete value v identified, we introduce a constraint $BC_b := (b = v)$. Since the update semantics can be expressed as the access constraints C of the register read access, the hardware behavior can be derived as:

$$B_{UNDR} := \left(\bigwedge_b BC_b, C\right) \quad (8)$$

A.2 Write-Update Dependency Resolution

In the example listed in Listing 5, the value `bitMask` is written to the `PRESETCTRLSET` register, and the `PRESETCTRL` register is expected to get updated to `bitMask`. However, since `bitMask` is not constrained, the write and update semantics cannot be inferred using previous methods.

```
1 /* set bit */
2 SYSCON->PRESETCTRLSET[regIndex] = bitMask;
3 /* wait until it reads 0b1 */
4 while (0u == (SYSCON->PRESETCTRL[regIndex] & bitMask)) {}
```

Listing 5: LPC51U68 SYSCON driver code snippet.

We observe that the expected update value for Reg_B is typically linearly related to the value written into Reg_A. To address this, we propose synthesizing linear formulas that satisfy these relationships. The approach involves establishing a linear equation $val_u = A \times val_w + B$, where val_u represents the expected value for Reg_B, val_w represents the value written into Reg_A, and A and B are constants to be determined. By substituting Reg_B in the access constraints C_B, we use a SMT solver to find concrete values for A and B that ensure the constraints in C_B are always true. In the given example, the substituted C_B becomes `(A × bitMask + B) & bitMask` $\neq$ `0`. With the determined values for A and B, we successfully synthesize a linear formula between val_u and val_w, allowing us to derive the hardware behavior as:

$$B_{UNDR} := (Reg_A = val_w, Reg_B = A \times val_w + B) \quad (9)$$

SoK: Security of Programmable Logic Controllers

Abstract

Billions of people rely on essential utility and manufacturing infrastructures such as water treatment plants, energy management, and food production. Our dependence on reliable infrastructures makes them valuable targets for cyberattacks. One of the prime targets for adversaries attacking physical infrastructures are Programmable Logic Controllers (PLCs) because they connect the cyber and physical worlds. In this study, we conduct the first comprehensive systematization of knowledge that explores the security of PLCs: We present an in-depth analysis of PLC attacks and defenses and discover trends in the security of PLCs from the last 17 years of research. We introduce a novel threat taxonomy for PLCs and Industrial Control Systems (ICS). Finally, we identify and point out research gaps that, if left ignored, could lead to new catastrophic attacks against critical infrastructures.

1 Introduction

Programmable Logic Controllers, or PLCs, are small rugged computers that have programmable memory to store functions such as timers and logic gates. These functions can control *physical* machines, such as water pumps or centrifuges [33]. PLCs are rather unique systems due to two main characteristics: First, they act as a bridge that connects the cyber and physical worlds; therefore any attack carried out on them can have an immediate effect in the real world. Second, they have opaque, heterogeneous architectures that are different from traditional computer architectures, comprising multiple firmware, which makes them difficult to secure [165].

Before the introduction of PLCs, physical processes were controlled by *relay* panels. Relays are switched either *on* or *off* by an electric current, and thus they can be used in logic circuits. Ladder logic was created as a way to configure relay panels to automatically launch actuation commands based on sensor information. As industrial processes became more complex and varied, relays were not enough to meet the new requirements. An evolution of PLCs, first based on microprocessors, then on networks, and more recently on modern technology paradigms, such as virtualization, has introduced multiple benefits, but at the same time increased the attack surface of these systems.

The first PLC, the *Modicon 084*, was introduced in 1968 [35]. Unlike relays, PLCs could be programmed and reprogrammed to adjust to the process requirements without any physical changes to the control system. A flurry of programming languages emerged, extending ladder logic and introducing new paradigms. Eventually, in 1993, the IEC 61131-3 standard unified these multiple languages into basic standards for PLC programming languages [171].

The first PLCs communicated with the physical world as well as with other computers via analog or serial communications. As computer networks became more reliable and available in the IT world, Ethernet communications were introduced to PLCs. This network connectivity keeps increasing. For example, the Siemens S7-1500 PLC includes up to 4 Ethernet ports, whereas the legacy S7-300 needed an expansion module to support Ethernet connectivity. At the same time, network accessibility now allows remote attackers to deploy classical network attacks against PLCs.

Nowadays, with the advent of Industry 4.0 and IIoT [160], PLCs are going through another paradigm shift bringing even more functionalities like cloud integration, web services, and virtualization. New players like CODESYS and OpenPLC have also entered the market, challenging the long-standing practice of using proprietary hardware and proprietary software products that dominated the PLC industry. These changes pose many open questions about the security of PLCs to the research community.

In order to advance the security of PLCs and the systems they interact with, plenty of research has been produced in the past decades. In particular, research output increased after the term Cyber-Physical System (CPS) was coined in late 2006 by the NSF in the United States [47]. However, the community still lacks an up-to-date general understanding of where the security of PLCs stands and what directions should (or should not) be taken in the future.

To address this challenge, we introduce a comprehensive analysis of the security of PLCs by integrating knowledge from multiple fragmented origins (scientific and grey literature), comprising many existing attack and defense methods in the literature. In addition, we introduce a novel threat model as well as classification and evaluation criteria for summarizing and structuring the existing knowledge about PLC security.

In summary, we make the following contributions:

- We provide a systematization of the literature that consists of **133 papers**, which include **119 attack methods**, and **70 defense methods** (one paper might include one or more attack or defense methods).
- We present a comprehensive taxonomy[1] that integrates the scientific literature with the existing ATT&CK for ICS Matrix in collaboration with MITRE ATT&CK®.
- We identify important PLC security research gaps and discuss future research directions and recommendations.
- We provide **three public tools** to facilitate and foster research and collaboration on this topic. **1)** Our full systematization dataset[2], which other researchers can use to replicate our results and perform their own analyses. **2)** A PLC security artifacts repository[3], which acts as a centralized database for artifacts updated by the community. **3)** A reference graph[4] that enables researchers to further analyze the reviewed literature in this SoK.

2 Background

We now introduce some relevant background topics on PLCs that will be leveraged in future sections.

2.1 PLC System Environment

PLCs [152] are an essential component of most physical critical infrastructures such as water treatment systems and gas pipelines. PLCs are commonly found in Industrial Control Systems and Supervisory Control and Data Acquisition (SCADA) systems.

In the last few years, two new concepts have emerged in the context of Cyber-Physical Systems: Industrial IoT (IIoT) and Indystry 4.0. IIoT is a subset of IoT concerned with connecting industrial assets, e.g., PLCs, with information systems and business processes. Industry 4.0, on the other hand, is a subset of IIoT and refers to the use of Internet technologies to improve production efficiency by employing smart services in smart factories [160]. Furthermore, IIoT and Industry 4.0 have changed PLCs in two ways: First, they have introduced support for modern network protocols, which we discuss further in Sec. 2.3. Second, they have changed the hardware and software architectures to support virtualization and compatibility. We further discuss these topics in Sec. 2.4.

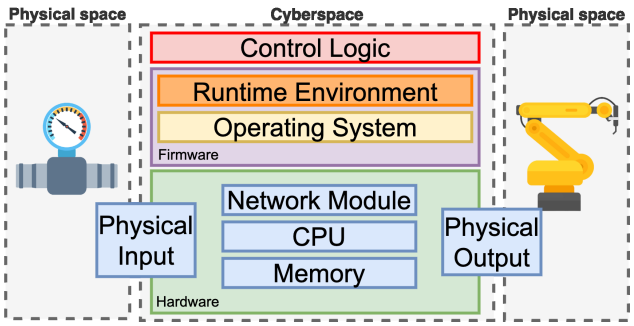

Figure 1: A Generalized PLC Architecture. Based on [33, 59].

PLCs' industrial environment, however, remains largely the same and typically includes the following [166]:

Actuator. A hardware component that moves or operates a device in the physical world. Examples of actuators include valves, motors, and piezoelectric actuators.

Sensor. A device that generates an electrical analog or digital signal that represents a physical property of a process. Examples include temperature or magnetic field sensors.

Engineering Station. A general-purpose computer that is used to write the control logic or ladder logic code for the PLC to execute. It is usually connected to the PLC so that the compiled control logic program can be uploaded.

Human Machine Interface (HMI). The hardware or software used to interact with the PLC, e.g, a physical control panel with buttons and lights or a software display.

We further discuss PLCs' underlying architecture and environment in the extended version of this paper [105].

2.2 PLC Basic Components

As shown in Fig. 1, a typical PLC has the following basic components that are susceptible to attacks:

Control Logic. A control logic program contains the instructions that the PLC executes to interact with its environment. The IEC 61131-3 standard [171] specifies the syntax and semantics of a unified suite of programming languages for PLCs. Control programs are written in one of these supported languages, e.g., Structured Text, and then compiled into machine code or bytecode. For instance, Siemens PLCs run proprietary MC7 bytecode [126] compiled by the SIMATIC S7 Manager software [157].

Runtime Environment. The runtime environment executes the process control code [59] and interacts with the I/O modules. It can be proprietary, e.g., Schneider, or open source like the OpenPLC runtime [17].

Operating System. Most PLCs have a Real-Time Oper-

ating System (RTOS) [164]. RTOS are operating systems that meet strict processing time requirements and support real-time applications. Vendors support a variety of RTOS in their platforms. For example, Siemens supports the Nucleus RTOS [159] and VxWorks [158].

Firmware. The firmware bridges the gap between the PLC hardware and software. While simple PLCs might run applications as bare metal (without an OS) [24, 196], modern PLCs use the firmware under an RTOS. Firmware can be upgraded via SD cards or through a network connection [83].

CPU. The CPU interprets the input signals and executes the logic instructions saved in memory. The CPU chassis has slots where other components may be attached, e.g., a network module. It may also include USB ports and SD Card slots.

Memory Unit. It stores the program that the CPU will execute along with input data. The memory unit may include different types of memory blocks, which are further discussed in the extended version of this paper [105].

Network Module. Modern PLCs can have one or more ports to communicate with the supervisory control network (regular computers monitoring the process) or the fieldbus (actuators and sensors).

Physical I/O Modules. These include input modules with metal pins that receive information (via a voltage or current analog signal) from sensors. The output modules send analog data to actuators such as servo motors.

PLC Scan Cycle. It is the cycle in which the PLC reads the sensor inputs, executes the current control logic program and updates the output to the actuators. It is measured in ms and should stay constant. If its time increases, PLCs implement a watchdog timer that sends the PLC to a *Fault* mode [6, 21].

2.3 PLC Communication Protocols

As discussed in the introduction, PLCs are becoming more connected via modern communication protocols. Many of these protocols were not designed to include strong security features [85], allowing for the proliferation of vulnerabilities that make the PLCs running them susceptible to attacks [31, 189]. Protocols commonly used in practice include, but are not limited to, the following:

Fieldbus. PLCs use Fieldbus [170] protocols to talk to sensors and actuators. Historically these communications were done through serial-based interfaces or analog signals. Sample standards include Profibus, CAN bus, Modbus, and DeviceNet. They all differ in features and implementation, resulting in limited compatibility [57, 96].

Supervisory Network Protocols. PLCs communicate with other controllers or classical computers through a variety of proprietary and standardized protocols. These protocols use the IEEE 802.3 Ethernet standard [84] in industrial environments [111]. For example, the EtherNet/IP protocol combines IEEE 802.3 and the TCP/IP Suite [54]. Some are designed to operate on LANs (they do not use IP addresses but only MAC addresses), such as GOOSE, while others use TCP/IP and can be used on LANs and WANs, such as Modbus TCP.

Industry 4.0 Protocols. These protocols include support for cloud connectivity, compatibility between devices, and security features. Examples include MQTT (Message Queuing Telemetry Transport) [122] and OPC-UA (Open Platform Communications-Unified Architecture) [176]. Currently, some PLC models support Industry 4.0 protocols [41], whereas older PLCs can be retrofitted to support them [80].

2.4 SoftPLCs

The term SoftPLC has been used in the scientific literature since the late 1990s [49, 142, 162]. Although it has not been well defined, generally a SoftPLC is a software runtime environment that executes PLC programs, for example, programs that follow the IEC 61131-3 standard [171]. The runtime is portable and compatible with multiple hardware that can range from microcontrollers to cloud servers [129]. The two major SoftPLC projects are CODESYS [44] and OpenPLC [129]. CODESYS supports approximately a thousand different device types from more than 500 manufacturers [43]. OpenPLC, first proposed in 2014 [20], includes a runtime and an editor, and it is compatible with 18 platforms including Windows and Linux [129]. One of the biggest differences between OpenPLC and CODESYS is that OpenPLC's runtime is open source [17], unlike that of CODESYS. For the remainder of this work, we will refer to traditional PLCs as *HardPLCs*, in order to differentiate them from SoftPLCs.

3 Research Questions and Methodology

In this section, we first elaborate on the research questions addressed in this paper, and we then describe the methodology we followed to systematize knowledge by collecting, analyzing, and evaluating works in the literature.

3.1 Overview of Research Questions

RQ-1: ***What are the attack methods against PLCs?*** We aim to categorize and analyze attack methodologies targeting PLCs introduced in the literature in the last 17 years.

- **RQ-1.1:** *Which components of the PLC are targeted?* We aim to identify what internal components of a PLC, e.g., the CPU described in Sec. 2.2, are being targeted, in an effort to identify patterns such as the components that have received the most attention in the literature.
- **RQ-1.2:** *How difficult is it to deploy attacks?* We also aim to identify the level of effort required by attackers to successfully carry out attacks against PLCs. In Sec. 4, we elaborate on a threat model and classification criteria, including the

potential attack vectors as well as the level of access required by attackers, e.g., Internet access, needed to deploy an attack.

- **RQ-1.3:** *What is the impact of deploying attacks?* Finally, we are interested in identifying the impact that attacks against PLCs may have if they are deployed successfully. This includes the level of disruption achieved, e.g., modifications to control logic programs as shown in Sec. 2.1.

RQ-2: *What are the defense methods to protect PLCs?*
In addition to attacks, we want to systematize the PLC defenses proposed in the literature in the last 17 years.

- **RQ-2.1:** *Which components of the PLC are protected?* We want to identify which of the components introduced in Sec. 2.2 are the focus of defenses to understand which of them have received less attention and may therefore remain unprotected.
- **RQ-2.2:** *How difficult is it to deploy defenses for PLCs?* We also study the level of effort required to deploy defense mechanisms for PLCs. As shown in Sec. 4.5, this includes the organizational effort from administrators and/or operators to modify and adjust a given PLC/ICS Environment and the performance overhead.
- **RQ-2.3:** *Are there enough defenses addressing reported attacks for PLCs?* Finally, we are interested to know if enough defenses exist in the literature to counteract the attacks we have identified as a part of this work. This way, we aim to identify research gaps and discuss the directions of future work as we describe in Sec. 6 and Sec. 7.

3.2 Knowledge Systematization Methodology

To answer the Research Questions raised in Sec 3.1, we use the systematization methodology shown in Fig. 2. First, we perform a systematic literature review. Second, based on the data obtained in the literature review, we perform data analysis and modeling. Finally, we assess the data.

❶ **Systematic Literature Review**. We review both scientific and grey literature to collect PLC attack and defense methods. We also define the final SoK scope based on the specified inclusion criteria.

Scientific Literature Review. We consider scientific literature to mean the literature that is based on the scientific method that uses evidence to develop conclusions. It uses previous literature to develop theories and hypotheses while taking care to cite the authors and tools that are used. For the scientific literature review, we carried out the following steps: **1)** Search Querying. We used search queries based on keywords such as *"plc"*, *"ics"*, and *"security"*. The complete list of keywords can be found in Appendix A. **2)** Consulting literature resources. We used these queries to search the selected resources such as Google Scholar and the ACM Digital Library. The complete list of consulted resources can be found

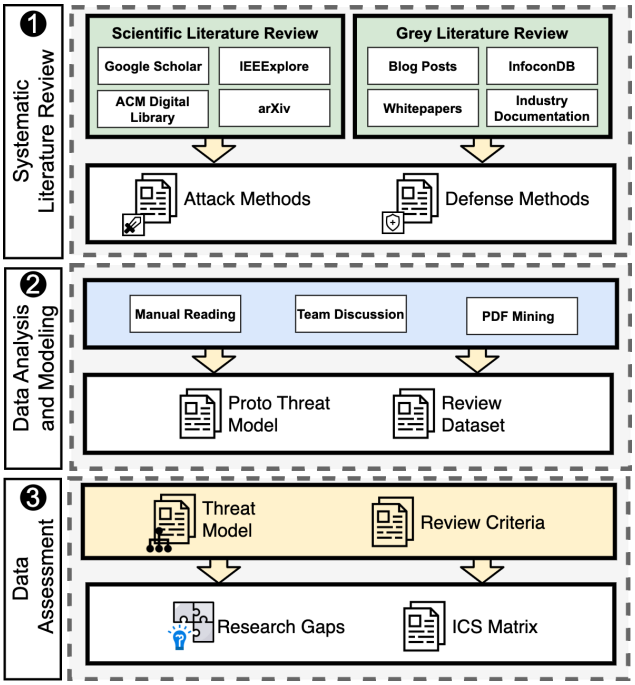

Figure 2: Our systematization methodology. Based on [100].

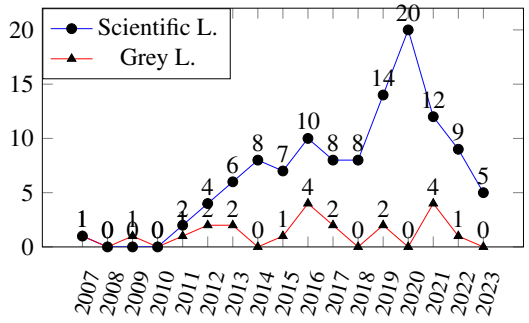

Figure 3: Literature focused on PLC Security per Year.

in Appendix A. **3)** Applying inclusion criteria. After collecting all these papers, we include them only if they meet the following three criteria. A) The paper must include the term "PLC" or "Programmable Logic Controller". B) It proposes an attack or defense method. C) It includes an experimental evaluation of an attack or defense with at least one PLC. **4)** Applying snowballing. We applied the snowballing technique [187] on all the papers that matched the above criteria to find papers that went unnoticed during the initial search.

Grey Literature Review. We consider grey literature as literature with limited distribution (i.e., not included in academic publishing libraries). It includes unpublished reports, policy documents, white papers, and technical reports [45]. To perform our grey literature review, we followed the same steps used in the scientific literature review, except that in step 2) (consulting literature resources) we instead searched in the grey literature resources listed in Appendix A.

Final SoK Scope. As a result of the scientific and grey literature reviews we collected 133 papers with the earliest being from 2007 and the latest from 2023. Although we searched for papers before 2007, we did not find any that met our criteria. To the best of our knowledge, and based on our exhaustive research, there was no research on designing new attacks or defenses for PLCs before 2007. Fig. 3 shows the final number of scientific and grey papers included in our selection criteria per year of publication, depicting an overall increase in PLC security research over the years, peaking in 2020.

❷ **Data Analysis and Modeling**. In this phase, we first read and analyzed each paper to extract important security-relevant information such as attack vectors, PLC models and manufacturers, and PLC target component. Second, we matched each of the attack and defense methods to their corresponding MITRE technique, subtechnique or mitigation category. The MITRE framework is further discussed in Sec. 4.1. Third, we recorded this information in a spreadsheet. The result of this data analysis and modeling was the identification of the building blocks for a first draft of our threat model depicted in Fig. 4 and the classification criteria discussed in Sec. 4., e.g., the access level and PLC target component.

❸ **Model Assessment**. In this phase, we evaluate the data, threat model, and criteria developed in ❷ to produce the SoK contributions. We use these results to summarize our findings and identify the research gaps discussed in Sec. 6. Finally, we evaluate the results to produce the ICS threat taxonomy discussed in Sec. 4.1.

4 Classification and Evaluation Criteria

In this section, we present the criteria to classify and evaluate the works considered for this SoK. These criteria and the symbols introduced alongside them will later be used in Tables 1 and 2. Our first research question RQ-1 is addressed in Sec. 4.2, Sec. 4.3, and Sec. 4.4. Our second research question RQ-2 is addressed in Sec. 4.5, Sec. 4.6 , and Sec. 4.7.

4.1 ICS Threat Taxonomy

To better classify attack and defense methods in the following sections, we extended the MITRE ATT&CK for ICS Matrix [112] and the Hybrid ATT&CK Matrix [9] to create the ICS^2 Matrix, a taxonomy of threats against PLCs and ICS. The taxonomy includes adversary tactics that describe "what" is the adversary's goal and attack techniques that describe "how" the adversary can complete their goal. Additionally, it includes mitigations that prevent a technique from being successfully executed. The ICS^2 Matrix incorporates the scientific knowledge accumulated during the past 17 years of PLC security research by adding 6 new attack techniques and 5 new mitigation categories based on the literature reviewed in this SoK. Due to space restrictions, we provide a condensed version of our taxonomy in the extended version of this paper [105]. The full ICS^2 Matrix version is publicly available[5] for the security community to use and extend. Additionally, at the time of writing this paper, we are actively working with MITRE to integrate our research findings within the next version of MITRE ATT&CK for ICS [112] and D3FEND Knowledge Graph [90, 121].

Matrix Integration. One of the main limitations of the MITRE ATT&CK for ICS Matrix [112] is that it does not incorporate techniques based on security research findings but instead focuses on techniques based on real-world ICS cyber-attacks. For example, the "system firmware" technique [169] includes a reference to Triton discussed in the extended version of this paper [105]. However, it does not include any references to any of the PLC Firmware research listed in Table 2. This was also confirmed by MITRE during one of our communications. Our ICS^2 Matrix fills this gap. To integrate our systematization findings with the existing MITRE for ICS Matrix, we needed to add techniques not already covered by MITRE. To develop these new techniques, we used MITRE's official guidelines [120]. This document outlines the information required to create a new MITRE-style technique, for example, a matching "tactic" and "procedure example". In the extended version of this paper [105] we describe in detail how we developed and included one of these techniques.

4.2 Attack Classification

Considering RQ-1.1, the following criteria classify attacks according to the taxonomy technique, e.g., Adversary-in-the-Middle, the basic components that are targeted, e.g., the CPU or Memory, and the attack vectors that can be ultimately used against a PLC.

Target PLC Component. Each attack method was classified according to the PLC Basic Component that is the primary target, following the description previously shown in Sec. 2.2. Such information was retrieved based on the descriptions explicitly provided by the paper's authors.

Attack Category. Each attack method was sorted into one *technique* category, based on our ICS^2 Matrix. The technique categories allowed us to determine what kind of defenses might (or might not) counter them.

Attack Vector. When launching an attack against a PLC, there might be one or more vectors or paths available to the adversary to deliver the payload. The complete list of attack vectors we considered is shown in the extended version of this paper [105]. Most of the time the attack vector is a vulnerability in the implementation of a network protocol, e.g., S7comm. However, there are other vectors like inserting an SD card into the PLC chassis, for instance, the work by Garcia et al. [65].

[5] https://github.com/efrenlopezm/ics2matrix

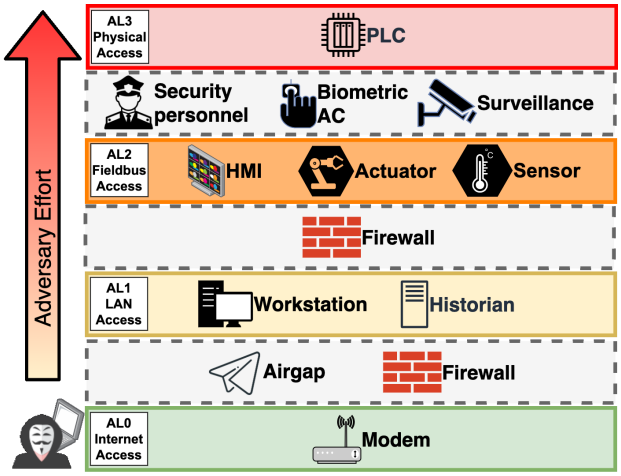

Figure 4: PLC-centered Threat Model. Based on [166].

4.3 Attack Complexity

Following RQ-1.2, the criteria shown next are intended to understand, qualify, and quantify how complex it is for an attacker to carry out an attack against a target PLC.

Environment Knowledge. This criterion evaluates how much knowledge of the cyber-physical system environment where the PLC lives, e.g., the system topology discussed in Sec. 2.1, is required to launch the attack. An attack may require *zero knowledge* (○), e.g., a DoS [193] attack targeting the PLC network module only requires an IP address and does not require any environment knowledge. *Partial knowledge* (◑) may require basic information only, e.g., a high-level description of the physical process. CaFDI [116], for example, requires limited local information about the substation configuration. Finally, *extensive knowledge* (●) requires detailed information about the cyber-physical environment. For example, SABOT [115] requires the adversary to encode their understanding of the system behavior into a specification.

Available Source Code. This criterion evaluates whether the attack source code is publicly available (●) or not (○).

Access Level. We also consider the level of access an attacker needs to carry out the suggested attacks. Our threat model, shown in Fig. 4, is divided into four distinct *Access Levels* (ALs) labeled from AL0 to AL3. Adversaries might try to move through the ICS environment in order to reach the PLC and deliver their exploit payload. Overall, our threat model helps us answer two main questions: *1) What access level is required to attempt the attack?*, and *2) What attack surfaces are available to the adversary?*

AL0: Access to PLC via the Internet (0). An adversary may be able to access a PLC through an Internet-compatible protocol, e.g., S7comm. This is usually a private network where a remote SCADA computer connects to a PLC via an industrial protocol such as DNP3. Attacks may also be launched if a PLC is publicly exposed on the Internet. At first, this might seem like a ludicrous idea: Why would anybody make a PLC publicly available over the Internet? However, a preliminary Shodan search suggests that the number of publicly accessible PLCs (excluding Shodan-identified honeypots) is over 6,500 as of September 2023[6]

AL1: Access to Supervisory LAN (1). This level requires an attacker to have access to the LAN network of the industrial process. This can be achieved if the attacker compromises workstation computers, data historians, or similar operational computers. Some industrial protocols run only on Ethernet and are non-routable (such as GOOSE), so an attacker targeting a vulnerable GOOSE stack on a PLC will have to do so in the same LAN.

AL2: Access to PLC Fieldbus Network (2). As mentioned in Sec. 2.3, fieldbus represents the lower level of communications between the PLC and nearby field equipment such as actuators and sensors. An attacker can compromise any of these devices to exploit a vulnerability in the fieldbus code implementation. The attacker can also launch Adversary-in-the-Middle attacks in this network, as fieldbus communications are rarely authenticated in practice.

AL3: Physical Access to PLC (3). Lastly, this level assumes the adversary has bypassed environmental and physical protection measures (e.g., locked doors) of the target. Having physical access to the PLC may be the most difficult scenario for an adversary but can still be achieved by malicious insiders or disgruntled employees. An attacker with physical access can use a JTAG interface.

4.4 Attack Impact

Following RQ-1.3, the criteria below are intended to understand and quantify the potential impact of a successfully carried out attack, e.g., the *payoff* in return of the effort invested, as discussed in Sec. 4.3.

Potential Damage. This criterion evaluates the *immediate* damage inflicted to the physical operation of the ICS. The damage is *limited* (1) if the attack does not change the operation of the process but instead aims to collect information or gain unauthorized access, for example, a password sniffing attack [184]. The potential damage is *substantial* (2) if the attack can stop the industrial process partially or completely, e.g., a DoS attack [128]. The potential damage is *severe* (3) if the attack is able to insidiously control the physical process, e.g., a logic bomb or firmware modification attack, where the attacker can launch arbitrary control commands to the system (similar to Stuxnet, discussed in the extended version of this paper [105].

HardPLC Targets. An attack may affect a *single* PLC model (○), e.g., the Siemens SIMATIC S7-300, or may affect *multiple* PLC models of the same manufacturer (◑), e.g., the Rockwell's Allen-Bradley 1100 and 1400 models. Also, an

[6] https://www.shodan.io/search?query=plc+-%22792%2F71644%22.

attack may affect *multiple* PLC models from two or more manufacturers (●), e.g., Siemens' SIMATIC S7-1500 and Modicon's M221. An attack that is effective against various devices is an indicator of the severity of the problem, while an attack focusing on a single device might be contained.

SoftPLC Targets. Finally, this criterion indicates if a SoftPLC was used to evaluate the proposed attack. An attack may have been evaluated using *CODESYS* (C), *OpenPLC* (O) or *no SoftPLC* at all (-) (i.e., the attack only focused on HardPLCs).

4.5 Defense Classification

After describing our criteria for attacks, we now focus on defenses by looking at RQ-2.1.

Defense Category. Each defense method was sorted into one *mitigation* category, based on our ICS^2 Matrix. The mitigation categories allowed us to determine what kind of attacks might (or might not) be countered.

Defense Vector. The defense vector is the path used to stop the attack payload from being delivered. The available defense vectors are defined in our threat model for PLCs in the extended version of this paper [105]. Most of the time, the attack and defense vectors will match. However, they can differ. For example, *Rajput et al.* use the JTAG interface as a defense vector [139].

4.6 Defense Deployability

Following RQ-2.2, the following criteria evaluate how difficult it is to deploy a defense method to protect PLCs.

PLC Overhead. This criterion quantifies the overhead that the defense method incurs on the PLC itself, which can be either *zero* (1), *negligible* (2), or *considerable* (3).

Infrastructure Overhead. This criterion quantifies the cost that comes with setting up the required infrastructure to implement a defense method. That may involve *no changes* (1), or it may involve *either* an infrastructure change, e.g., setting up new VLANs or an additional hardware component, e.g., bump-in-the-wire (2). Finally, a defense may involve *both* infrastructure changes and hardware components (3).

Maintenance. This criterion quantifies the level of post-deployment maintenance required by a given defense method. A defense method may require *no maintenance* (1), *sporadic maintenance* (2), or *constant maintenance* (3).

Source Code Availability. This criterion evaluates whether the defense source code is publicly available (●) or not (○).

4.7 Defense Robustness

Following RQ-2.3, we also characterize how the defense mitigates attacks.

Defense Stage. Defenses can be categorized in three different stages of the security process. 1) *Prevention Defense* (PR) aims to reduce the possibility of an incident *before* a known vulnerability is exploited. 2) *Detection Defense* (DE) aims to identify and alert about a *current or recent* attack. 3) *Recovery Defense* (RE) aims to reduce the damage of an attack *after* it has been carried out successfully.

Effectiveness. The defense method's effectiveness is indicated by its accuracy. The accuracy values are taken from the research paper itself. If the paper did not report or specify the accuracy, it is marked as *N/S* (not specified). We selected accuracy because it is the most reported metric across the defense method papers. We recognize that this metric does not work for all defense methods, however, it is the most frequently reported quantitative metric available in the current literature. We further discuss this problem in Sec.7.

HardPLC Scope. This criterion evaluates the number of different PLC models that are protected by the defense. The defense may protect a *single* PLC model (○), e.g., the Siemens SIMATIC S7-300, or it may protect *multiple* PLC models of the same manufacturer (◑), e.g., the Rockwell's Allen-Bradley 1100 and 1400 models. Also, a defense may protect *multiple* PLC models from two or more manufacturers (●), e.g., Siemens' SIMATIC S7-1500 and Modicon's M221.

SoftPLC Scope. This criterion indicates if any SoftPLC was used to evaluate a defense, either *CODESYS* (C), *OpenPLC* (O) or *no SoftPLC* at all (-).

5 Overview of Attacks

By using the systematization methodology presented in Sec. 3 and the criteria discussed in Sec. 4, we obtained Tables 1, and 2. These tables use the *PLC target component* categorization defined in Fig. 1.

We now illustrate examples of attacks per target component. Due to the large number of papers in our SoK (133 papers), we cannot discuss all of them. To select the papers systematically, we picked the two papers with the most citations from each category. We used Google Scholar to perform the search on June 3, 2023. In the next paragraphs, we discuss the insights provided by these highly-cited papers.

Attacks that Target the PLC Communications Module. *Urbina et al.* [177] introduce an AitM attack between the PLC and the field devices (AL2). An interesting observation of that paper is that field networks tend to follow a ring topology rather than the typical star topology of switched Ethernet networks; therefore, an AitM attack does not need to use ARP (Address Resolution Protocol) spoofing or similar techniques to place itself between two devices. It just needs to inject the attack between the two attacked devices. An AitM attacker can then send false sensor readings to the PLC or false control commands to actuators.

Wardak et al. [184] introduce another network attack, which focuses on password sniffing on the network interface between a workstation and the PLC (AL1) in Fig. 4. Several of the connections between the workstations and the PLCs are not encrypted (or authenticated). Thus, passwords can be

sniffed and then used to gain access to protected actions in the PLC (e.g., start and stop PLC commands).

Attacks that Target the Control Logic. Two of the most important challenges for modifying the control logic of a PLC are 1) how to infect the PLC without being detected and 2) how to hide the infection from the engineering workstation. To address challenge 1, *Yoo and Ahmed* [194] propose two control logic infection attacks that bypass network intrusion detection systems (IDS). In the first attack, they bypass IDS that look for transfers of control logic (compile code) by injecting control code in data blocks and then modifying the execution pointer to execute code in data blocks. The second attack uses fragmentation and noise to further obfuscate these control logic transfers to the PLC.

Kalle et al. [89] target both challenges (infection and stealthiness). They consider a different problem in code injection, where they assume they have a binary they want to modify. They then develop a decompiler transforming low-level control logic to a high-level instruction list to help them inject the malicious code before recompiling it into a binary that can be uploaded to the vulnerable PLC. They also develop a virtual PLC that interfaces with the engineering workstation (via an AiTM attack); this virtual PLC then sends previously captured network traffic of the original uninfected control logic back to the workstation.

Attacks that Target the PLC CPU. As discussed in the extended version of this paper [105], PLCs generally have three CPU operating modes: "STOP," "RUN," and "PROGRAM." Attacks targeting the PLC CPU focus on disabling the CPU remotely (AL3 or AL2) with STOP commands. Beresford [28]'s work is an example of such attacks. *Biham et al.* [31] created a rogue engineering station that could remotely start or stop these newer PLCs by compromising a vulnerable key exchange protocol.

Passwords can protect CPU modes of operation, but a compromised password can still enable remote attacks. Higher-end PLCs protect their CPU modes with physical methods, such as using a physical switch or a physical key. These methods are further discussed in the extended version of this paper [105].

Attacks that Target the PLC Firmware. Firmware modification is one of the most powerful attacks in any platform, as the attacker can control access to the input and output modules of the PLC while remaining undetected. *Basnight et al.* [24] pioneered methods on PLC firmware reverse-engineering and how to develop modified firmware as a proof of concept.

The most cited firmware attack paper in our study is Harvey [65]. The authors extracted firmware images from the update packages of the PLC vendor's website and the PLC memory through the JTAG interface of the PLC processor. Then they identified the subroutines that allowed them to modify the inputs and outputs for the PLC. To upload the firmware, they rely on vulnerabilities to protect remote firmware update functions (AL0, AL1 or AL2 in Fig. 4) or directly through the JTAG interface (AL3 in Fig. 4).

Attacks that Target the PLC I/O. The two most cited papers targeting the inputs and outputs of the PLC focus on how to use input or output physical signals as covert channels to exchange information. For example, *PHYCO* [66] proposes a method where two compromised PLCs can talk to each other, even when a firewall exists between them. One PLC can send an output to increase power generation, and the other PLC can read the increased generation as a bit of information. Adversaries can also use the PLC I/O to exfiltrate data. *Krishnamurthy et al.* [98] illustrate how a PLC sending control commands to a motor can leak information about the status of a chemical plant.

Attacks that Target the PLC Runtime. An illustrative example of runtime attacks is provided by *Abbasi et al.* [2], by introducing Pin Control Attacks. This attack involves tampering with the SoC configuration within the PLCs, aiming to disrupt the communication between the PLC runtime and the hardware peripherals. By implementing this attack, the adversary severs the connection between the runtime software and the physical world, allowing them to manipulate the control data within the actual physical process.

Runtime attacks can also target the availability of the system; for example, *Gjendemsjø et al.* [71] proposed an XML Bomb Attack that causes the PLC runtime to crash by modifying an XML file.

Attacks that Target the PLC Operating System. There are not a lot of papers focusing on attacking the OS of PLCs. In their comprehensive study of the attack surface of a PLC, *Abbasi et al.* [4] touch upon an intriguing aspect of PLC security: the vulnerability of the Siemens Adonis Real-Time Operating System. Although their primary focus lies on the bootloader security of Siemens PLCs, they also explore security weaknesses inherent in the Adonis RTOS.

Attacks that Target the PLC Memory. Some network or control logic attacks target the memory of the PLC as part of their infection chain by modifying memory blocks or by getting memory dumps. The most cited efforts focused on developing worms stored in memory [140, 163].

So far, we have introduced the most cited examples of attacks per target, but we have not illustrated representative defenses. Because of limited space, we refer the reader to a discussion of defenses in the extended version of this paper [105].

6 Research Gaps

We now focus on identifying research gaps, and recommendations for future work by analyzing the data from Tables 1 and 2.

Most of the Attacks Require Zero Environment Knowledge. We found that 82% (97/119) of the attacks that may cause either *limited* (1) (36% (35/97)), *substantial* (2) (56% (54/97)), or *severe* (3) (8% (8/97)) damage require *zero*

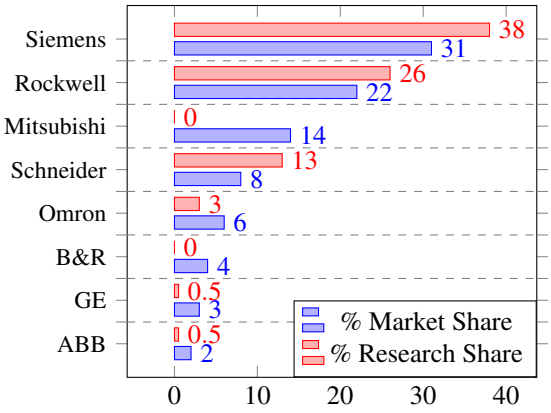

Figure 5: Comparison of Research Share vs Market Share.

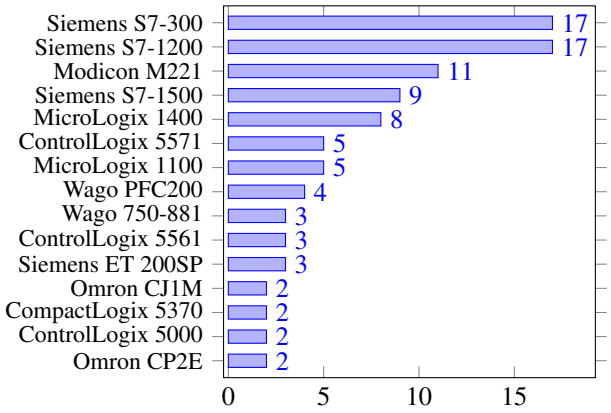

Figure 6: The 15 Most Common PLC Models.

knowledge (○) of the environment in which the PLC lives, following the description presented in Sec. 2.1 and the criteria discussed in Sec. 4.3. This may imply that adversaries can potentially launch non-trivial attacks against power grids, chemical plants, water treatment plants, etc. by targeting PLCs without having to invest time performing reconnaissance or learning the specifics of actuators, sensors, etc. Moreover, we were able to identify that only a few defense methods, e.g., *Formby et al.* [59] and *Bellettini et al.* [25], make use of such important environmental information. We therefore recommend that future defenses make use of environment knowledge in their strategy to increase their effectiveness.

The Security of Important PLC Brands Has Not Been Explored. We found that the security of some important PLC platforms widely used in practice has been ignored. As shown in Fig. 5, the *market* share percentage of important PLC manufacturers such as Mitsubishi, Omron, ABB, and GE is considerably higher than their *research* share, e.g., the number of papers explicitly using them for attack/defense evaluation purposes. For example, even though Mitsubishi PLCs account for 14% of the global market, they contribute to 0% of the research share in our review (they only appear once in our

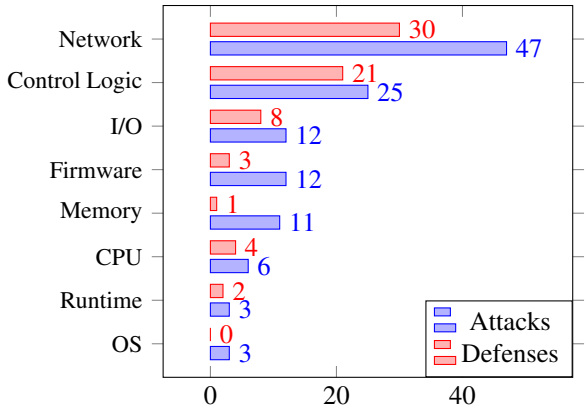

Figure 7: Defense vs Attack Methods per Target Component.

Grey literature survey [38]).

This means that there are potentially thousands of PLCs deployed in the world whose security has not been explored or may not have been adequately understood. We therefore recommend future lines of work specifically addressing these devices, exploring the effectiveness of existing attacks and defenses as discussed in this work, as well as the introduction of newer security methods tailored for them.

Lack of Defenses at the Recovery Stage. We found that most defense methods are designed for the Prevention (PR) and Detection (DE) stages discussed in Sec. 4.7, 47% (33/70) and 47% (33/70) out of 70 respectively, whereas the Recovery (RE) stage accounts for only 6% (4/70). This means that in the event of a successful attack there are limited options to recover and bring the PLC back to operation.

Most Attacks and Defenses are Evaluated on a Small Subset of PLCs. Our results show that the top 5 most common PLC models in our literature review (as shown in Fig. 6) account for 40% of all studies. This may result in a narrow understanding of PLC security that excludes the rest of the PLC models in the market. Additionally, we found that 80% (95/119) of attack methods and 81% (57/70) of defense methods were evaluated using a single HardPLC model (○). This means that most attack and defense methods are shown to work with a single HardPLC model, making it unclear whether or not the defense method can be generalized to other PLC models and manufacturers. Therefore, we recommend that future research include an evaluation of multiple PLCs.

Important Tactics have Little to No Research. Our ICS^2 Matrix includes 14 Tactics. However, as Fig. 8 shows, most of the attack methods focus on Impair Process Control, Inhibit Response Function, Exfiltration, Collection, and Persistence. On the other hand, important Tactics like Command and Control, Lateral Movement, Evasion, Credential Access, and Initial Access have not been investigated. One reason that might explain why these tactics have not been explored in previous research is that they are too specific or custom-fit. For ex-

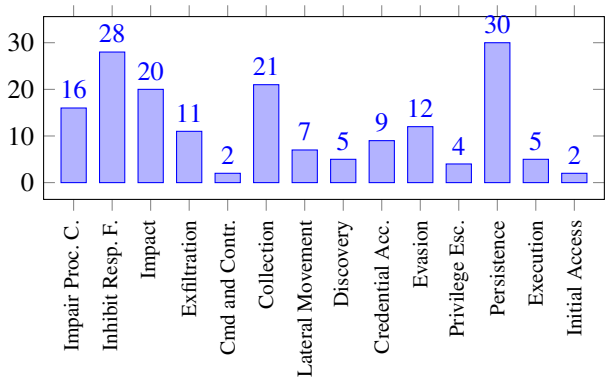

Figure 8: Attack Methods according to their Tactic.

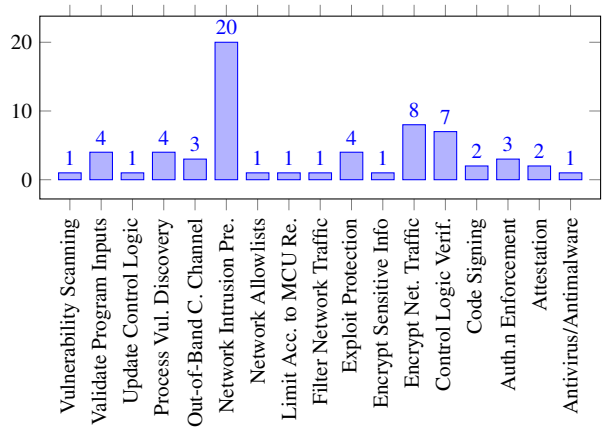

Figure 9: Defense Methods per Mitigation Category.

ample, the Command and Control tactic includes techniques such as *Commonly Used Port* and *Standard Application Layer Protocol*, which depend on specific network protocols and ports. This specific focus on network ports might limit the scope of research that can be carried out for this tactic.

Most Mitigation Strategies have Little to No Research. We found defense methods that match 17 Mitigation categories. However, as shown in Fig.9, the majority of these defenses fall into the Network Intrusion Prevention, Encrypt Network Traffic and Control Logic Verification categories. The remaining 14 Mitigation categories have only 4 or fewer defenses. These include important categories like Antivirus/Antimalware, Vulnerability Scanning, and Attestation, which are especially important given the rise of ICS malware such as the ones described in the extended version of this paper [105].

Weaknesses of State-of-the-Art Defenses Based on the results shown in Tables 1 and 2, we identified the following three major weaknesses when it comes to defending PLCs: **1)** No ransomware detection. Even though researchers have shown that ransomware attacks against PLCs are possible [60, 199] and there are multiple documented ransomware attacks against ICS, there is no available research focused on how to detect and stop PLC ransomware. To address this research gap, future research should introduce new defense methods that take advantage of state-of-the-art malware and ransomware detection techniques such as sandbox detection [179] and static and dynamic analysis [130]. **2)** No web-based malware detection. Research shows that attackers target PLCs' web interfaces [106, 148] and that it is possible to compromise PLCs via their web applications [134]. However, there is no available research focused on how to detect and stop malware targeting PLCs' web interfaces. **3)** No Exfiltration over Covert Channel Detection. This is one of the new techniques that we introduced in our ICS^2 Matrix, which includes methods such as *PHYCO* [66]. Introducing this technique lays the groundwork for identifying the need for mitigations against such techniques. Currently, there is no known mitigation for this type of attack. Indeed, in 2014 *Garcia et al.* wrote: "There has been no detection solution capable of identifying such hidden communications in the physical power system," [66] which still holds true.

7 Discussion

We now discuss research challenges that have not attracted enough attention and may become relevant as PLCs evolve.

Reproducible Research. Based on our analysis and the results presented in Tables 1 and 2, few defense and attack methods provide publicly available research artifacts. During our literature review, we searched for research artifacts for each paper. We searched the paper itself on Google and the author's website. We were able to find the source code for 19 papers (only 16%). This limits the reproducibility of attacks and defenses. In an attempt to find the artifacts for papers without openly available code, we contacted 91 authors via email requesting their research artifacts, receiving 16 responses (17.6%). Ultimately only 3 shared a research artifact. The other 13 did not share the source code for the following reasons: **1)** The project was completed long ago or the first author moved on to a different institution (30%). **2)** There were funding or distribution restrictions (25%). **3)** The authors were working on it and will publish it later (15%). **4)** There were no plans to release it to the public (30%). 16% is a low number of papers with artifacts, this does not even consider documentation quality or if they are easy to run. Therefore, we encourage researchers to release their PLC security artifacts so that research can be replicated and built upon and to leverage our PLC security artifacts repository discussed in Sec. 1 to disseminate their artifacts. We acknowledge that given the criticality of PLCs it is not always possible to release artifacts at the time of publication if at all. For example, the US' Cybersecurity & Infrastructure Security Agency (CISA) recommends researchers "provide us a reasonable amount of time to resolve the issue before you disclose it publicly [180]."

A second challenge that compounds the problem of lack of reproducible research is the absence of standardized perfor-

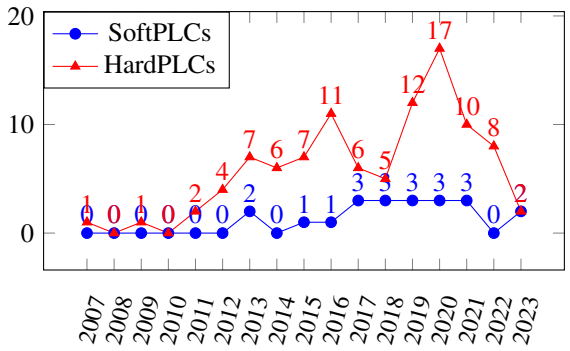

Figure 10: Papers evaluated using SoftPLCs vs HardPLCs.

mance metrics. Based on the results in Tables 1 and 2, few defense methods reported detailed PLC overhead or effectiveness metrics as described in Sec. 4.7. This makes comparing and building upon previous research almost impossible. To overcome this challenge we recommend that future defense methods report detailed quantifiable metrics. First, papers that propose methods such as Intrusion Detection Systems (IDS) should report a complete and detailed confusion matrix. The work by *Salehi et al.* [144] provides an excellent example. Second, future research on defense methods should report detailed and quantifiable benchmark metrics, e.g., memory overhead. Existing benchmarks such as *BenchmarkIoT* [11] can be customized for PLCs to overcome this challenge.

Transition from HardPLCs to SoftPLCs. As discussed in the introduction, PLCs are going through a paradigm shift with support for new protocols and new functionalities. Support for SoftPLCs appears to be increasing. While SoftPLCs currently have a minimal market share, large manufacturers like Siemens and Rockwell are preparing hardware-agnostic products [161]. This paradigm shift has also reached the scientific community. As shown in Fig. 10, PLC security research has diverged into two different strands: evaluations that use HardPLCs and evaluations that use SoftPLCs.

Considering this trend, future research should be aimed at addressing the following challenges: **1)** Developing transitional defense methods that secure both HardPLCs and SoftPLCs. For example, developing *bump-in-the-wire* solutions that are compatible with HardPLCs and SoftPLCs. This may involve evaluating research on both HardPLCs and SoftPLCs. **2)** Investigating defense mechanisms available for SoftPLCs that were previously unavailable for HardPLCs. For example, HardPLCs' proprietary nature limited their access control and encryption capabilities by incorporating weak encryption protocols. SoftPLCs' less opaque architecture provides the opportunity to solve this problem. **3)** Investigating both attack and defense methods that are possible only with SoftPLCs. For example, CODESYS' SoftPLCs can be connected to the cloud [42], which opens new ways to collect data that can be used to train machine learning-based IDS.

8 Related Work

SoKs on PLCs. To the best of our knowledge, the work by *Sun et al.* [168] is the only SoK focused on attacks and defenses on the control logic of PLCs. However, our work is different in two ways. First, *Sun et al.* focuses on PLCs' control logic, while we take a more comprehensive approach that includes 8 additional PLC components. Second, our SoK includes papers with practical evaluations, while *Sun et al.* focus on formal or theoretical research.

PLC Honeypots. While previous work includes approaches for PLC honeypots [62, 106], their focus is intelligence gathering rather than attacking PLCs.

Fuzzing and Binary Reverse Engineering. There is also noticeable research on fuzzing and reverse engineering for ICS and PLCs in the literature [56, 91, 127, 173, 183]. Our focus, however, is not on software analysis or patching but on outlining specific attacks.

Embedded Controllers. While they have received most of the attention in the security literature, PLCs are not the only embedded equipment in ICS. Remote Terminal Units (RTUs) and Intelligent Electronic Devices (IEDs) are even more prevalent in energy transmission systems and substation automation [131, 143, 167]. We need further research into the security of these other embedded controllers.

9 Conclusion and Future Work

In this paper, we provide a systematic review of currently-known attacks and defenses for PLCs. We also pointed out research gaps that should be tackled in the future so that the security of PLCs can be better understood, thus helping avoid future attacks against ICS and PLCs. We hope this systematization is useful to newcomers to the field as well as experienced PLC researchers looking to contextualize their work. As a part of Future Work, we are developing an experimental testbed as discussed in Sec. 2.1. This way, different attack and defense strategies can be replicated to provide experimental evidence on their effectiveness, deployability, and robustness, thus ultimately complementing the results provided in this work.

Acknowledgments

We thank our shepherd and the anonymous reviewers for their helpful suggestions towards improving this paper. This work was partially supported by NSF awards CNS-1929410, CNS-1931573, CNS-2150351, and CNS-2131263, and the SAGE Fellowship from Texas A&M University-Corpus Christi. We further thank the Saarbrücken Graduate School of Computer Science for their funding and support.

Abstract

The rise of IoT (Internet of Things) devices has created a system of convenience, which allows users to control and automate almost everything in their homes. But this increase in convenience comes with increased security risks to the users of IoT devices, partially because IoT firmware is frequently complex, feature-rich, and very vulnerable. Existing solutions for automatically finding taint-style vulnerabilities significantly reduce the number of binaries analyzed to achieve scalability. However, we show that this trade-off results in missing significant numbers of vulnerabilities.

In this paper, we propose a new direction: scaling static analysis of firmware binaries so that *all* binaries can be analyzed for command injection or buffer overflows. To achieve this, we developed MANGODFA, a novel binary data-flow analysis leveraging value analysis and data dependency analysis on binary code. Through key algorithmic optimizations in MANGODFA, our prototype Mango achieves fast analysis without sacrificing precision. On the same dataset used in prior work, Mango analyzed 27× more binaries in a comparable amount of time to the state-of-the-art in Linux-based user-space firmware taint-analysis SaTC. Mango achieved an average per-binary analysis time of 8 minutes compared to 6.56 hours for SaTC. In addition, Mango finds 56 real vulnerabilities that SaTC does not find in a set of seven firmware. We also performed an ablation study demonstrating the performance gains in Mango come from key algorithmic improvements.

1 Introduction

The Internet of Things has spawned a device ecosystem that allows users to control and automate everything in their homes—from their locks to their lights. This increase in convenience comes with increased security risks, as IoT devices frequently run (often out-of-date) firmware with vulnerable services [17, 26].

Modern IoT firmware frequently takes the form of an entire embedded Linux distribution that uses user-space binaries to expose services that can be accessed over the network. These services vary from web interfaces for device configuration, complex IoT-specific protocols (e.g., Matter [13] and Zigbee [14]), or custom file-sharing servers with varying levels of complexity. Many services invoke backend binaries to gather system and environment information, commit configuration changes, or render webpages.

While complex and feature-rich services make modern IoT devices powerful, this complexity breeds vulnerabilities [3, 39]. Therefore, automated techniques for scalable and precise detection of these vulnerabilities in the firmware of IoT are in pressing need.

Researchers have proposed analysis techniques to automatically identify vulnerabilities in IoT firmware, which generally fall into two categories: (1) static analysis techniques that attempt to statically identify vulnerabilities in the binaries in a firmware image using binary analysis techniques [9,36], and (2) dynamic analysis techniques that attempt to identify vulnerabilities through execution of said binaries [7, 22, 50, 51]. Broadly speaking, static approaches tend to discover more vulnerabilities (by covering much of the binary's behavior during analysis) while also reporting false positives (because static analyses cause over-approximation of the binary's behavior). At the same time, dynamic approaches lead to much fewer false positives (as dynamic techniques typically have a concrete input that triggers the vulnerability) while also missing vulnerabilities (due to incomplete code coverage).

Dynamic techniques are particularly challenging to apply to the domain of binary firmware services. Executing a target service is difficult due to dependencies on the underlying IoT operating system (OS) and hardware. Much of the research direction in this area is geared toward running a target service or emulating the hardware. But even the best firmware rehosting technique only successfully rehosts around 32% of 1,764 real-world firmware targets [44], hampering the application of dynamic techniques and making static techniques more promising.

The tantalizing promise of static analysis techniques is that they can be applied to *any* binary firmware service, as there

is no need to run or emulate the underlying OS or hardware. These techniques, while capable of finding real vulnerabilities, take significant resources: On Karonte's dataset of 49 firmware images SaTC [9] spends 870 hours processing, while Karonte [36] takes 463 hours. Even more troubling, to achieve even this level of scalability, Karonte and SaTC paid a significant price in either low coverage or high false negatives, respectively.

To improve scalability, Karonte introduced the concept of *Binary Dependence Graph* (BDG): a graph of nodes representing user-space binaries in a firmware image, with edges between those binaries denoting data flows. The BDG is anchored by binaries that are deemed to be network services, and only binaries that exchange data with them are analyzed. On Karonte's dataset, this reduces the number of binaries analyzed per firmware sample by Karonte to an average of 5 binaries and SaTC, which uses a similar strategy, to an average of 3, thus reducing the analysis requirement significantly from an average of 174 total binaries per firmware.

This technique, though novel, comes with a cost: the strict filtering induced by BDG, which is necessary to ensure scalability, filters out *actual vulnerabilities*. For example, the cross-binary vulnerability described in Section 2.2 is undetectable by the BDG technique, as implemented by Karonte and SaTC, as it requires limiting the analysis scope to a few binaries determined by their likelihood of interacting with user-input.

In this paper, we propose Mango, a static analysis technique for finding taint-style vulnerabilities in Linux-based user-space firmware services that scales so well that it removes the need for aggressive BDG-based filtering while maintaining reasonable precision. Mango's novel, context-sensitive static data-flow analysis, MANGODFA, which leverages intuitive execution patterns and trace shortening, requires no access to source code. MANGODFA uses both value analysis and data dependency analysis to enable precise reasoning about the *composability* and *exploitability* of values that flow into vulnerable sinks. For example, MANGODFA can correctly deduce that

```
sprintf(buf, "ls %s", itoa(input));
system(buf);
```

is not a vulnerability while

```
snprintf(buf, 50, "echo hello %s", input);
system(buf);
```

may be vulnerable to command injection.

To improve scalability, we draw inspiration from how human reverse engineers find taint-style vulnerabilities in software: Starting from vulnerability sinks and iteratively tracing backward through potential parent functions to determine if any data flows are likely vulnerable. Moreover, instead of analyzing each callee in every function along the call tree, human reverse engineers decide on a per-call basis if the call to a callee function would impact the data flow. These two steps are critical for reducing false positive rates and increasing analysis speed.

Using this inspiration, we implement two novel optimizations in MANGODFA, namely *Sink-to-Source Analysis* and *Assumed Nonimpact*, which mimic humans' actions during manual vulnerability discovery, and these optimizations are key for achieving scalability.

MANGODFA allows Mango to significantly increase the analysis scope *while simultaneously improving overall performance.* Mango analyzed *all 6,920 binaries* across the 49 firmware samples in the Karonte dataset in 946 hours, while SaTC analyzed 131 total binaries in 860 hours of CPU time and Karonte analyzed 153 binaries in 463 hours. While these performance numbers were done on different hardware at different times, Mango analyzed 27× more binaries in a comparable amount of time that it took SaTC to analyze 131 binaries. Mango's average per-binary analysis time is 8 minutes compared to 6.56 hours for SaTC and 3.0 hours for Karonte.

The current implementation of Mango supports two classes of vulnerabilities: CWE-78 (OS Command Injections) and CWE-121 (stack-based buffer overflows). Both comparative solutions, Karonte and SaTC, work explicitly on Linux-based user-space binary firmware services and not on monolithic or RTOS-based firmware. Through a comparative study on the firmware dataset on which SaTC and Karonte evaluated (with 49 unique firmware samples), we demonstrate that Mango generates 56 true positives that are never alerted by SaTC and similarly 203 true positives that are missed by Karonte.

We also conduct an ablation study to demonstrate the effect of Sink-to-Source Analysis and Assumed Nonimpact on efficiency and effectiveness. The improved efficiency of Mango allows us to conduct a large-scale vulnerability discovery on a new dataset with 1,698 firmware samples from nine vendors. Mango reports every potential bug it finds, 83,644 alerts in total. However, this number of alerts cannot be reasonably triaged. To aid in separating bugs from vulnerabilities, we introduce the concept of ranked alerts, which we call TruPoCs. Manual analysis on a sample set of these alerts suggests a true positive rate of 57% for command injections and 38% for buffer overflows. For every 10 command injection alerts a human analyst triages, 5 will be actual vulnerabilities.

Contributions. Our paper makes the following contributions:

- We build a novel data-flow analysis, MANGODFA, on the domain of integers and fixed-length strings, enabling scalable discovery of taint-style vulnerabilities. This new domain allows precise reasoning of string values that flow into vulnerable sinks, and is more precise than traditional taint analysis.
- We further propose two optimizations, Sink-to-Source Analysis and Assumed Nonimpact, which are critical for the efficiency and false negative reduction of MANGODFA.

- We implement MANGODFA in a prototype system, Mango, and evaluate it against the state-of-the-art solutions for finding taint-style vulnerabilities in firmware binaries.

In the spirit of open science, the source code and artifacts of Mango, along with a Docker image for replicating our experiments, can be found at https://github.com/sefcom/operation-mango-public. The contributions in this paper will also be integrated into angr [47].

2 Background

Before diving into the technical details of Mango, we provide the necessary background information on vulnerabilities in binary firmware services and discuss the associated challenges in discovering them with state-of-the-art static analysis techniques.

2.1 Firmware Types

Qasem et al. [34] categorized firmware into three types: Type I, where there is a clear separation between the Operating System (OS) and the contained firmware services (in terms of files and processes), Type II, where the OS and services are combined into a monolithic binary blob, and Type III, where there is no OS but only logic embedded in a blob.

Type II and Type III firmware are typically used to implement software for programmable logic controllers (PLCs) and real-time, low-power embedded devices (generally with less complicated logic). Type I firmware is more commonly seen in feature-rich and complex IoT devices such as routers, webcams, or networked CCTVs, where the OS is usually embedded Linux and services are ELF binaries (of varying architectures). A 2014 study by Costin et al. [15] found that over 86% of firmware samples in a large dataset of 32,356 images were Type I firmware using embedded Linux as the OS. Similar to prior work [6, 29] in this area, our research focuses on finding taint-style vulnerabilities in the user-space services of Type I firmware.

2.2 Motivating Example

Listing 1 shows a vulnerability in the Netgear R6400 router, which is in the dataset for Karonte and the ablation dataset SaTC used. The vulnerability here is straightforward: a command injection based on the `iserver_passcode` front-end keyword. SaTC missed this vulnerability, and Karonte would have as well if it supported command injections. Both of these tools missed this vulnerability because the border binary analysis for both tools does not include `dlnad` as a potential target. For example, SaTC prioritizes binaries with more references to frontend keywords and limits border binaries to three per firmware image. Due to the simple functionality and small size of `dlnad`, it is excluded by the border binary selection algorithm in SaTC.

Listing 1: Decompiled code of the `httpd` and `dlnad` binary from the Netgear R6400. Mango can identify this vulnerability while Karonte and SaTC will not analyze `dlnad`.

```
// R6400 /usr/sbin/httpd
int __fastcall sub_6F800(char *a1, int a2)
{
  sub_18764(a1, "iserver_passcode", v11, 2048);
  strcpy(v10, v11);
  v4 = acosNvramConfig_set("iserver_remote_passcode", v10);
  acosNvramConfig_save(v4);
  system("killall -SIGUSR1 dlnad");
}

...

// R6400 /usr/sbin/dlnad
int main(int argc, const char **argv, const char
↪  **envp)
{
  v10 = acosNvramConfig_get("iserver_remote_passcode");
  sprintf(v11, "echo \"NoDeviceName\r\n%s\" >
↪  /tmp/shares/forked_daapd.remote", v10);
  system(v11);
}
```

2.3 Firmware Vulnerability Analysis

For finding taint-style vulnerabilities in firmware, prior work proposes two genres of techniques: (1) firmware rehosting and dynamic analysis and (2) static analysis.

Firmware rehosting and dynamic analysis. Given the limited computing capabilities of IoT devices, researchers attempt to run firmware services on commodity systems, usually using an emulator such as Qemu [1] to leverage dynamic analysis techniques such as fuzzing. While researchers have focused on making taint-style analysis more approachable [11, 31, 32], the performance of dynamic techniques is limited by the effectiveness of firmware re-hosting, the quality of input seeds, and efficient coverage exploration, making it difficult for dynamic techniques to find taint-style vulnerabilities with reasonable scalability.

Consider the motivating example in Listing 1: to use a dynamic analysis technique, an analyst must first identify the connection that `dlnad` has to `httpd` through NVRAM variables. It would be an unlikely target because it does not actively process user input like a web server would. Further, even if an analyst wanted to analyze `dlnad`, it requires a specific combination of NVRAM values and properly formatted user input for the variables to trigger.

Static analysis. Static analyses sacrifice precision for higher scalability. Analyzing binaries statically requires a deep un-

derstanding of the binary format, the underlying architecture, and the operating system for which the binary is built. A typical static analysis workflow includes disassembling, lifting to an intermediate language (IL), CFG recovery, and various types of advanced analysis atop.

Symbolic execution on binaries [23, 47] allows tracking data flows in a binary: It simulates the execution of the target binary on a value domain of both concrete values and symbolic values (e.g., variables with unknown values), collects path constraints, and solves path constraints to derive possible values for symbolic values. The caveat is that symbolic execution is computationally expensive and suffers from path explosion [25]. Another technique for tracking data flows in a binary is static taint analysis [38]. It marks the source of the data and tracks it through the program, approximating the effects of function calls until reaching sinks. Static taint analysis may suffer from over-tainting, marking values as tainted when they are not, and under-tainting, missing tainted values.

Depending on the analysis goals, these static analyses may adopt value domains (e.g., the concrete domain where only concrete values are considered, or the value-set domain [4] where every value is modeled using its bits, lower- and upper-bounds, and its stride) with varied precision.

Firmware taint analysis. State-of-the-art static analysis techniques for finding firmware vulnerabilities, such as Karonte [36] and SaTC [9], start their analysis from *border binaries*, binaries that they determine to be reachable from the local network. SaTC takes it one step further: It identifies common keywords in web API interfaces and ignores all other interfaces.

While sometimes users knowingly communicate with their IoT devices via front-end web services (e.g., logging into a router's management portal), this is not the only available input vector for firmware services. Many services, such as `miniupnpd`, communicate without frontend interfaces but are open to receiving data from the local network, if not the Internet. By only focusing on border binaries and common web-API-style endpoints, Karonte and SaTC are likely to miss a large portion of vulnerability sources, which leads to false negatives (i.e., missed vulnerabilities).

While static analysis is the more viable approach for finding taint-style vulnerabilities, both Karonte and SaTC severely limit the potential vulnerability sources (by only analyzing border binaries and input locations with specific keywords), which impacts their ability to find vulnerabilities. Because MANGODFA is more scalable, Mango takes a different approach: It analyzes *every valid binary* in each firmware sample, flagging and filtering potential vulnerabilities.

2.4 Threat Model and Scope

Unlike Karonte or SaTC, we do not limit which binaries handle user input. Both use the concept of Border Binaries to limit the scope of their analysis to both reduce false positives and analysis times. However, Mango does not need this limit as it is able to analyze entire firmware samples in a reasonable amount of time. We do this exclusively on Linux-based user-space firmware binaries.

Bug reports and triggerable vulnerabilities. Because Mango runs on every binary in a given firmware, it identifies legitimate bugs in the current firmware regardless of whether the bugs are triggerable. For example, Mango can identify a vulnerable function that is unused or in an executable on the file system that an attacker cannot currently execute. While finding these bugs is essential, in this paper, we give a higher priority to finding *triggerable* vulnerabilities [1]. We coin these triggerable vulnerabilities *True PoCable vulnerabilities*, or *TruPoC*s in short. We implement a filtering system (described in Section 8) to prioritize bug reports that are more likely to be reachable by an attacker, thereby separating triggerable vulnerabilities from ordinary bug reports.

3 Challenges

It is possible to extend the functionality of Karonte and SaTC to analyze all binaries and all input sources in firmware samples. However, this will result in severe precision and scalability problems, which we demonstrate in an ablation study in Section 11. Here, we briefly present the major challenges that Mango faces and our solutions for solving each challenge.

3.1 Challenge 1: Precision

A static vulnerability discovery technique that reports a high number of false positives will quickly overwhelm users and fall out of use. Researchers find similar human behaviors when studying programmers facing compiler warnings [27].

Our solution to address the precision problem is three-fold. First, we realize that SaTC achieves high scalability but much lower precision by relying on a taint-tracking engine. SaTC can only track if an input value impacts key values at vulnerability sinks, but not *how* this input value is used. As such, some false alerts that SaTC generates result from imprecision during taint tracking, which frequently occurs when identifying command injection vulnerabilities as tainted values are often processed (and even sanitized) before reaching the sinks.

To address this problem, we create a novel data-flow analysis, MANGODFA, encompassing both value analysis and data dependency analysis over a mixed value domain of integers and fixed-length strings. MANGODFA tracks how a value is composed, e.g., which functions generated the value and

[1] When we conduct responsible disclosure for vulnerabilities to vendors, they would only accept vulnerability reports that come with Proof-of-Concept exploits (PoCs) that trigger the vulnerability and proactively reject vulnerability reports without PoCs.

which operations were applied to it before it is used at vulnerability sinks. We will present the details of MANGODFA in Section 5.

Second, as detailed in Section 5.3, we created function summaries for common library functions, many of which are in `glibc`. These function summaries are particularly helpful in string-related operations where functions have complex internal logic. Precisely emulating the binary code of library functions is expensive, and, as such, state-of-the-art tools fail to accurately capture the effects of these library functions.

Third, we implemented an alert filtering system that prioritizes alerts which are more likely to be reachable by an attacker that we call TruPoCs. Our goal is to provide TruPoCs for which users can easily generate PoCs and demonstrate the vulnerabilities. The details of how the ranking of alerts is determined can be found in Section 8.

3.2 Challenge 2: Scalability

To analyze every binary in each firmware sample, the analysis must be fast. Karonte takes an average of 9 hours to analyze a firmware sample where each sample only has five border binaries on average [36]; SaTC takes an average of 17 hours to analyze a firmware sample, but it hyper-focuses on a limited number of input sources for only a small set of binaries with keywords detected. The time SaTC needs for analysis increases significantly if we cover more than the initial border binaries. We extended SaTC to analyze all binaries in a firmware image (instead of the maximum of three border binaries). In our experiment using the Karonte Dataset, where each firmware image contains 127 analyzable binaries on average, SaTC took an average of six hours per binary and 762 hours per firmware image.

We propose two key optimizations in MANGODFA to significantly improve the scalability of static data-flow analysis.

The first optimization is *Sink-to-Source Analysis*, traces *backwards* from the callsite of a vulnerable sink to all potential sources of input that do not resolve to constant or known legitimate values. A key performance improvement is achieved through quickly eliminating paths that would otherwise resolve to constant values. We discuss the details of Sink-to-Source Analysis in Section 6.

The second optimization is *Assumed Nonimpact*, a technique for determining, at each call site, whether the callee function is essential to the data flow that leads to the vulnerability sink. This analysis technique can increase false positives caused by pointer aliasing and un-tracked global values; however, our evaluation shows a false-positive rate similar to SaTC. We present Assumed Nonimpact in Section 7.

4 Approach Overview

Mango takes a firmware image as input, analyzes all binary executables (not including library files) in the unpacked file system, and generates TruPoCs for potential vulnerabilities given the specified vulnerability class. Similar to Karonte and SaTC, Mango also supports multi-binary interactions and values derived from front-end keywords. After ingesting the firmware image, Mango automatically performs subsequent analyses. Finally, Mango outputs ranked POCs termed TruPoCs for the user to review.

The major analysis steps Mango performs are as follows:

Firmware Pre-processing. The main goal of Mango is to analyze ELF executables and identify potential vulnerabilities. It is important to note that we specifically do not analyze libraries as their vulnerabilities are more difficult to definitively categorize as true positives or false positives in a given firmware. Mango takes a firmware image as input, uses existing tools (such as binwalk [2]) to unpack the firmware sample, and finds all ELF executables. For all binaries, we gather their imported library function names. As long as the binary is not stripped and statically linked, we can recover function names such as `system` or `strcpy`. Later, we will use these symbols to determine whether or not to analyze a given binary.

Keyword Discovery. SaTC introduced keyword-guided analysis, which increases the attack surface user input can reach and reduces the number of binaries that need to be analyzed. Mango also gathers front-end keywords from HTML, JS, ASP, and PHP files. These keywords are a combination of string-literals and object fields that identify user input locations in backend binaries.

IPC Discovery. Mango uses Inter-Process Communication (IPC) data-flow tracking, first proposed by Karonte, to detect potential interactions between binaries in a given firmware sample. Specifically, Mango considers inter-process interactions that involve NVRAM entries and environment variables. Mango performs static analysis (based on MANGODFA) to collect all NVRAM and environment variables that each binary either sets or retrieves. Mango transforms these accesses into a dictionary of setters and getters keyed by the function and recovered value (if applicable) along with which binary the value originated from and its callsite within the binary.

Resolving Vulnerability Sinks. Resolving vulnerability sinks is the core step of Mango, where, for each vulnerability sink (e.g., the glibc `system` function) in each binary, it recursively resolves the sink to a *Rich Expression*, which captures the source values and all operations (e.g., `strcpy` and `sprintf` with format strings) applied to these source values. The sink-resolving procedure is inter-function within the same binary and inter-binary if source values originate from NVRAM entries or environment variables that Mango recovered during the IPC Discovery step.

Mango continues sink resolving until (1) it reaches the entry point of the binary, (2) all sink values are resolved to either *legitimate values* or *unresolvable values*, or (3) it times out. Legitimate values are not attacker-controllable or exploitable, such as constant values, constant pointers, or sanitized user

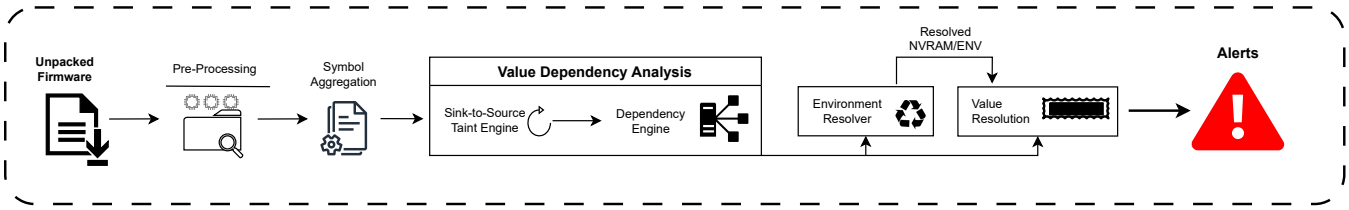

Figure 1: The workflow of Mango. Mango searches for all potential vulnerable and environment ELFs. It first analyzes all ELF files that can affect the environment and then analyzes all ELF files containing designated sinks with the context provided by the initial environment analysis.

input. All other values are unresolvable, including user or external input and buffers with unresolvable content due to missed or unsupported library calls.

5 MANGODFA

The core static data-flow analysis is MANGODFA, which is a combination of a static value analysis that tracks all possible values for each variable (in binary analysis, variables refer to value containers, such as registers, memory cells, etc.) at each program location and a data dependency analysis that tracks where each value is defined and used. This is a critical difference from prior work: Both Karonte and SaTC use taint-tracking, which means they can only mark certain variables and values as *tainted* by input data or not. In comparison, MANGODFA creates def-use graphs, with which Mango can reason about how any value was created from its source values and what operations have been applied. We call these expressions *Rich Expressions* because they capture not only the concrete values but also rich information about their history and dependencies.

An example Rich Expression is: `"df -d " .. itoa(atoi(input_1)) .. " -h " .. input_0)` where "`..`" represents the string concatenation operation. In this case, the underlying Rich Expression can be broken into its 4 components, `"df -d "`, `itoa(atoi(input_1))`, `" -h "`, and `input_0`, at any time with their corresponding dependencies already held in a global dependency graph. If a call to `system()` has a Rich Expression as the first argument (such as the one described), Mango can determine that `input_1` does not lead to arbitrary command injection as its value was derived from an integer. In contrast, `input_0` may lead to a command injection vulnerability as its origin value is unhindered. Neither Karonte nor SaTC could determine that `input_1` would not contribute to a vulnerability, which leads to higher false positive rates and reduced analysis speed due to over-tainting.

MANGODFA is the foundation for various sub-analyses on which Mango depends, such as calling convention inference and function prototype inference. Mango uses calling convention inference to determine the ABI of each function, which can be different even for functions within the same binary. Mango further uses function prototype inference to determine the number and the sizes of arguments for each function and if there is a return value. Both types of information are necessary for inter-function analysis. These sub-analyses are purely engineering work of existing research [5, 49] and are not our scientific contributions in this paper.

5.1 MANGODFA Basics

Value domain. MANGODFA employs a value domain that is specifically designed for finding command injection vulnerabilities. Basic value types in this domain include bit-vectors (integers and strings with fixed lengths) and a TOP ($\top$) value. Each value in this domain is either a *MultiValue* that contains at most N bit-vector values, a $\top$ value, or an *Expression* that is composed of *operations* that are applied on MultiValues. Each instance of MultiValue and Expression is of a fixed number of bits. MANGODFA is flow-sensitive but not path-sensitive, which means that whenever multiple paths merge, the values in each variable will be merged, creating MultiValues with more than one basic value inside. A MultiValue with more than N bit-vectors becomes a $\top$, and overly deep expressions (we empirically limit it to 20) also become $\top$. We choose a small N ($N = 5$) to guarantee fast convergence of the data-flow analysis.

Data dependency tracking. The data dependency analysis in MANGODFA is similar to traditional, source-code-based data dependency analysis: MANGODFA tracks where each variable is first defined and keeps a separate record for program locations where each defined variable is used. The definition record is associated with each value (bit-vectors or $\top$ values). During path merging, MANGODFA will adjust the association of definition records and re-associate definition records of old values to newly created $\top$ values if needed.

Memory model. The abstract state used in MANGODFA models "loads from" and "stores into" for registers, global memory regions, stack regions, and heap locations in a bit-precise manner. Because MANGODFA performs intra-function analysis by default, it only models one stack frame (also known as activation record).

5.2 Inter-function Analysis

To resolve sinks, Mango requires inter-function analysis. Building an inter-function MANGODFA from an intra-function MANGODFA is straightforward. At every call site, Mango makes a copy of the abstract analysis state thus far, creates a new stack frame to simulate the call, invokes a new MANGODFA on the copy of the abstract state, and then waits until the new MANGODFA instance terminates. Then, Mango merges all exit states that the new MANGODFA yields to get a new output state and uses that state to resume the outer-level MANGODFA analysis.

5.3 Function Summaries

The more accurately MANGODFA models the execution of a binary, the higher level of precision Mango can achieve. Karonte and SaTC are based on taint tracking, which models dependency relationships between input arguments and output values of certain library functions. Precisely propagating taints through many library functions (especially in `glibc`) can be difficult due to the complexity of the logic and implementations of these library functions, which may lead to excessive amounts of false positives and false negatives. Therefore, Mango implements function summaries for common library functions to ensure that values and data dependencies are modeled as accurately as possible.

Re-implementing library functions has the added benefit of reducing false positives caused by changes in value types. It is a common and normal execution pattern for programs to manipulate strings into non-injectable forms, such as using `atoi` to transfer the string into an integer or the `"%d"` format specifier for the `printf` function family, making injections impossible. SaTC does not recognize these input type changes and will report a (false-positive) vulnerability even if the tainted value is not injectable.

6 Sink-to-Source Analysis

Finding all input sources and performing forward data-flow analysis to find all vulnerability sinks is expensive. It is frequently unknown if values that depend on input sources will eventually flow into the vulnerability sink with a meaningful degree of control or exploitability. Shorter call traces for forward data-flow analysis imply a shorter analysis time because no extra time is spent analyzing irrelevant functions.

We propose a new workflow, Sink-to-Source Analysis, inspired by human reverse engineers. Reverse engineers tend to work *backwards* from potentially vulnerable program locations (e.g., a call to `system()`) to understand which input sources (if any) can reach this location instead of working from the input sources and exploring every possible path the inputs can take. These special program locations frequently coincide with vulnerability sinks for taint-style vulnerabilities.

Algorithm 1: Reverse Trace Analysis

```
1:  function ReverseTraceAnalysis(sink, max_depth)
2:      all_traces = {}
3:      traces = FindTraces(sink, max_depth)
4:      for trace in traces do
5:          state = {}
6:          white_list = list()
7:          rev_trace = {sink}
8:          for caller, callee in Reversed(trace) do
9:              intra_functions = CoarseAnalysis(caller, callee)
10:             for function in intra_functions do
11:                 if DependsOn(callee, function) then
12:                     rev_trace = rev_trace ∪ caller
13:                     white_list.append(function)
14:                 end
15:             end
16:             if DependsOn(callee, caller) then
17:                 rev_trace = rev_trace ∪ caller
18:             end
19:             else
20:                 if CalleeArgsResolved(callee) then
21:                     state = callee
22:                 end
23:                 all_traces[rev_trace] = (state, white_list)
24:                 break
25:             end
26:         end
27:     end
28: end
```

In the context of human reverse engineering, these special locations are also referred to as *beacons* [46].

Tracing backward from vulnerability sinks instead of forward to the sinks limits the explored program paths to only those directly relevant to the sinks. By analyzing caller function by caller function, backward through a call stack, Sink-to-Source Analysis limits the analysis required to determine reachability. Source-to-Sink Analysis may explore any number of unimportant paths to discover how or even if tainted data will reach the sink.

DTaint [10] employs a similar Sink-to-Source approach, but it requires analysis of every function in the callgraph backwards to the highest-level source, thereby analyzing many functions that ultimately do not affect the sink. During our Sink-to-Source analysis, if MANGODFA determines that a data flow flows into an unexploitable variable (e.g., a properly sanitized string or a string that is ultimately converted into an integer), it immediately abandons this variable and terminates the data flow. Consider the example `sprintf(buf, "cal %d", year)`, MANGODFA performs a data-dependency analysis that determines that `buf` will never contain a vulnerable string and terminates its analysis. However, DTaint will continue to analyze up through the call chain until it can find a source for `year`.

```
void foo() {
    bar("Hello!");
}

void bar(char *unused) {
    char *name_buf = nvram_get("your_name");
    say_hello(name_buf);
}

void say_hello(char *buf) {
    char[256] cmd;
    sprintf(cmd, "echo \"Hello %s\"", buf);
    system(cmd);
}
```

Listing 2: An example of Sink-to-Source Analysis.

Our Sink-to-Source Analysis algorithm, as shown in Algorithm 1, begins by finding all possible traces to the sink for a given CFG. We perform a coarse-grain value dependency analysis on each caller-to-callee pair, working backward from our sink in every trace. The analysis results determine if data reaching the sink solely depends on data from the specified caller in the trace.

Suppose there is a call to `system` with a command that is entirely dependent on the result of reading a file, environment variables, NVRAM variables, or data from the network; the analysis is halted as higher-level caller functions in the call-stack will not contribute to the data that `system()` ultimately depends on. If no variables are dependent on the caller function arguments, there is no need to analyze anything further, but we must keep the current trace depth for data dependencies inside the caller function. If the data depends on function arguments, the analysis continues up the call stack. However, if during the analysis of the next call-depth, all callee functions have constant or fully resolvable values, then we discard the current call-depth and retain a final state with set arguments for the callee. To analyze the caller function of a fully analyzed function, we simply repeat all steps from the beginning except instead of the caller/callee pair being a parent function and the sink, the parent function of the sink becomes the new callee.

In the case of Listing 2, MANGODFA starts analyzing from *say_hello* and marks *buf* with an unresolved value as it could contain anything at this point in the analysis as far as MANGODFA is aware. MANGODFA will trace the dependency of *buf* to *say_hello*'s arguments and decide to analyze *say_hello*'s parent functions to resolve the values in *buf*. The analysis will continue from *bar*, the parent function of *say_hello*, and MANGODFA will determine that there is no need to analyze any of *bar*'s parent functions, in this case *foo*, as the data in *buf* is only dependent upon the result of the call to *nvram_get*.

Algorithm 2: Assumed Nonimpact

```
1:  function AnalyzeFunction(state, white_list, sink)
2:      for func in white_list do
3:          intra_funcs = state.TaintAnalysis(func)
4:          if DependsOn(sink, func.ret_val) then
5:              if func.call_depth == maximum_depth then
6:                  continue
7:              end
8:              intra_white_list = {}
9:              for intra_func in intra_funcs do
10:                 if DependsOn(intra_func, func.ret_val) then
11:                     intra_list.append(intra_func)
12:                 end
13:             end
14:             AnalyzeFunction(func, intra_list, func.ret_val)
15:         end
16:     end
17: end
```

The ablation study described in Section 11.5 evaluates the benefits of Sink-to-Source Analysis. With all things equal, Sink-to-Source Analysis improves analysis time by 25.61%.

7 Assumed Nonimpact

Traditional inter-function data-flow analysis cannot effectively analyze firmware at scale. One fundamental problem is that forward inter-function data-flow analysis usually must enter and analyze every callee; otherwise, it misses the artifacts that the callee generates. However, consider well-formed C programs where functions all have clean input/output interfaces and are defined by their arguments and return variables: in this case, we may safely skip the analysis of certain callees if pointers to the values and variables that we care about are not passed into these functions. Skipping these callees means that we can consider them a black-box, and that we cannot capture any information inside them. This is acceptable because MANGODFA only cares about the effects that would impact the values that are being tracked.

Therefore, we propose *Assumed Nonimpact*, a best-effort execution strategy for function callees during data-flow analysis. Selectively analyzing callees significantly reduces the analysis time of MANGODFA.

Algorithm 2 describes the process of Assumed Nonimpact. When MANGODFA analyzes a new function *A*, it recovers calling convention, prototype, and accessed global variables for each callee that *A* calls. With calling conventions and prototypes of callees, MANGODFA has enough information to determine, at every call site, if (1) any pointer that points to values and variables that MANGODFA tracks is passed to the callee function, or (2) any values that the callee function returns and is ultimately used by the sink in some form. When neither situation holds, we assume the call will not impact the

values and variables that MANGODFA tracks and skip the call.

TChecker [28] discusses a similar technique to Assumed Nonimpact. The novelty in Mango lies in adapting the technique for binaries, whereas TChecker only works on PHP applications. Achieving this in binaries is significantly more challenging compared to PHP source code because high-level semantic information, such as data structures, are discarded during compilation. Additionally, analyzing binary code requires reasoning about binary-specific features such as calling conventions, function prototypes, and precisely tracking data flows. Further, Mango works on binaries of multiple architectures, each with nuances, further increasing the difficulty.

While MANGODFA caches the calling conventions and prototypes for callee functions, it must determine whether to skip a call at each call site. The decision to skip a callsite depends on the value of the arguments to the callee and if those values are mutable as MANGODFA progresses, making the decision heavily dependent on the context of the call.

Loss of soundness. The fundamental assumptions underpinning Assumed Nonimpact are that (1) all callees are well-formed (i.e., they will not add a constant to the stack pointer and use it to overwrite values that belong to the caller's stack frame) and (2) all recovered calling conventions, prototypes, and accesses to global variables are accurate. These assumptions do not always hold for stripped binaries, especially when structs (not pointers to structs) are in use, where MANGODFA frequently recovers incorrect calling conventions and prototypes. Another error source is global struct member accesses, where it is difficult to determine the size of global structures, leading to incorrect assumptions of what ranges of data a callee function may access. Our evaluation shows that Assumed Nonimpact works well in most cases, and we hope future advances in binary analysis research will alleviate these issues and reduce the loss of soundness.

8 From Alerts to TruPoCs

When disclosing a vulnerability to vendors, they often require a PoC to demonstrate that the vulnerability exists and is triggerable. As such, Mango focuses on finding TruPoCs. We design a filtering system in Mango that takes vulnerability alerts it finds and generates TruPoCs. These vulnerabilities have clearly defined paths through single or multiple programs stemming from user-controlled sources to sinks.

During static analysis described in Section 5, we build a dependency graph of data flows from all sources to sinks. We use this dependency graph to discover and categorize possible interesting sources of input.

We categorize potential external data sources into five categories: *file_ops* consists of file operations, such as `fgets`, `fread`, etc. *network_ops* covers `socket`. *env_ops* contains all references to `frontend_params`, `getenv` and `nvram_get` style operations, which retrieve stored data. *argv* denotes paths that appear to originate from a program's command line. Finally, *unknown* is a category used for all data from any sources not listed above.

In the context of firmware, it is easy to identify sources for *env_ops*. If the *env_op* of an alert has a known location that sets its value or it is determined to be a user-controllable `frontend_param`, then Mango will report the alert as a TruPoC.

9 Environment Resolution

A key advancement that Karonte suggested is modeling multi-binary interactions through analyzing Inter Process Communications (IPCs). During multi-binary data-flow analysis, Karonte propagates constraints from source binaries to sink binaries, including environment information extracted along the way. The environment resolution in Mango employs a similar tactic. However, Mango does not perform symbolic exploration or propagate constraints across binaries that interact through IPCs. Instead, Mango directly links setter values and getter variables during data-flow analysis, which achieves *cross-binary* vulnerability sink resolution. Our solution is more scalable than Karonte because it avoids path explosion issues in symbolic exploration and runtime overhead involved in constraint solving. Mango also applies the same environment resolution approach to front-end keywords analysis that SaTC pioneered.

10 Implementation

We implemented the Mango prototype in approximately 9,500 lines of Python code. The multi-binary analysis for finding NVRAM entries and environment variables as well as MANGODFA was built on top of angr [41], a widely used multi-architecture binary analysis framework. The core of Mango includes the IPC and front-end variable identification and the data-flow analysis on firmware binaries. Mango supports all architectures and platforms that angr supports, e.g., X86, AMD64, ARM, AArch64, MIPS, PowerPC, etc. We also implement a set of scripts to enable the parallelization of Mango analysis in local Docker containers or a Kubernetes cluster.

11 Evaluation

We evaluated Mango using firmware running on real-world routers to answer the following research questions:

RQ1. How effective and efficient is Mango compared to SaTC at identifying vulnerabilities on real-world firmware?
RQ2. How do the scalability optimizations Sink-to-Source Analysis and Assumed Nonimpact impact scalability and precision?

RQ3. How does Mango perform on a significantly large-scale dataset of firmware (100× larger than what was used in prior work)?

11.1 Datasets

We evaluate Mango on three different firmware datasets.

Karonte Dataset. The Karonte Dataset[2] contains 49 firmware samples across four different vendors (Netgear, D-Link, TP-Link, and Tenda). There are 3,599 binaries in all of these firmware samples.

SaTC Selected Dataset. SaTC also compared against Karonte on seven additional firmware images from Netgear, D-Link, and Tenda. As such, we will compare against SaTC on these seven additional images containing 384 binaries in total.

Large-scale Dataset. We use the dataset that Greenhouse uses [44]. This dataset comprises 1,698 firmware samples from nine different vendors: Netgear, Asus, Belkin, Linksys, TPlink, Trendnet, Tenda, D-Link, and ZyXEL containing over 385,000 binaries.

11.2 Methodology

For every dataset, we run Mango on each ELF binary in the firmware sample that contains a vulnerability sink. In this evaluation, we only compare against SaTC and not Karonte as SaTC strictly improves upon the amount of vulnerabilities found per firmware image compared to Karonte.

11.2.1 Vulnerability Confirmation

Where possible, we manually analyze a subset of Mango's TruPoCs to determine which are true positives (actual vulnerabilities) and which are false positives (not vulnerable). The TruPoCs are considered true positives if an attacker in our threat model (Section 2.4) can exploit the vulnerability as a user connected to the device with credentials. We have generated PoCs and successfully exploited 70 vulnerabilities based on our TruPoCs. We are working with vendors to responsibly disclose these vulnerabilities.

11.3 Karonte Dataset Results

Table 1 shows the results of Mango and SaTC on the Karonte Dataset. After analyzing 3,599 binaries over 946 hours, Mango generated 2,310 TruPoCs. This compares to SaTC analyzing 131 binaries in 860 hours and generated 144 TruPoCs.

Mango achieves comparative speeds to SaTC despite analyzing 6,920 binaries vs SaTC's analysis of 131 binaries. The speed of our analysis, despite the scope of our threat model, is attributed to our contributions of Assumed Non-impact and Sink-to-Source Analysis optimizations (demonstrated through an ablation study in Section 11.5).

To better understand Mango's effectiveness, we manually analyzed a subset of the generated TruPoCs. Table 4 shows the results of our manual analysis. We randomly sampled 100 Mango command injection TruPoCs and manually verified them. 57 were true positives, with a 57% true positive rate, 43 were false positives, with a 43% false positive rate. With the addition of TruPoCs, Mango's 57% true positive rate is higher than SaTC's at 32.77%.

We also randomly sampled 230 Mango buffer overflow TruPoCs and verified them. Mango found 109 and 121, giving it a true positive rate of 47%.

Our manual analysis of the buffer overflow results found several cases where Mango identified a vulnerability that Karonte or SaTC could not (due to their reliance on the Binary Dependence Graph). Our motivating example (Listing 1) showcases this exact issue.

11.3.1 Baseline Comparison

Taint-style vulnerability analysis is usually paired with the inherent worry of whether the analysis itself has any effect—with the level of vulnerabilities that we identify, would a naïve approach to generate a TruPoC on any vulnerable sink function call be just as effective? To answer this question, we designed a naïve baseline approach.

The baseline approach marks every vulnerable sink function call as a potential vulnerability. However, the user's effort does not stop there, as they must verify the vulnerabilities by analyzing the context of the vulnerable sink function call. Therefore, a fair comparison is the TruPoCs generated by Mango compared to the number of context paths backward from a vulnerable sink function call. We limit the depth of the backward context traversal to 7, mimicking how far back Mango will go to find unique path contexts.

Table 2 shows the results of this comparison for the command injection Mango TruPoCs and vulnerable context paths and the same for buffer overflows. Mango significantly reduces the burden on the human analyst by reducing the number of vulnerable context paths they need to reason about from 7,251,623 to 2,094 for buffer overflows and 347,405 to 216 for command injections.

11.4 SaTC Selected Dataset Results

SaTC evaluated their tool against 7 selected firmware, and on these firmware, Karonte produced zero true positives. We evaluated Mango against these same firmware images, and to do so fairly, we evaluated only on command injections just as SaTC did in their foundational work. Table 3 shows the results of this experiment.

		SaTC						Mango					
Vendor	**Samples**	**Total**	**Cmdi**	**Overflow**	**Total Time**	**Analyzed Bins**	**TruPoCed Bins**	**Total**	**Cmdi**	**Overflow**	**Total Time**	**Analyzed Bins**	**TruPoCed Bins**
Netgear	17	138	42	96	450:27	50	22	2,089	143	1,946	502:29h	1,950	127
D-Link	9	2	0	2	174:34	18	7	36	0	39	178:08h	696	18
TP-Link	16	0	0	0	153:55	42	17	56	0	56	192:32h	610	8
Tenda	7	4	2	2	82:02	21	5	129	73	56	73:11h	343	21
Total	49	144	44	100	860:58	131	52	2,310	216	2,094	946:22	3,599	174

Table 1: Comparison of SaTC and Mango on Karonte Dataset. *Analyzed Bins* are the amount of binaries Mango analyzed while *TruPoCed Bins* are the amount of binaries with TruPoCs. A subset of TruPoCs were manually analyzed for correctness, the results of which are shown in Table 4.

	Buffer Overflows	**Command Injections**
TruPoCs	2,094	216
Vulnerability Sinks	4,725	3913
Vulnerability Context Paths	7,251,623	347,405

Table 2: An analysis of Mango against a baseline approach. In the naïve baseline approach, every vulnerable sink function call is marked as a potential vulnerability. However, to verify the user must analyze the paths backwards from the vulnerable sink function. Therefore, Mango reduces the need to look at Vulnerable Context Paths to TruPoCs, thus reducing significant verification effort from the human analyst.

Mango analyzed 384 binaries in 49 hours and generated 145 TruPoCs, while SaTC analyzed 21 binaries in 93 hours and generated 65 TruPoCs. Mango generated a total of 89 (61%) true positive TruPoCs versus SaTC's 36 (55%). In addition to more than doubling SaTC's true positive TruPoCs, Mango also ran 90% faster than SaTC.

Mango generated 145 command inject TruPoCs from 31 binaries whereas SaTC's 65 originate from 13 binaries. There is an overlap of 13 binaries between Mango and SaTC for these seven selected firmware. Therefore, the TruPoCs generated by the other 18 binaries that Mango found are false negatives for SaTC. However, SaTC found 11 TruPoCs in the seven firmware for which Mango did not generate a TruPoC, resulting in a few false negatives for Mango. Despite this, the reduced analysis scope induced by the Binary Dependence Graph technique introduces significant false negatives.

11.5 Ablation Study

To answer RQ2, we evaluated Mango on the Netgear firmware R6400v2 and measured the impact of Assumed Nonimpact and Sink-to-Source Analysis. All runs were done on the exact same set of binaries, and the times reported are only on binaries that were ran successfully across all options. As a baseline, we ran Mango normally, enabling both Assumed Nonimpact and Sink-to-Source Analysis.

Table 5 shows the results of this analysis on the 60 binaries in the firmware for command injection sinks. Mango achieved an average execution speed of 4 minutes per binary and an overall run-time of 275 minutes.

11.5.1 Disabling Assumed Nonimpact

Theoretically, Assumed Nonimpact allows Mango to run faster by analyzing fewer paths and functions along the way to our sink. With only Assumed Nonimpact disabled, i.e., analyzing every path and function in-line to the sink, the runtime is 632 minutes with an average of 10 minutes spent on each binary. Thus, Assumed Nonimpact provided a speed increase of 129.82%. It should be noted that Assumed Nonimpact also generates more TruPoCs and true positives than Mango without Assumed Nonimpact.

11.5.2 Disabling Sink-to-Source Analysis

We conducted a similar analysis by disabling Sink-to-Source Analysis. This forward tracing approach results in a decrease in speed against our Sink-to-Source Analysis. The average runtime of a binary is 5 minutes with a total of 345 minutes. Enabling Sink-to-Source Analysis results in a speed increase of 25.61%. This is notably faster than default Mango and generates many more TruPoCs and true positives.

11.5.3 Disabling Both Optimizations

Finally, we evaluated our approach against the standard taint approach by disabling both Assumed Nonimpact and Sink-to-Source Analysis. Without these optimizations, the average time taken to analyze a binary was 26 minutes, and it took 1,575 minutes to analyze the given firmware.

The number of TruPoCs generated for this approach is much lower than our approach of using both Assumed Nonimpact and Sink-to-Source Analysis. To analyze all context sensitive paths in a timely manner, we place a timeout of six minutes on individual Sink-to-Source path analysis. There can be hundreds if not thousands of paths from all sinks that need to be analyzed (as Section 11.3.1 shows). We used Sink-to-Source Analysis to find the highest common call-depth for triggering bugs, which distills the shortest unique path to each sink.

11.6 Large-scale Dataset Results

The Large-scale Dataset consists of largely ARM and MIPS based router firmware in addition to some NAS firmware. We

Vendor	Device	SaTC					Mango				
		TruPoC	TP	Time	TruPoC Bins	Total Bins	TruPoC	TP	Time	TruPoC Bins	Total Bins
Netgear	R6400	4	4	30:23h	1	3	16	9	6:30h	4	76

Table 3: Comparison of SaTC and Mango on SaTC Selected Dataset. *TruPoC Bins* are the amount of binaries with actual TruPoCs found.

	TruPoCs	TP	TP Ratio	FP	FP Ratio
Command Injection	100	57	57%	43	43%
Buffer Overflow	230	109	47%	121	53%

Table 4: Results of manual analysis on a subset of Mango's TruPoCs generated from the Karonte Dataset.

performed the evaluation on a Kubernetes cluster composed of 2.30GHz Intel Xeon CPUs, with each process running strictly on one core and at least 5GB of RAM allocated per binary.

Table 6 shows the results, and Mango analyzed 770,374 binaries, generating 10,834 TruPoCs over a total CPU time of 339 Days 21h. On average, Mango only took 38.12s to fully analyze a binary and 5h 32m to analyze any individual firmware. This time per firmware is much lower than the results reported by either SaTC or Karonte.

12 Discussion

We discuss our view on the quality of the data set as well as the limitations of Mango in this section.

12.1 Threats to Validity

Based on our experience, there are many more taint-style vulnerabilities in IoT firmware than in traditional software. We believe this is partially due to the lack of proper software engineering practices in major IoT device vendors as well as the lack of security defenses in compilers and OSes for embedded devices. For example, many MIPS binaries that Mango analyzed did not have stack canary enabled, and the majority of MIPS CPUs do not support address space layout randomization. Therefore, while our proposed techniques and algorithms can apply to finding taint-style vulnerabilities in traditional software and commercial off-the-shelf (COTS) binaries, the improvement over traditional forward data-flow analysis may not apply there. However, given the sheer number of IoT devices in our community, Mango represents a step forward in automated firmware vulnerability analysis.

We used the Karonte Dataset for the sake of consistency as it is a common point that was evaluated on both SaTC and Karonte. However, the dataset is slightly outdated as there are many more newer firmware from all of the presented vendors. In an attempt to combat this and show Mango is practical even on newer and larger firmware we present an evaluation based on a larger and newer dataset as shown in Table 6.

12.2 Limitations

Assumed Nonimpact may cause soundness losses. As discussed in Section 7, Assumed Nonimpact may lead to soundness issues due to incorrect or unreliable analysis results from calling convention, function prototype, and function I/O interface inference.

Balancing between false positives and false negatives. The design of Mango inherently determines that it may report false positives (i.e., vulnerability alerts that are not real vulnerabilities). These can be caused by broken data dependencies (usually the result of incomplete CFGs or missing edges on a CFG) or intended functionality. Unlike Karonte and SaTC, which aim for low false positive rates, we believe that it is vital for a vulnerability detection tool to report as many TruPoCs as possible (i.e., lower false negatives) while keeping the false positive rate at an acceptable level. Many vulnerabilities that Mango finds are impossible for Karonte or SaTC to find.

12.3 Future Work

Although Mango has significantly improved finding vulnerabilities in firmware using static analysis, there is yet more room for improvement. Currently, Mango focuses solely on command injections from various functions and buffer overflows resulting from *strcpy*. The scope of covered vulnerabilities can be widened to path traversals, SQL injections, and other string-related vulnerabilities.

Firmware	Assumed Execution	Source-To-Sink	Average Per Binary (minutes)	Total (minutes)	TruPoCs	TP	Errors
R6400v2	✓	✓	4:35	275:08	16	9	13
	✗	✓	5:45	345:41	21	9	37
	✓	✗	10:32	632:18	13	5	22
	✗	✗	26:15	1,575:02	8	1	29

Table 5: Results of the ablation study where four different configurations of Mango are evaluated on R6400v2 firmware.

Vendor	Samples	Binaires				Time	AVG Time	AVG Bin Time
		Total	TruPoCs	Error	OOM			
Netgear	305	182,600	6,716	4,240	52	84 Days 3h	6h 37m	39.82s
Asus	158	104,422	635	1,174	45	46 Days 16h	7h 05m	38.62s
Belkin	62	20,018	2,102	353	12	14 Days 13h	5h 38m	62.94s
Linksys	67	46,470	211	440	8	20 Days 14h	7h 23m	38.33s
TPlink	484	239,020	166	3,339	93	89 Days 5h	4h 25m	32.26s
Trendnet	178	41,878	31	5,585	3	6 Days 18h	0h 51m	13.02s
Tenda	104	29,650	56	576	9	18 Days 6h	4h 12m	53.24s
D-Link	320	95,788	907	2,626	25	54 Days 1h	4h 12m	50.56s
ZyXEL	20	10,528	10	254	2	4 Days 0h	4h 48m	32.85s
Total	1,698	770,374	10,834	18,587	249	339 Days 21h	5h 32m	38.12s

Table 6: Large-scale evaluation run on 1,698 firmware samples. This table lists the vendors belonging to the firmware run on the largescale dataset for Mango's analysis and all numbers shown are relative to said vendor.

In addition, buffer overflows from bounded operations such as *strncpy*, *snprintf*, and *memcpy* can be introduced with some basic value set analysis. A more comprehensive application of value set analysis [4] allows for informed decisions on which branches should be taken to trigger a vulnerability which will improve Assumed Nonimpact's performance. This can also filter out false positive results with the bounding of buffers provided by value set analysis.

13 Related Work

Static solutions. Karonte [36] was one of the first to introduce multi-binary interactions to static analysis in the context of IoT devices. Their approach models several input sources, such as environment variables and NVRAM entries, and propagates that information from producer binaries to consumer binaries. SaTC [9] continues their approach, but instead of including network interactions as their sources, they use keywords found in front-end files such as JavaScript and PHP. They capture directly exploitable vulnerabilities via user input in these front-end files. This increases the likelihood that TruPoCs will be true positives. However, they ignore other critical binaries in favor of their border binaries. Both Karonte and SaTC severely limit the scope of analysis for efficiency and reduced false positive rates. For example, Karonte and SaTC only analyze binaries that are obviously reachable from the outside network; SaTC limits input sources even more by enforcing keyword matches. As such, they both suffer from high numbers of missed vulnerabilities, as is evidenced by the discrepancy of true positives between Mango and SaTC on Karonte's dataset. Mango avoids this limitation by significantly increasing the analysis efficiency through design benefits (using static data-flow analysis instead of taint tracking and symbolic exploration) and algorithmic improvements (Sink-to-Source Analysis and Assumed Nonimpact).

Saluki [20] produces an extremely fast static analysis through the micro execution of paths in the binary. Though this approach is much faster than previous work, it requires precise vulnerability descriptions using their custom language, making the tool difficult to use and highly specific. Mango takes a much more general approach where categories of sinks defined by function names are set. Arbiter [45] begins to cross into the boundary of dynamic analysis with their use of Under-Constrained Symbolic Execution (UCSE). They approach the problem of vulnerability verification with a static taint analysis followed by UCSE for reachability verification. However, their approach only works on x86-64 binaries, unlike Mango, which also runs on MIPS and ARM binaries. Firmalice [40] provides backdoor detection and verification in firmware binaries using symbolic execution but is bound by the overhead of symbolic exploration. Similarly, FIE [18] uses symbolic execution to analyze open-source MSP430 firmware binaries, but there are various firmware binaries that are intractable to analyze with this tool.

Firmware rehosting and dynamic analysis. Firmware rehosting refers to the process of running or emulating firmware on workstations or servers for interaction and security auditing. Most work in this area conducts full-system emulation of firmware targets, but several have extracted pieces to be

analyzed separately [15, 35]. Once rehosting succeeds, researchers usually move on to vulnerability testing (e.g., using Metasploit) or fuzzing [8, 37]. Costin et al. [16] used full-system emulation to rehost COTS firmware, and then used web penetration tools to find vulnerabilities in web servers on rehosted firmware. Firmadyne [7], Avatar [48], Avatar^2 [33], and FirmAE [22] provides more automation into the full-system rehosting process by QEMU-system to rehost firmware images in a large scale.

Unfortunately, rehosting is usually exceptionally tedious and error-prone, and access to peripherals only available on the original IoT devices is lost. Therefore, PROSPECT [21], CHARM [43], and SURROGATES [24] conducts hardware-in-the-loop operations during firmware emulation. HALucinator [12] and DICE [30] emulate Hardware Abstraction Layers (HALs) and the DMA (Direct Memory Access) channel. Usually, fuzzing is a natural application after firmware rehosting [19, 42, 50, 51].

14 Conclusion

IoT devices are riddled with security vulnerabilities, not only due to shoddy coding practice but also without many of the layers of modern defenses that we take for granted on desktops and mobile devices. And yet, we invite these devices into our homes and onto our networks, where attackers leverage their (apparently) innate insecurity to gain a foothold and wreak havoc.

We believe that Mango represents a significant step forward in identifying these vulnerabilities *before* an attacker ruins our day. By quickly statically analyzing all binaries on a firmware for security vulnerabilities, we can help raise the bar for IoT device security.

Table 7: Mango analysis on six unique firmware outside the dataset of Karonte and SaTC.

A Additional Experiments

A.1 Additional Firmware Tests

To show our extensibility beyond the Karonte Dataset, we randomly selected 6 firmware samples from different vendors (Shown in Table 7). There was no additional effort or analyses added to Mango to generate these results; they were produced in the same manner as the results discussed in table 1 and table 3. Mango found a significant number of TruPoC's in these firmware samples, including TruPoC's in Belkin and Linksys firmwares which were not tested at all in the Karonte Dataset. Each generated TruPoC was manually analyzed to determine the overall TP rate, which was 41.3%

SCAVY: Automated Discovery of Memory Corruption Targets in Linux Kernel for Privilege Escalation

Erin Avllazagaj, Yonghwi Kwon, Tudor Dumitraș
University of Maryland, College Park

Abstract

Kernel privilege-escalation exploits typically leverage memory-corruption vulnerabilities to overwrite particular target locations. These memory corruption targets play a critical role in the exploits, as they determine which privileged resources (e.g. files, memory, and operations) the adversary may access and what privileges (e.g. read, write, and unrestricted) they may gain. While prior research has made important advances in discovering vulnerabilities and achieving privilege escalation, in practice the exploits rely on the few memory corruption targets that have been discovered manually so far.

We propose SCAVY, a framework that automatically discovers memory corruption targets for privilege escalation in the Linux kernel. SCAVY's key insight lies in broadening the search scope beyond the kernel data structures explored in prior work, which focused on function pointers or pointers to structures that include them, to encompass the remaining 90% of Linux kernel structures. Additionally, the search is bug-type agnostic, as it considers any memory corruption capability. To this end, we develop novel and scalable techniques that combine fuzzing and differential analysis to automatically explore and detect privilege escalation by comparing the accessibility of resources between executions with and without corruption. This allows SCAVY to determine that corrupting a certain field puts the system in an exploitable state, independently of the vulnerability exploited. SCAVY found 955 PoC, from which we identify 17 new fields in 12 structures that can enable privilege escalation. We utilize these targets to develop 6 exploits for 5 CVE vulnerabilities. Our findings show that new memory corruption targets can change the security implications of vulnerabilities, urging researchers to proactively discover memory corruption targets.

1 Introduction

Kernel exploitations typically *start* by triggering vulnerabilities that enable memory corruption and *end* by overwriting particular memory locations with specific values, to put the system in an exploitable state where the attacker may change the system's behavior. These targeted memory locations for corruption, which we call *memory targets* hereafter, are *orthogonal* to the exploited vulnerability: attackers may use them again when exploiting other vulnerabilities, and defenders often focus on the memory targets to prevent the exploitation of unknown vulnerabilities. For example, Figure 1 shows an exploit created by combining a vulnerability and a memory target (A), resulting in multiple combinations (or exploits) such as B and C. While prior research has focused on discovering and exploring vulnerabilities, comparatively less attention was given to the discovery of memory targets that are needed in the last step of the exploitation process.

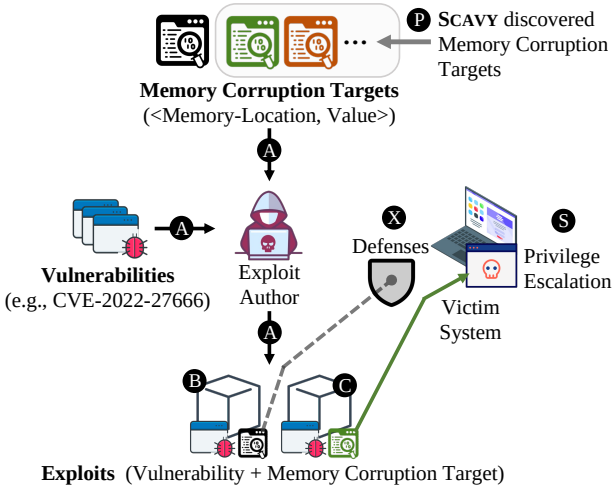

Figure 1: Memory Targets in Exploit

Assume that a privilege escalation exploit (B in Figure 1) seeks to corrupt *a function pointer* in a kernel data structure to execute a malicious payload that escalates the privilege. Unfortunately, the attacker in this exploit utilizes an *unnecessarily strong* capability, leading to a rather *obvious* exploitation method (i.e., control flow hijacking) for privilege escalation which is prevented by popular defenses such as CFI (X). A *new memory target* can enable the attacker to escalate the privilege (C) without being detected (S). For

example, corrupting other memory targets such as `username`, `inode` numbers, or the `task_struct::addr_limit` field, can accomplish privilege escalation. In particular, the `addr_limit` field [1] was famously employed in 2019 by the NSO group to install the Pegasus spyware on Android devices [2]. The vulnerability had been found by Syzkaller in 2017, but it was not patched in many released devices for many years, as its security implications were unknown [2]. As a result, in 2020, the `addr_limit` was used in over 40% of the Android kernel exploits in the wild [3]. This results in the removal of the field from the Linux kernel to prevent such attacks [4]. As such, the discovery of new memory targets enables the exploitation of many vulnerabilities including those that are *previously considered unexploitable or not critical* [5]. Moreover, new types of memory targets can enable exploits to evade existing defenses focusing on the popular memory targets [6–10]. Discovering memory targets is also beneficial in a defensive context, as several techniques (e.g., freelist pointer obfuscation [11]) can secure these kernel objects [12].

Despite its importance, finding memory targets has been challenging and typically done *manually*, relying on expertise in the Linux kernel code base. The prior research on automating kernel exploit generation [13, 14] has focused on exploring specific vulnerabilities with limited types of memory targets (e.g., function pointers or reference-count fields). Consequently, the fields of Linux kernel data structures that privilege-escalation exploits can target have not been systematically researched. For instance, among the 6,582 structures in the Linux kernel version 5.15.80, only 746 (11.3%) of them contain either function pointers (142; 2.1%) or pointers to structures containing function pointers (604; 9.2%) that are considered security-sensitive and have been actively addressed by previous work. The remaining 88.7% represent an *unexplored attack surface*. Moreover, even for the previously addressed 11.3%, an additional thorough search is desirable as [13, 14] only examined reachable memory areas from existing proof-of-concept (PoC) code and [15] focuses on a few kernel objects that induced crashes during the analysis.

We propose SCAVY[1], a framework for systematically discovering *memory targets* in the Linux kernel for privilege escalation (Ⓟ in Figure 1). SCAVY searches for *broader types* of memory targets, beyond the pointer-type memory targets that existing techniques focus on [16–19]. In particular, SCAVY aims to discover new diverse types of targets that can impact (or enable) many existing and unknown vulnerabilities.

During the analysis of the kernel structures and memory areas for the memory targets, SCAVY encounters two challenges: (1) examining a large number of potential memory targets and (2) lack of oracles that can detect diverse forms of potential privilege escalations. SCAVY handles the two challenges by leveraging a differential analysis-based multi-execution reasoning, that are more efficient than existing techniques rely on symbolic and taint analysis. Specifically, it runs multiple executions with and without memory corruption and checks the program states of the executions in terms of the accessibility of security-sensitive resources. The results are analyzed to guide the search process and detect privilege escalations.

SCAVY generated 955 PoC exploits that can potentially escalate privileges, by corrupting 275 unique fields in 86 kernel structures. From the PoC exploits from `CVE-2022-27666`, we create *two* fully functional privilege escalation exploits with new SCAVY identified memory targets (Section 3.1 and Section A.2). Our exploits do not require bypassing popular kernel defenses (e.g., KASLR, SMEP/SMAP, and CFI), unlike the original exploits that had to handle them.

In summary, we make the following contributions:

- We revisit the definitions of memory targets and post corruption program states to identify broader types of memory targets in the Linux kernel.
- We design and implement SCAVY, a framework that systematically discovers memory targets, along with the values needed to achieve privilege escalation. We discuss the design choices for each step of the search and the differential analysis-based execution reasoning.
- We evaluate the effectiveness of SCAVY by finding 20 memory targets in 12 kernel structures, where, notably, *17 of the targets have not been used in publicly available privilege escalation exploits*. We demonstrate that the memory targets found by SCAVY are vulnerability agnostic by developing 6 exploits for 5 different CVEs.
- We open-source our technique for future research [20].

2 Problem Statement

Despite important advances in *discovering* software vulnerabilities, incorrect assessments of their security implications remain common and can have a pernicious impact. For example, expert recommendations for prioritizing patches [21, 22] initially omitted `CVE-2017-0144`, the vulnerability later exploited by WannaCry and NotPetya; `CVE-2019-2215` was discovered in 2017 but was not patched in many Android devices because its security implications were unknown, before it was exploited by the NSO group [2]. *Exploitability* assessments are challenging because they require reasoning about state machines with an unknown state space and emergent instruction semantics [23], known as "weird machines". For privilege escalation, in particular, exploitability assessments hinge on the ability to overwrite specific memory targets.

2.1 Problem Definition

SCAVY aims to solve a problem of finding memory targets that can lead to privilege escalation. In our context, a memory target is a field of kernel data structure and privilege escalation is defined as a change of a privilege that allows access to an

[1] SCAVY is an abbreviation for 'Scavenger.'

unauthorized resource without using legitimate methods (e.g., permission changing APIs). To facilitate the discussion, we divide a program's execution state into three different states based on how an exploit progresses to achieve its ultimate goal (e.g., taking over the system's control).

1. Before an exploit starts, a process's execution is in an **unexploited state**.
2. After an exploit triggers a vulnerability to corrupt system states to escalate privilege, granting access to resources the exploit wants to compromise, the state becomes an **exploitable state**. This state has access to the exploit's target resources, meaning that the exploit has *achieved all accesses needed* for its ultimate objective but *has yet to achieve* it (i.e., has not compromised the system yet).
3. After the exploit achieves its objective, the execution state becomes an **exploited state**.

Threat Model. We assume a local unprivileged adversary seeking to use a vulnerability in the Linux kernel with a *memory target by* SCAVY to escalate privileges. This threat model is relevant in various settings, such as cloud computing (e.g., Docker), Android [24], and malware exploiting kernel vulnerabilities [25]. As SCAVY finds memory targets for any given exploits, our threat model includes a wide range of diverse memory corruption capabilities of exploits. Note that it also means that SCAVY found memory targets may require vulnerabilities with certain capabilities. As described in Section 4 and Section 3, creating an end-to-end functional exploit from the SCAVY identified memory targets requires manual efforts. Automating the exploit generation process is out of the scope.

2.1.1 Unexploited, Exploitable, and Exploited States

Figure 2 illustrates the two critical states for our problem definition (i.e., unexploited and exploited states), including privileges of various resources under the states. We first define five different types of privileged resources in Figure 2:

- **Read-only Resources**: These are the files that are configured to be read-only (e.g., Apache [26]'s configuration file are read-only to prevent unauthorized modifications [27]). `setuid` files are also read-only.
- **Inaccessible Resources**: Sensitive files or root owned files/directories (e.g., `/etc/shadow` or `/root`) are not readable and writable by an unprivileged process.
- **Privileged System calls**: There are system calls specific privileges (e.g., `mount` and `chroot`). If an unprivileged process calls them, the request will be denied and failed.
- **Kernel/Other Processes' Memory**: An unprivileged user process is not allowed to read/write kernel memory. Other processes' memory is also not accessible (i.e., cannot read/write) due to the memory space isolation.

We define the three states with privileged resources.
Unexploited State. An execution under this state follows the permission configured for each resource. For example,

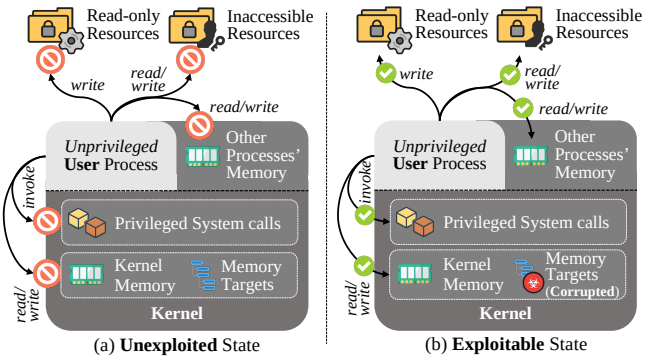

Figure 2: Unexploited and Exploited States

as shown in Figure 2-(a), it cannot read or write inaccessible files/folders (e.g., `/etc/shadow` and `/root`) and cannot write read-only files such as `/etc/passwd`, without calling permission/privilege changing APIs. Kernel memory, privileged system calls, and memory of other processes are inaccessible.
Exploitable State. Suppose a prohibited operation (e.g., read-/write) on any of the privileged resources in the unexploited state becomes available *after corrupting a memory target*. In that case, we consider that the execution's state has changed to an *exploitable state*. Note that there exist multiple instances of different exploitable states depending on which resource's privilege is escalated. For example, an exploitable state can have escalated privilege on `/etc/passwd` while another exploitable state provides access to a prohibited memory area. Hence, depending on the exploit's ultimate goal and its environment, a particular exploitable state would be needed. To this end, describing the exact *escalated privilege* and *prerequisite conditions* of an exploitable state is important to determine whether it can be used to achieve the exploit's goal.
Exploited State. An exploitable state becomes the *exploited* state, if the exploit achieves its ultimate goal with the escalated privileges (e.g., adding a root user with the escalated `/etc/password` and `/etc/shadow`). Note that the definition of the exploited state is *specific to each exploit's goal*. For example, to change configurations of Apache, an exploitable state execution with write access to `httpd.conf` is required.

2.2 Goal and non-goals

Goal. SCAVY aims to find a memory target that can change an unexploited state to an *exploitable state* when the target is corrupted. To clearly define the memory target's applicability, it is important to identify (1) the prerequisite of corrupting the memory targets and (2) the post-conditions (or escalated privileges) of the corrupted memory targets. In particular, the prerequisites and post-conditions are defined as follows.

- **Prerequisites**: (1) Required privilege and method for allocating the memory target, (2) Privilege required for corrupting the memory target (e.g., memory write permission if the target is read-only), and (3) Memory corruption capability (i.e., corruptible memory location, size,

and possible values) for the memory target.
- **Post-conditions**: (1) Escalated privilege/permission, (2) Name or path of the escalated resource, and (3) Area (i.e., offset and the range) of the escalated resource.

Non-goals. SCAVY does not focus on identifying new vulnerabilities. SCAVY's new memory targets may allow us, in some cases, to repair exploits that have been rendered inoperable by system-level defenses (e.g., SMAP), but they do not improve the exploits' *capability* or *reliability* (as defined in Section 4). While we demonstrate the ability to transit from an *exploitable* to an *exploited* state by developing a few functional exploits (see Section 3), automating this step is out of our scope. Finally, our goal is not to construct an automated *end-to-end* exploitation tool.

3 Motivating Examples

We describe two exploits using memory targets identified by SCAVY, to motivate its impact and practicality.

3.1 Corrupting `vm_area_struct::vm_file`

Target Kernel Structure. The `mmap` system call creates a memory-mapped file with an opened file descriptor. It will create a memory buffer containing the file content, and if it is created with the write permission, changes to the buffer will be written back to the original file, when the file is closed.

The Linux kernel uses the `vm_area_struct` structure, shown in Listing 1, for the memory-mapped files. The structure contains the address range of the mapped memory (`vm_start` and `vm_end`), its permission (`vm_page_prot`), and a pointer to the file (`vm_file`).

```
struct vm_area_struct {
    unsigned long vm_start;     /* mmap() retval. */
    unsigned long vm_end;
    ...
    pgprot_t      vm_page_prot; /* pg. permissions */
    ...
    struct file*  vm_file;      /* victim field */
    ...
};
```

Listing 1: Declaration of `vm_area_struct`.

Discovery. SCAVY automatically discovers that corrupting `vm_file` can impact the content of the corresponding memory-mapped file, potentially causing privilege escalation. Specifically, SCAVY first creates two executions access the same file (so that they will access `vm_area_struct::vm_file`). Then, it corrupts the `vm_file` with a random value in one of the executions. SCAVY compares the two executions (i.e., with and without the corruption) to discover the two executions obtain different contents of the file.

Next, SCAVY creates the third execution to check whether it can achieve privilege escalation. This time, instead of a random value, SCAVY uses other instances of valid values of `vm_area_struct::vm_file`. Specifically, SCAVY opens a set of both privileged and unprivileged files to obtain the values of `vm_file` instances. SCAVY copies the values to corrupt the `vm_file` and checks whether the third execution can access contents of any files that their `vm_file` values were copied.

This checks whether copying the content of `vm_file` from a privileged file to adversary-owned file would allow the adversary to *access the privileged file's content* using the adversary-owned file's permission. For example, if an adversary copies the `vm_area_struct::vm_file` of the password file (i.e., `/etc/passwd`) to an unprivileged temporary file's `vm_area_struct::vm_file` (e.g., `/tmp/file`), the adversary can read and write the password file. To this end, SCAVY identifies `vm_area_struct::vm_file` as a memory target.

Completing the Exploit. We use `CVE-2022-27666`, which provides an out-of-bounds write capability [28], to corrupt the memory target. The exploit first opens two files: (1) a dummy file with a read/write permission and (2) the password file (`/etc/passwd`) with a read permission. Then, it creates a few thousand memory maps of the files using `mmap` (e.g., 3,000 times in this example). Note that each `mmap` call results in allocating an instance of `vm_area_struct` in kernel. We then leverage the vulnerability to leak *neighboring pages* of the created structures to read the `vm_file` that maps `/etc/passwd`. Next, we use the vulnerability again to copy the content of `vm_file` of the `/etc/passwd` into the dummy file's `vm_file`.

Finally, the exploit calls `msync` with the corrupted `vm_area_struct::vm_start`. This makes the kernel synchronize the mapped page with the content of `/etc/passwd`, using the permissions of the dummy file which is the read and write permissions. To this end, the attacker can add a new root-level account by modifying the `/etc/passwd`.

Appendix A.2 presents more details of this exploit, along with the option of using `file::f_mapping`, another memory target discovered by SCAVY, to exploit `CVE-2022-27666`. In Section 7.3.3, we discuss the exploitation of two additional vulnerabilities corrupting `vm_area_struct::vm_file`.

3.2 Corrupting `key::description`

Target Kernel Structure. The `keyctl_instantiate` system call allocates the `key` structure in the kernel, shown in Listing 2. It contains fields to store permissions (`perm`), the owner's identifiers (`uid` and `gid`), and a text description of the key (`description`). This time, we target `description`, which is a string pointer where its text is used by the `keyctl_search` system call which allows a user to search a keyring.

```
struct key {
    refcount_t       usage;
    ...
    kuid_t           uid;
    kgid_t           gid;
    key_perm_t       perm;
    ...
```

```
    unsigned long    len_desc;
    char*            description;
    ...
};
```

Listing 2: Declaration of `key`.

Discovery. SCAVY discovers that once the `description` field is corrupted, an attacker can call `keyctl_describe` to read a string value from the corrupted address, allowing an arbitrary memory read. Specifically, SCAVY creates two processes which call (1) `add_key()` with a crafted description including payload to create a key and (2) `keyctl_read()` to access the created key. In one process, SCAVY injects a corruption that overwrites `key::description` with a value from another instance of `key`. The other process runs without any memory corruption. At the end of both executions, SCAVY compares the return buffers of `keyctl_read()` to detect the deviation, discovering a privilege escalation on the kernel memory, which is inaccessible to unprivileged user processes.

Completing the Exploit. We modified an existing exploit for `CVE-2016-0728`, that overwrites `key::key_type::revoke`. The field is a function pointer; thus it allows an adversary to hijack the control flow. However, in practice, this made the exploit unreliable in Android devices, either due to lack of kernel symbols [29] or SMEP/SMAP [30].

Instead of corrupting the function pointer, we focus on `key::description`. As with the original, our exploit first triggers the vulnerability by overflowing `key::usage` to '0', which is a reference count. This frees the structure prematurely and gives us a use-after-free primitive. We use this primitive by allocating a '`msg_msg`' object, which includes a buffer where we can insert arbitrary data (a message). The buffer overlaps with the fields of the `key` object and allows us to overwrite the length (`len_desc`) and the description pointer (`description`), which is the target. If done properly, this allows an adversary to read from arbitrary kernel addresses. With this capability, the adversary can bypass KASLR, leak kernel memory, and read secret keys from other Android apps' keyrings, potentially leaking session cookies.

4 SCAVY in the Kernel Exploitation Development Pipeline

In this section, we contextualize our work with respect to the prior research on the Linux kernel exploitation development. As shown in Figure 3, a functional kernel exploit is created through *four stages*: ❶ Identifying a vulnerability causing a crash, ❷ Discovering the vulnerability's other capabilities that can corrupt various memory targets, ❸ Combining the capabilities to escalate privilege, and ❹ Creating a reliable exploit escalating privilege while bypassing defenses.

– **Stage ❶**. Vulnerability Discovery.

Fuzz Testing Approaches. To find a vulnerability that can change a system's behavior, various testing techniques, such as fuzzing, have been proposed. Syzkaller [31] is a popular fuzzer that is specialized for finding Linux kernel vulnerabilities. Recently, various advanced fuzzers have been proposed, including those leveraging hybrid fuzzing [32], symbolic execution [33], and state-based exploration [34–36] to improve the effectiveness of testing for vulnerability discovery.

Exploiting Violation Detectors. Violation detectors [37–41] are runtime techniques that raise exceptions when they detect operations violating desired properties (e.g., out-of-bounds reads/writes [37], use-after-free [38], and race conditions [39,40]). When they are applied to the target system, they essentially turn the violations into crashes, helping fuzzers identify the violations that can be a strong indicator of potential vulnerabilities. Recently, leveraging such detectors has become a typical tactic in the Linux kernel fuzzing [41].

Relevance to SCAVY. An exploit requires a vulnerability that can corrupt a specific memory, which can lead to privilege escalation. A vulnerability in this stage typically causes a crash, often because it corrupts a critical memory. However, it is unclear whether it can corrupt a specific memory target with a desired value. SCAVY focuses on discovering memory targets, but not finding the vulnerabilities.

> In Section 3.1, this step is equivalent to choosing a known vulnerability (i.e., `CVE-2022-27666`).

– **Stage ❷**. Capability Discovery.

Capability of a Vulnerability. A vulnerability is often released with a *single memory corruption target*, which typically causes a kernel crash when triggered. However, such an initial capability may not be sufficiently powerful and versatile enough to achieve privilege escalations. As a result, investigating a vulnerability's other capabilities has become a critical step to see if the vulnerability can be exploitable. A line of research exists that searches a vulnerability's full capabilities [13–15]. Specifically, [13] introduced capability-guided fuzzing to investigate out-of-bounds write vulnerabilities. [14] leverages fuzzing and symbolic execution to explore various contexts of a use-after-free (UAF) vulnerability and determine if the attacker can control the system to reach an exploitable state. [15] explores multiple crashes of the same bug in an effort to observe more exploitable crashes. AlphaExp [42] discovers fields of kernel structures that can be exploited to achieve arbitrary code execution (ACE) or arbitrary address writing (AAW) capabilities but not privilege escalation. It focuses on a different set of structure fields, missing structures such as `vm_area_struct` that SCAVY found.

Relevance to SCAVY. This stage explores whether the vulnerability can corrupt a more diverse memory range. As SCAVY discovers memory targets which are essentially kernel data structures' fields, capabilities of are vulnerability is critical to see whether it can be used to corrupt the SCAVY's memory targets. To use a SCAVY's memory target, a vulnerability should have a capability that can corrupt the memory target.

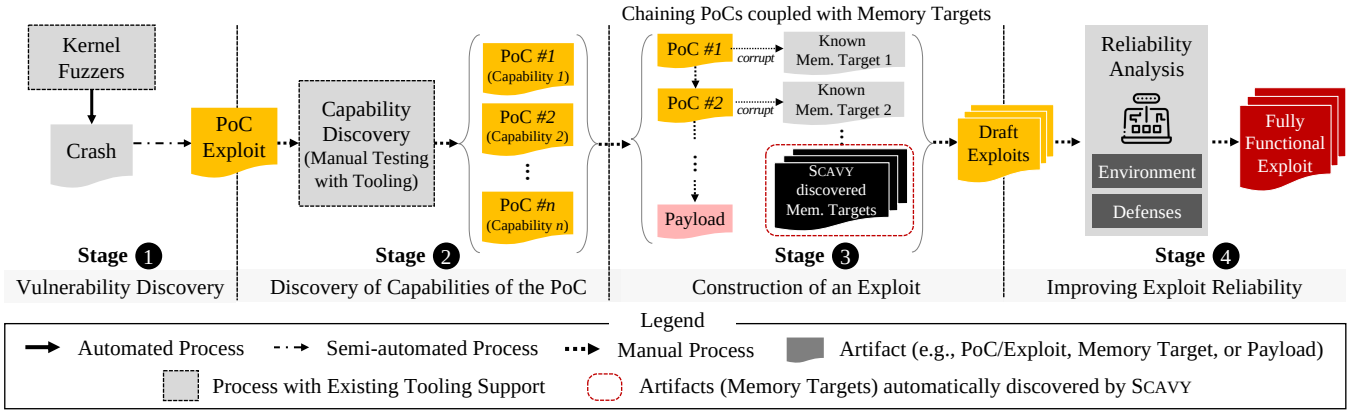

Figure 3: SCAVY in the Linux kernel exploit development pipeline

In Section 3.1, the vulnerability's exploit *already has the capability* of corrupting the memory target.

– **Stage ❸**. Construction an Exploit.

Escalating Privilege. Privilege escalation is typically achieved either (1) by gaining *arbitrary code execution* or (2) by *elevating privilege of the current user/resource* to root.

First, existing approaches [13, 14, 43] automatically test whether a vulnerability can corrupt a known field of data structures that can hijack the control flow (e.g., function/data pointers). Second, existing scripts [44] search for fields of kernel structures related to known critical system configurations (e.g., `uid`, `gid`, or credentials [5]) that can lead to privilege escalation if corrupted. However, they focus on *known fields* or *limited types of fields* (e.g., code or data pointers [13,14,43] and *reference counter* [45–47]). While approaches searching for other types of memory targets [45–49] exist, they are either manually done or focusing on certain types. For example, [48] focuses on structures handling variable-length data, which can allow out-of-bound reads if corrupted and [49] looks for structures with data pointers, which allows adversaries to control the referenced data if corrupted.

Some exploits require *chaining multiple vulnerabilities (or PoCs)* to corrupt multiple memory targets (e.g., leaking a value first and corrupting a field with the value), achieving privilege escalation. Finally, a payload is followed to achieve the exploit's ultimate goal (e.g., taking over the system).

Relevance to SCAVY. Typically, only the vulnerabilities capable of corrupting *a few known memory targets* are used to construct an exploit. Vulnerabilities that can corrupt other memory targets but not those known ones were considered usable. SCAVY discovers new memory targets, enabling more vulnerabilities to be usable for an exploit. SCAVY found memory targets allow an exploit to achieve privilege escalation in more diverse and subtle ways.

In Section 3.1, the vulnerability is used to corrupt a new SCAVY found memory target, `vm_area_struct::vm_file`, achieving the privilege escalation of a single file, instead of escalating an entire process's privilege [50]. Note that we chain two capabilities to first *read* the value of `vm_file` and then *write* the leaked value to another `vm_file` field.

– **Stage ❹**. Improving Exploit Reliability.

Consistently Corrupting Memory Targets. While an exploit is created in the previous stage, it might not reliably achieve privilege escalation, due to the randomness of memory layout and timing during the execution of the exploit. Hence, exploit authors leverage various techniques [43, 51, 52] to achieve an environment for reliable memory corruption. Specifically, [52] shows a method called *heap feng-shui* that extends to all slab caches and thus can be recycled for multiple kernel exploits. [43] automatically finds system calls to allocate objects of interest in a desired heap memory layout. [51] tests commonly known heap layout manipulation and exploit stabilization methods to aid the exploit development.

Bypassing Defenses. A reliable exploit should also evade existing defenses [10, 53, 54]. To this end, researchers have proposed various techniques to bypass the defenses. Specifically, [55] chains kernel-side ROP gadgets to bypass modern control flow integrity-based protections (e.g., CFI [10]). [56, 57] present methods to bypass the Kernel Address Space Layout Randomization (KASLR) [53]. [54] and [58] have proposed a method to bypass Supervisor Mode Execution Prevention (SMEP) [59] and SMAP (Supervisor Mode Access Prevention), respectively. [50] presents practical tricks to improve the reliability of an exploit.

Relevance to SCAVY. While SCAVY is not directly relevant to this stage, using some SCAVY found memory targets makes it easier to achieve reliability. For example, an analysis of the published PoC exploit for `CVE-2016-0728` mentions that existing defenses such as SMEP/SMAP [9, 59] can throttle the success rate of the exploit [30], where some SCAVY found memory targets can avoid the detection of those defenses.

In Section 3.1, SCAVY found memory target can achieve privilege escalation without violating the integrity of code pointers, without requiring a defense bypass.

5 Design

Figure 4 shows an overall procedure of SCAVY, consisting of three phases: (1) Instrumentation and Analysis (Section 5.1), (2) Discovery of Potential Memory Corruption Targets (Section 5.2), and (3) Detection of Memory Corruption Targets for Privilege Escalation (Section 5.3).

5.1 Instrumentation and Analysis

Type Casting Instrumentation. To identify memory corruption targets, SCAVY needs to identify types of allocated memory (e.g., types of structures) in the kernel and corrupt them. While previous techniques such as GREBE [15] rely on expensive taint analysis, they cannot be used for the sheer number of potential memory corruption targets SCAVY deals with. To this end, SCAVY instruments type casting operations.

Note that the Linux kernel coding-style guideline document [60] indicates that a memory allocation should be type-casted. In LLVM, it uses `CastInst` [61] for the type casting operation. Hence, we instrument `CastInst` by inserting a `call` to a dummy function that takes two parameters: (1) the memory address of the variable that is being type-casted, and (2) its new data type, passed as a string at compile-time. Note that we only instrument `CastInst` when its source and destination types are different (e.g., '`void*`' is assigned to a structure). At runtime, we use Kprobe [62] to log the dummy function's parameters to user space along with the return value of memory allocators (e.g., `kmalloc()`). Later, the fuzzer associates allocated memory addresses with their data type.

Analysis for Kernel Data Structures. During the instrumentation and analysis process, SCAVY aims to extract memory layouts of kernel structures of interest, so that it can guide the subsequent analyses of SCAVY. While we can extract them from the source code via an LLVM pass, they may not be accurate if a compiler optimizes the memory layouts of the structures. Specifically, structures that are not packed (i.e., structures without the '`((packed))`' attribute) may have unused memory space between fields, making the offsets of structures' fields in a binary different from the structure's definition in the source code. For example, if a structure has a 6 bytes of character array followed by an integer (i.e., `struct { char s[6]; int n; }`), a compiler may insert two unused bytes between the two fields (i.e., after `s[6]` and before `n`, resulting in `struct { char s[6]; char unused[2]; int n; }`). Hence, we use `pahole` [63] to find the sizes and offsets of structures at the binary level. We use construct a lookup dictionary mapping between a structure's name and the structure's fields' offsets, sizes, and types. Note that structures inside a structure are resolved recursively.

Memory Corruption Bridge. Most of SCAVY's components run in user mode, which do not have direct access to the kernel memory. Hence, we implement a kernel module that allows SCAVY's user mode components to corrupt the kernel memory. Specifically, the kernel module exposes an interface via `ioctl()`, providing read and write capabilities of the kernel memory to the user mode programs. During the instrumentation process, we include the bridge module into the kernel.

5.2 Discovery of Potential Memory Targets

Three Stage Operations of Exploits. We observe that most exploits in practice exhibit a pattern of three distinctive operations: (1) *allocating* a resource associated with a memory target, (2) *corrupting* the memory target to obtain sufficient permissions for privilege escalations, and (3) *conducting privileged actions* or actions escalating privilege.

Figure 5-(a) shows the exploit described in Section 3. It first creates two files. The memory targets are associated with the files (❶). Then, it corrupts the memory target, which is a kernel structure storing information of the file via the vulnerability (❷). This allows an adversary to obtain the permission of the root-owned file '`/etc/passwd`.' It then adds a new user by writing the '`/etc/passwd`' file, escalating privilege (❸). Figure 5-(b) follows a similar procedure. It creates a process that allocates the memory target `task_struct` (❶), and then corrupts the '`task_struct::euid`' associated with the created process, changing the process's effective user to the root user (❷). Finally, it creates a privileged shell via `execve()`.

Search Space for Each Stage. As each stage conducts a different operation, candidate operations for each stage may exist in a different space, requiring a distinctive focus. Specifically, to search operations for the first stage, one may look for system calls that *allocate* memory buffers, regardless of whether they will access the buffers or not. For the second stage, one should focus on the contents of the memory buffers and the impact of the corruption on the system. For the last stage, we should focus on the system calls dependent on the corrupted memory (i.e., system calls using the corrupted data).

Due to, in part, the different focus on each stage, in practice, different tools are used. For example, Syzkaller [31] is effective for searching the first stage because it aims to achieve higher code coverage. Intuitively, covering more code would exercise more program paths that may allocate data structures. For the second stage, KOOBE [13] and FUZE [14] are effective as they implement heuristics for detecting memory corruptions, such as overflowing into other co-allocated objects. Unfortunately, there are no popular tools for the third stage as it is manually done in practice.

SCAVY's Approach. Unlike existing tools that are only effective for each stage, SCAVY proposes to apply different criteria and metrics for each stage dynamically. Specifically, for the first stage, we use code coverage of system calls as a metric. Intuitively, by covering most of the code, it might also

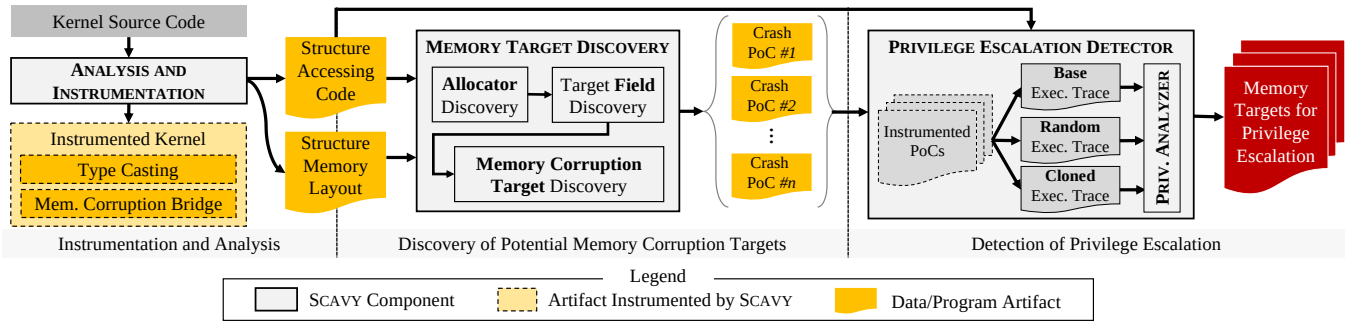

Figure 4: Overall SCAVY Design

```
1  for (int i = 0; i < 100000; i++)
2      open("/etc/passwd", O_RDONLY);
3  int wf = open("/tmp/writablefile.txt", O_RDWR);
4
5  CORRUPT_FILE_MAPPING(/* SPRAYED OBJ. MAPPING */);
6
7  write(wf, "root2:x:0:0:root2:/:/bin/bash\n", 32);
8  close(wf);
```

12     exit(0);
13 } else {
14     waitpid(pid);
15     setuid(0);
16     execve("/bin/sh");
17 }
```

(b) Exploit that Corrupts **euid**

Figure 5: Exploits Consisting of Three Steps

cover all the kernel structure allocation code of interest. For the second stage, we use coverage of instructions that *load* the corrupted memory to identify whether the corruption has an impact on the system or not. In the third stage, we focus on code coverage of the code dependent on the corrupted memory, to explore diverse consequences of the corruption.

5.2.1 Allocator Discovery

Objectives. This stage aims to identify a list of system calls that allocate kernel structures, which are the memory corruption targets. We aim to find system calls allocating as many unique kernel structures as possible because all the subsequent analyses are limited to the result of this stage. SCAVY runs every system call, tracks accesses to all allocated memory buffers, and detects types of allocated kernel structures.

Tracking Allocated Structures. We track memory allocations and memory accesses to identify allocated kernel structures as follows. We use Kprobe to set breakpoints on `kmalloc()`[2] and `kmem_cache_alloc()` to capture their return values (i.e., base addresses of allocated kernel structures).[3] We also set a breakpoint on the dummy function in Section 5.1 to capture its arguments. SCAVY then processes the Kprobe's output to associate addresses from typecasting operations with their allocation addresses. Note that analyzing type casting (and not using expensive taint/symbolic analysis [15]) is a key design choice that makes SCAVY scalable, allowing us to conduct the analysis on millions of generated sequences.

Coverage Guided Searching. SCAVY tries to cover more code allocating kernel structures, aiming to discover allocators for diverse memory targets. We use code coverage, *without changing the fuzzer and the coverage*, as, intuitively, covering more invocations of `kmalloc()` and `kmem_cache_alloc()` would likely find allocators for various memory targets.

5.2.2 Memory Target (Structure Field) Discovery

Objectives. Corrupting certain parts of the kernel structures change the system's behavior, while other parts may not have an observable impact on the system. Hence, SCAVY aims to find which fields of the structures can be memory targets causing an observable impact. Specifically, among all the allocated structures in the first stage, we search, one field at a time, which fields of structures can impact the system when corrupted (e.g., a crash). Similar to Section 5.2.1, we search conservatively, as the subsequent analyses depend on it.

Conservative Target Searching. We use a *conservative* definition that *if a corrupted field of a kernel structure is read at least once, it may impact the system*, meaning that it is a potential memory corruption target. Specifically, we corrupt each 4-8 byte field of the kernel structures with random bytes and use the `hardware watchpoint` [64] to monitor instructions that load the corrupted field. If we identify any such *load* instructions, the field is considered a potential memory target, and SCAVY moves on to the search for the next field. The `watchpoint` is lightweight and reports sufficient information on the memory access (i.e., whether the field was accessed).

5.2.3 Memory Target Discovery

Objectives. With the potential memory target for structures, SCAVY uses a fuzzer to execute various system calls that may access corrupted memory and cause a crash. In this stage, we *prioritize* code that *accesses the corrupted memory* (i.e., the

[2] While it is `__kmalloc()`, we simply call it `kmalloc()` hereafter.

[3] We track `kmalloc()` and `kmem_cache_alloc()` in the process of interest.

corrupted field of structures). However, during fuzzing, there can be crashes (i.e., kernel panic) on the first access of the corrupted memory, which we call *premature crashes*. Those crashes may prevent the fuzzer from exploring the full impact of the corruption, missing later corrupted memory accesses.

Focused Fuzzing on Relevant Code. To facilitate the search in this stage, we make two adjustments on our fuzzing process. First, we make it focus on the code that is accessing the kernel structures of interest. Specifically, we make our fuzzer only accept coverage from functions accessing structures.

Second, we prioritize the instructions loading the corrupted memory by detecting executions running the instructions and seed them. Specifically, recall that SCAVY collects information about the code related to the structures of interest in the instrumentation and analysis phase, as shown in Figure 4 (Structure Access Code). SCAVY uses hardware breakpoints[4] to detect those instructions and make them seed.

Avoiding Premature Crashes. We propose an approach that executes a generated program call twice to avoid premature crashes. In the first execution, we run it *without corrupting* the memory target. The fuzzer collects the code coverage accordingly and re-executes it by corrupting the memory target with a random value. If the execution crashes or we see a deviation in the code coverage (indicating potential privilege de-escalation), we log the execution to be analyzed later.

5.3 Detection of Privilege Escalation

The outcome of Section 5.2 is a list of programs causing crashes, some of which may cause privilege escalations. In this phase, we aim to detect which of them from the previous phase are causing privilege escalation. Specifically, SCAVY uses a differential-analysis-based approach to detect privilege escalation as follows. First, we run a given program thrice: one run without corruption, one with corruption using a random value, and another with corruption copying the value of the memory target from other valid structures created by a privileged process. Second, all three runs will execute privileged operations (e.g., operations requiring root permission) such as `setuid(0)` and `read`/`write` on privileged resources. If the first and the third runs have differences, we consider it may have escalated or de-escalated privilege.

5.3.1 Inserting Privilege Dependent Operations

Read and Write System Calls. For each PoC, we insert read and write system calls for all the resources (e.g., files and sockets) created during the PoC, as their behaviors will be different if privilege escalation happened. For example, as shown in Figure 5-(a), we add read and write system calls for all the files (i.e., '`/etc/passwd`' and '`/tmp/writablefile.txt`').

[4] Since hardware breakpoints require addresses of the instructions, we use `addr2line` [65] to obtain the corresponding instruction addresses.

Privileged Operations. As shown in Figure 5-(b), privileged operations behave differently based on the current privilege. We add privileged operations (i.e., root) such as `seteuid(0)` and `setegid(0)`. `sync()`, `msync()`, and `fsync()` are added for all the resources created before the memory corruption. We provide a list of all the added syscalls in Table 7.

5.3.2 Detecting Exploitable States

Three Executions for Privilege Escalation Testing. SCAVY runs three executions to detect a potential privilege escalation. First, we run the exploit on an unprivileged system without memory corruption. We expect all the privileged operations to fail and unprivileged operations to succeed. Second, we run the exploit on the same system with memory corruption using a random value. If privileged/unprivileged operations behave differently from the first execution, we consider it to have reached an exploitable state. Third, we run the exploit on the unprivileged system with memory corruption using the memory contents of another instance of the same type kernel structure. Specifically, we borrow a value of a structure's field from a root process with the same structure. Again, any deviations from the first run suggest privilege (de-)escalation. Note that the random and cloned values are complementary. Cloning works well for complex kernel data structures with certain formats as they are difficult to generate randomly. However, cloned values limited to what the system created. For example, cloning `uid` will never result in an invalid/unknown `uid`, which a randomly generated value can.

Detecting Exploitable States. For each run, we collect 4 indicators: (1) the return value of system calls, (2) the system call's return buffer's (or read buffer's) data, (3) the addresses of instructions loaded the corrupted memory, and (4) the code coverage. We consider two executions to be the same if the following 4 conditions are satisfied: (1) return values of the system calls are identical, (2) return buffers' contents of the system calls are identical, (3) executed `load` instructions on the memory target are identical, and (4) Jaccard similarity [66] of the code coverage is greater than 0.9 (accounting for noise in Kcov). Note that we have three runs to compare (2 pairs to compare). We compare the run without corruption with the two other runs with different corruption methods. If the run with corruption is different with any of the comparisons are not the same, we consider it to reach an exploitable state.

For example, in Figure 5-(a), SCAVY first runs it without a memory corruption (line 5). The `write()` at line 7 will fail due to the missing privilege. In the second run, it corrupts the memory target (i.e., file mapping pointer) with a random value. The execution will crash or fail due to the invalid file mapping pointer. In the third run, it corrupts the memory target by cloning a valid file mapping pointer. Now, `write()` at line 7 will succeed and SCAVY detects differences in code coverage and `write()`'s returns. Similarly, in Figure 5-(b), executions have different coverages and `setuid()` return values.

6 Implementation

SCAVY is written in Go (2068 LoC), C (331 LoC), C++ (827 LoC), and Python (2199 LoC). We customized the Syzkaller in Go. In C, we wrote the in-tree kernel driver used by the fuzzer to corrupt and set up hardware tracing. We also developed 3 LLVM passes, two of which produce the input to the fuzzer and the third to instrument the kernel typecast. Our privilege escalation detector module is written in Python.

Modifying `Syzkaller`. We modify `syz-executor` to execute the same program twice, as mentioned in Section 5.2.3. For each execution, we collect data from `KCOV`, `Kprobe`, and `dmesg`. The original Syzkaller collects the code coverage from `KCOV`. Our modification allows it to collect the memory allocation, deallocation (i.e., `kfree()`), and typecasts from `Kprobe` and memory hits of the corrupted memory from `dmesg`. To collect data from `Kprobe`, our Syzkaller instructs `Kprobe` to set up its probe points for `kmalloc`, `kmem_cache_alloc`, `kfree`, `instrument_typecast_instruction`, and the instrumented dummy functions added after each typecast instruction. The fuzzer instructs `Kprobe` to print all parameters of the instrumented functions and `kfree`, including the return values of the memory allocators. The fuzzer spawn two threads in parallel to the fuzzing executions to (1) parse the output logs of `Kprobe` and filter out logs that are not generated by `syz-executor` and (2) parse the output of `dmesg`. To implement the focused fuzzing for memory corruption relevant code (Section 5.2.3), our fuzzer generates a large number of fake instruction pointers for each new corruption, making the fuzzer think that hitting an instruction accessing the corrupted memory leads to a significant coverage increase. This results in the fuzzer prioritizing the code and using it as a seed. We also disable the fork server, which makes it terminate after executing the requested sequence of system calls.

Privilege Escalation Detector. Our privilege escalation detector needs to reproduce the executions observed during the fuzzing, including the memory corruptions. To achieve that, we use `syz-prog2c` that generates a C program reproducing the fuzzing execution, provided by `Syzkaller` and add C statements that corrupts the target memory to the C program. Then, we implement a module that executes the C program (i.e., instrumented PoCs) with different mutation methods. Specifically, we wrote a C library (*827* LoC C++) that spawns 2 threads along with the original running PoC code: (1) a thread to set up `Kprobe` and a custom driver interacting code we wrote into `syz-fuzzer` and (2) another root user thread that synthetically opens the privileged resources. The first thread tracks the structures created by all the three processes.

7 Evaluation

We evaluate SCAVY from three aspects. First, we measure the coverage of the typecast instructions with respect to all the Linux kernel structures to evaluate the effectiveness of our typecast instrumentation[5]. Second, we evaluate the effectiveness of the fuzzer in exploring crashes that can lead to exploitable states. Third, we analyze the detection results of the differential analysis module and evaluate their reachability on real world exploits. We also compare our exploitable state definition with FUZE's to show that our broader definition helps discover new memory targets. All experiments were done on a system running Ubuntu 20.04 LTS with an 3.70 GHz Intel Xeon E3-1245 v6 and 32 GB of RAM.

7.1 Typecast Coverage

SCAVY statically instrumented 2,313 source code files (85% of the 2,700). 23% (2,130 out of 9,169) of the kernel data structures are instrumented[6] to track their types after their allocation at runtime. While analyzing the low coverage result, we find many structures that are covered are irrelevant to us. First, there are 2,587 structures for debugging purposes such as `kprobe_insn_cache` and `trace_event_raw_kfree` are used by Kprobe and Ftrace and are mostly unavailable on production kernels. Second, there are 1,989 stack-allocated structures that are destroyed on function return (e.g., `msg_receiver` and `msg_sender` in `do_msgrcv()` and `do_msgsnd()`). Those short-lived structures typically do not hold critical system states and, hence, are not our target. Third, 1,931 structures are members of our instrumented structures, which we can consider instrumented. For example `signal_struct` is contained within `sigpending` – there is no code that directly allocates it. Fourth, many of the remaining structures are processor-related global variables (e.g., `intel_watermark_params`) and architecture-specific structures (i.e., defined in `arch`) that we do not instrument or helper structures for accessing their other structures (e.g., `xfrm_skb_cb` for accessing `sk_buff->cb`).

To this end, we prune out 4,576 from 9,169 and additionally consider 1,931 structures to be covered, resulting in a new coverage of 88.4% (4,061/4,593). Our coverage can be interpreted as a lower bound of what our fuzzer can corrupt.

7.2 Fuzzer Effectiveness

We evaluate the effectiveness of our fuzzer, compared to the stock version (commit: 61f86278) of Syzkaller. Specifically, we measure the coverage of the code that is relevant to structures (e.g., allocating and accessing the structures of interest).

For a fair comparison, we improve the stock version of Syzkaller by adding hardware tracking of memory reads, our object allocation implementation, and corrupted memory access tracking. We run both fuzzers for 3 days on the identical QEMU VM (with 1 core and 1 GB RAM).

[5] If a typecast instruction is not instrumented, SCAVY may not analyze the specific use of kernel structure, possibly missing a memory target.

[6] We noticed that instrumenting certain boot files caused the kernel to crash. Hence, we restrict the instrumentation to directories other than '`arch`', '`boot`', '`kernel/panic`', and '`signal`'.

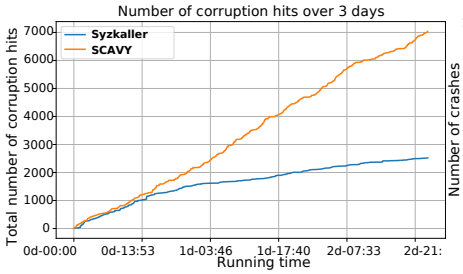

Figure 6: # of Observed Loading of the Corrupted Fields

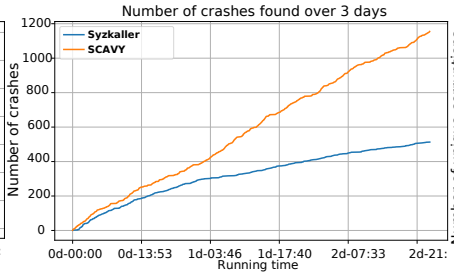

Figure 7: # of Crashes Observed

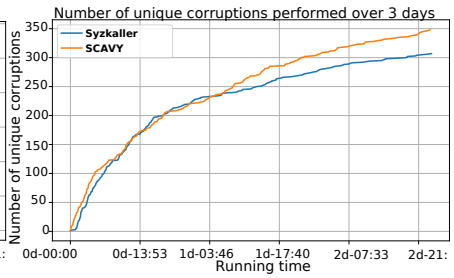

Figure 8: Comparison of the Number of Unique Fields Corrupted over Time

Code Coverage. Figure 6 shows the total number of read operations on any corrupted memory during the 3 days of fuzzing. This number indicates the number of *instructions loading the corrupted memory* executed during fuzzing. The graph shows that for the first 14 hours, the 2 fuzzers perform similarly, but the stock fuzzer seems to hit the corruption at a slower rate. When manually checking the corpus we find this happens because, in part, the stock fuzzer prioritizes exploring code paths, where some of them may not access the fields of structures of our interest. For example, the stock fuzzer may prefer to open a file and then immediately open a socket, instead of writing to the opened file, since opening a socket can lead to higher code coverage. In contrast, SCAVY prioritizes covering the code that is relevant to the data structures of interest (e.g., accessing the file in the example).

# of Crashed Observed. Figure 7 presents the number of crashes observed from the two fuzzers. While both fuzzers inject memory corruptions into the least represented structures, the stock Syzkaller does not prioritize hitting the memory it corrupts. This can be inferred by the lower number of crashes, suggesting the de-prioritization of corrupted memory accessing code while prioritizing the overall coverage. In contrast, our SCAVY fuzzer was able to generate more crashes as it prioritizes the instructions accessing corrupted memory. This is further evidence of the effectiveness of our approach, which prioritizes the exploration of the search space for exploitable states; focusing on the code coverage from source code that operates on the target structure type and adding synthetic code coverage based on code that loads corrupted memory.

# of Corrupted Fields. We measure the number of corrupted fields during the experiments to show that SCAVY covers diverse kernel data structures than state-of-the-art techniques. Specifically, we plot the number of unique fields of structures that are corrupted. Figure 8 shows that both fuzzers exhibit a similar rate of exploration in discovering new fields to corrupt.

While SCAVY focuses on a set of structures of interest, this graph suggests that our fuzzer does not become stuck corrupting limited types of structures. As described in Section 5.2.1, while SCAVY leverages redefined coverage that may focus on specific structures, our fuzzer still operates with some guidance from unfiltered code coverage, and as a result, it works well for both exploration and exploitation. Note that we repeat the 24-hours experiment 10 times, following the best evaluation practices for fuzzers [67]. We present the extended results in Section A.4. After proving distinction between the two distributions using the U-test [68], we conclude that the fuzzer without corruption-hit-guidance tends to cover more code, because, in part, they do not deal with crashes caused by the corruptions. However, the crashes caused by corruptions are potential privilege escalations detected by SCAVY, meaning that the original fuzzers' high code coverage is irrelevant to finding memory targets. In Section A.4 we show the effects of the modifications of the fuzzer on the code coverage.

7.3 Exploitable State Detection

To understand the impact of our new definition of exploitable state in finding memory targets, we conduct two evaluations. First, we compare the scope of our exploitable state definition to the commonly studied ones, such as write-what-where and control flow hijacking. Second, we demonstrate the efficacy of SCAVY by presenting its ability to discover both previously known and new memory targets. To conduct this experiment, we ran the fuzzer for 7 days. We identified 2,811 unique fields from 139 distinct kernel structures that could be exploited. The fuzzer generated a total of 3,863 PoCs whose corresponding object corruptions crashed the kernel.

7.3.1 Evaluation of the Exploitable State Definition

We run FUZE's symbolic executor and SCAVY to detect the exploitable states for all the PoC. To avoid the FUZE being stuck in an infinite loop, we disabled around 700K function call sites corresponding to KCOV, Ftrace, our custom driver, and part of KASAN. For a fair comparison, we used a 5-minute timeout (FUZE uses the same timeout). We then ran the same PoCs through our privilege escalation detector step.

FUZE found 354 PoCs that lead to at least one exploitable state, meaning that during the unconstrained symbolic execution, more than one value satisfies the branches taken to reach an exploitable state. The exploitable states FUZE found are mostly attacker-controlled write with a symbolic destination address. We show the number of PoCs that FUZE detected to reach at least 1 exploitable state in Table 3 (in Appendix).

Table 1: **Corruptions Found to Lead to Exploitable States.** Prerequisites are of the form: <exploit capabilities, generic/special slab cache,offset,size, value (kernel pointer or specific value)>. Post-conditions are of the form <observed capability, resource>. Resources are: Files(𝔽), Syscall (𝕊) and Memories of Process($\mathbb{M}_p$), Kernel($\mathbb{M}_k$) and other Virtual($\mathbb{M}_v$). ✪ indicates known field. We evaluate the exploitability of the corruptions using real-world CVEs marked in the table as: CVE-2010-2959 (♣), CVE-2014-3153 (♦), CVE-2016-0728 (✣), CVE-2017-7184 (♥), CVE-2017-7308 (♠), CVE-2022-27666 (✷).

Meanwhile, the detection step of SCAVY flagged *955* PoCs for having a deviation that can lead to an exploitable state. While our definition of exploitable state does not include control flow hijacking and write-what-where (i.e., it is not a superset of the prior work), the additional PoCs SCAVY found may imply the effectiveness of SCAVY's broader definition.

Among the 955 PoCs, many are corrupting the same field. Therefore, we decided to prioritize our manual analysis of the fields with the most positive detections and the ones we found within our expertise to analyze. In Table 1, we show 20 fields that were manually verified to lead to privileged operations and the exploitable state that was detected based on our definition in Section 2. The rest of the fields are presented in Table 6 in the Appendix. It is worth noting that the corruptions we report in this paper are *a subset of PoCs* we detected (in total, we detect 68). In Appendix A.1, we present details of the manual analysis we performed on the deviations detected by SCAVY. In the second column of Table 1, we summarize the capabilities required for the attacker to correctly corrupt the field, such as requiring both read and write or just write capability. For example, to exploit using `key::description`, the attacker needs to have the capability to **W**rite **8** bytes into the `key` cache at offset **32** the object with the value **0**. In the third column, we summarize the post-conditions, essentially escalated privileges, such as reading a pipe or writing a file. For example, after corrupting `key::description` with a valid kernel pointer, the attacker can read arbitrary kernel memory.

Evaluating with Real world Vulnerabilities. In the last column, we evaluate the reachability of SCAVY found memory targets using real-world exploits. Specifically, we first obtain exploits from KHeaps [51], as the authors provide vulnerable kernel environment that can reproduce their exploits. For each exploit, we first identify the part of the exploit that creates (or sprays) the victim kernel structure. Then, we check the exploit's memory corruption capability with the SCAVY's memory target's requirements. If the exploit has sufficient capability, we massage the memory layout [50] for our victim kernel structure (i.e., SCAVY's memory target) to be within the corruption range. Next, we replace the victim kernel structure creation (or spraying) code with SCAVY's PoC's code to allocate SCAVY's memory target. Finally, we trigger the vulnerability to corrupt SCAVY's memory target with an arbitrary value. After that, we replace the part accessing the corrupted memory in the original exploit with SCAVY's PoC's privilege escalation checking code, which invokes privilege-assessing system calls that eventually access corrupted memory and raise crashes if corrupted. If we get a crash with the corrupted value in its panic dump, we mark column 4 of this field with the respective CVE ID. We publish the modified exploits that can corrupt SCAVY targets in our repository.

7.3.2 Evaluation of the Privilege Escalation Detector

Among the 955 detected behavior deviations, we find that code coverage is the most common deviation. Other significant deviations include accessing random addresses (when modifying data pointer fields) and privilege de-escalations (when modifying non-pointer fields). Table 4 (in Appendix) summarizes our results. We also analyze the common system calls where the deviations occur. Table 5 (in Section A.3) shows the top 10 system calls exhibit deviations, helping detect reaching exploitable states. Among them, we observe the `seteuid` system call that we additionally instrument, helping 16 cases out of 955 (1.5%). Others are mostly I/O related system calls (e.g., `pread64`, `ioctl`, `socketpair`, and `sendmsg`).

7.3.3 Exploiting Real Vulnerabilities

We evaluate SCAVY found memory targets in terms of writing exploits with real-world vulnerabilities to illustrate its real-world impact and practicality. Our result is summarized in Table 2. Note that the vulnerabilities are from different software weaknesses, as denoted by the CWE (Common Weakness Enumeration), showing that SCAVY's memory targets do not

	CVE	CWE	Exploited Struct/Field
1	2017-7308	Type Conversion	vm_area_struct::vm_file
2	2017-7184	Input Validation	vm_area_struct::vm_file
3	2010-2959	Int Overflow	kioctx::internal_pages
4	2016-0728	Use-After-Free	key::description
5	2022-27666*	OOB Write	vm_area_struct::vm_file
6	2022-27666*	OOB Write	file::f_mapping
7	2009-3547	nullptr deref.	pipe_inode_info::bufs
8	2014-3153	Input Validation	cred::euid
9	2017-11176	Use-After-Free	task_struct::cred
10	2004-1235	Race condition	file_struct::fops

Table 2: Modified Real World Exploits (* indicates constructed fully functional exploit).

have specific requirements on the type of vulnerabilities.

We obtain the exploits from various sources. The first three exploits (1∼3) are from the original KHeaps [51] paper. The fourth exploit is borrowed from a public PoC[7]. Other exploits are from publicly available PoCs [50, 69]. For all the exploits except for the 2016-0728's exploit, we follow the procedure described in Section 7.3.1 to modify the exploits to corrupt SCAVY memory targets. The exploit for 2016-0728 is shown in Section 3.2. The exploits 5 and 6 are end-to-end exploits using 2022-27666 with SCAVY found memory targets. The entire exploits are presented in Section A.2. The exploits 7∼9, we found that the original exploits corrupt kernel structures that contains SCAVY's memory targets (in Table 1), while they target a different field to corrupt.

Note that we were unable to reproduce the 2004-1235 exploit as we could not reproduce the vulnerable environment (e.g., the kernel and OS); however, based on the developer email chain [70], we deduced that the exploit could control the content of a vm_area_struct and it had the vm_file field in the target kernel version (2.6), implying that the exploit can corrupt a SCAVY memory target. We release the exploits and vulnerable systems' VMs on [20].

8 Discussion

SCAVY Facilitating Defenses. There exist defenses for kernel data structure fields, such as XOR'ing their values, redzoning the fields [71], and applying write-once memory [72], while they cause significant overhead if applied to every kernel structure [6], Applying them only on SCAVY found memory targets would result in lower overhead, making them deployable.

Limitations. There exist a few sources of false positive in SCAVY's analysis. First, since SCAVY considers *any* differences between the executions with and without memory corruption as a potential privilege escalation if a divergent is caused by other reasons, such as a corrupted semaphore or lock fields causing an execution to hang and timeout, it would lead to a false positive. Second, if the device-specific pointers are corrupted, an execution may divert and be detected by SCAVY without escalating privilege, meaning it is a false positive case. For example, `bio::bi_private` is dedicated to device-specific structs and is usually `null`. When releasing, the kernel frees the pointer if it is not null, causing a deviation in code coverage. While SCAVY detects it, as per our definition, it does not lead to an exploitable state. Hence, it is considered a false positive. However, it is still a valid exploitation (while not a privilege escalation) as an attacker can corrupt this field to get an arbitrary-free capability. The `refcount` fields are also considered false positives as they do not escalate privilege but they can lead to valid use-after-free capabilities. Third, if it corrupts a file head, which maintains the file's current position for read and write, the file read API will return a different file portion, leading to different buffer contents. However, it does not escalate privilege. At last, we rely on a differential analysis method to detect privilege changes, meaning that SCAVY can only detect when system calls have *visible changes from userland* via the system calls in Table 7. For example, corrupting `addr_limit` to a larger value would not have immediately observable execution divergence, which will be missed by SCAVY.

Responsible Disclosure. We have responsibly informed and shared all the findings and artifacts (e.g., exploits) with the Linux maintainers and discussed its potential security consequences. We have their approval to disclose.

Future Work. Our work focuses on the impact of single-field corruption, while, in reality, an attacker may corrupt multiple fields. Also, SCAVY relies on manual analysis of the capabilities of prior exploits to provide a suitable target. We leave automating such tasks as a future work.

9 Conclusions

We designed and implemented SCAVY, which efficiently searches for memory targets that can lead to privilege escalation in the Linux kernel. Our design includes a new definition of the exploitable state for the Linux kernel in the context of local unprivileged attacks and differential analysis-based multi-execution reasoning to effectively detect potential privilege escalation. SCAVY discovered 17 memory targets in 12 kernel structures that can lead the system into an exploitable state when corrupted. We show the impact of SCAVY-found memory targets by demonstrating real-world PoCs of 9 CVEs corrupting the 17 memory targets.

A Appendix

A.1 Analysis of Detected Exploitable States

We present our manual analysis for the proof-of-concept code detected by SCAVY, focusing on exploring concrete privilege escalation exploits from the detected exploitable states.

A.1.1 Case 1: `file::f_mapping`

The `file::f_mapping` memory target can be leveraged to create exploits for two different scenarios.

Scenario 1: Attacking Inaccessible File. An exploit creates a root-owned process opening a privileged file, which is completely inaccessible in an unprivileged process. For example, it can spawn many '`passwd`' processes, spraying the slab memory with the '`/etc/shadow`' file's `file` kernel structures. Then, the exploit also creates an unprivileged file such as a temp file (e.g., `/tmp/file`). Next, the exploit leverages a vulnerability with a read capability to read the `file::f_mapping` of the '`/etc/shadow`,' which will be copied to the `file::f_mapping` of the temp file through a vulnerability with a write capability. In other words, the values of `file::f_mapping` of `/etc/shadow` and the temp file are swapped. After this, reading and writing the temp file is accessing the `/etc/shadow`'s content.

Scenario 2: Attacking Unwritable (but readable) File. Scenario 1 creates many root-owned processes (e.g., `passwd` processes), which might raise suspicion. If one wants to write an unwritable file (instead of read and write an inaccessible file, as we see in scenario 1), one can achieve it more subtly. Specifically, an exploit can open many '`/etc/passwd`' files

in read mode and a temp file in read/write mode. Swapping the `file::f_mapping` of the '`/etc/passwd`' and the temp file allows the exploit to write the '`/etc/passwd`', escalating the privilege. With the privilege, it can create a root-level account by editing the '`/etc/passwd`' file.

A.1.2 Case 2: `vm_area_struct::vm_file`

This memory target can, in practice, be used to access privileged files' contents if they exist in shared memory-mapped files (i.e., mapped with `mmap()` with the MAP_SHARED flag). Specifically, an exploit first creates a shared memory of a temp file with read and write permissions, which will create a `vm_area_struct::vm_file` kernel structure. Then, it overwrites the `vm_area_struct::vm_file` of the temp file with the values of the `vm_area_struct::vm_file` of a root-owned file, using vulnerabilities with read and write capabilities. After the corruption, an exploit invokes `msync` to synchronize the mapping with the corrupted new `vm_area_struct::vm_file`.

Note that, in Section 3.1, we show that one can modify our exploit of `CVE-2022-27666` to write into any of the dummy file's `vm_area_struct` so that it would access the content of `/etc/passwd`.

A.1.3 Case 3: `anon_vma_chain::rb`

SCAVY found this kernel data structure field as a potential memory target. However, we did not include it as a memory target as corrupting it does not escalate privilege.

SCAVY discovered this memory target by observing a crash during the execution of `semctl()` after corrupting the `anon_vma_chain::rb` field with a random value. Specifically, it crashes at `semctl$GETVAL` shown in line 8 in Listing 3. We further analyze the structure to understand the crash. In particular, the `anon_vma_chain` structure is used for anonymous virtual memory, which is essentially shared memory not backed by a file system. The `rb` field links the `anon_vma_chain` structure into a red-black tree [73] for search optimization. As a result, corrupting it with a random value, which is not a valid pointer, caused a memory dereference error. While we could not enhance the case to replace the `rb`'s value with another valid `rb`'s value, replacing a valid value may impact the search operations using the red-black tree.

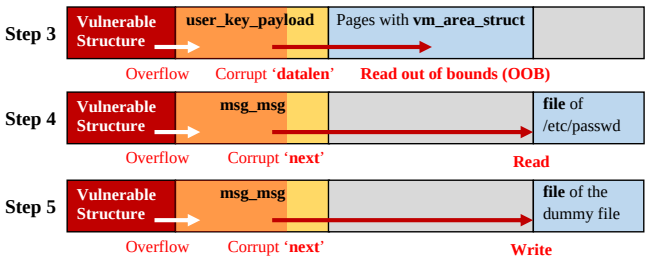

Figure 9: Visualizing Exploit of CVE-2022-27666.

A.2 Exploiting CVE-2022-27666

The exploit requires memory massaging of Linux page allocator. Hence, we borrow the same noise-mitigation and massaging technique from an existing exploit [50]. The rest of the exploit is summarized in six steps as follows:

1. Allocate `user_key_payload` next to the vulnerable structure. Then, overflow and corrupt `user_key_payload::datalen` to obtain the read out of the bounds (OOB) capability.
2. Open two files: one dummy file with read/write permissions and another root-owned unwritable file that can only be opened read-only by non-root users (e.g., `/etc/passwd`).
3. Repeatedly call `open()`[8] to assure the `file::f_mapping` structures allocate next to user key payload. Leak the two `vm_area_struct::file` pointers of the opened files.
4. Rearrange the memory to now put the `msg_msg` structure next to the vulnerable structure and overflow into it such that the `msg_msg::next` points to the leaked `file` structure. With the corruption, reading `msg_msg` leaks the content of the `file` structure of the `/etc/passwd`.
5. Rearrange the kernel memory to use the `msg_msg` to achieve arbitrary write capability [74], and use it to overwrite the `file::f_mapping` of the dummy file with the leaked `f_mapping` value of the `/etc/passwd`.
6. Call `write()` with the dummy file's descriptor to append a new root-level account on `/etc/passwd`. As shown in the blog post [75], the root privilege can be obtained by simply running `su` with the appended account.

In Figure 9, we illustrate the memory layout for the steps 3 to 5. After step 5, as SCAVY detected, the `/etc/passwd` becomes writable through the dummy file's descriptor.

[8] There is a limit of 1,000 invocations of `open()`. However, most of the allocations would fall in the memory holes created in step 1, without exhausting the limit. If necessary, one can use the following method to overcome the 1,000 limit: open both files once and `mmap` the opened files until the `vm_area_struct` are allocated next to the corrupted `user_key_payload`.

A.4 Comparing with the unmodified Syzkaller

We compare SCAVY's fuzzer against an unmodified Syzkaller baseline using the same methodology described in Section 7.2. We disabled the reproducer and ran it on 1 VM with the debug flag. Figure 10 shows that SCAVY's fuzzer achieved a lower code coverage than the original Syzkaller. This does not mean our fuzzer is ineffective, but highlights that SCAVY's fuzzer is more focused on the memory target accessing code rather than exploring irrelevant kernel code.

Abstract

Confidentiality, authenticity, integrity of data, and runtime security are ubiquitous concerns in modern computer systems. However, these security concerns have traditionally been addressed by separate mechanisms. Error-correcting codes (ECC) detect and correct DRAM errors, ensuring the integrity of stored data. Authenticated memory encryption provides data confidentiality and authenticity. Memory tagging enforces memory safety, thereby improving runtime security. The lack of a combined primitive increases system complexity, memory overheads, and the overall performance impact. In this work, we present Voodoo, the first combined scheme for authenticated encryption, DRAM error correction, and memory tagging. Our design extends the MAGIC mode for authenticated encryption and error correction proposed by Kounavis et al. [31]. With Voodoo, DRAM data is encrypted, and a tag-dependent message authentication code protects the integrity of the stored data while simultaneously allowing for the correction of DRAM faults. Thus, we can implement a wide range of tagged memory architectures *without introducing additional memory requests or storage overheads*. We present three tag encoding schemes providing up to 36 tag bits per cache line. Using the gem5 simulator, we implement and benchmark our design. Our evaluation shows a low runtime overhead of 1.4% on average compared to a system without any of the provided security features. We use a Monte-Carlo simulation of a DRAM fault model based on real-world DRAM fault behavior to demonstrate the corrective capabilities of Voodoo. Our results show that we consistently outperform traditional single-error correction, double-error detection (SEC-DED) codes in terms of error correction and detection. For multi-chip faults, Voodoo offers stronger error detection than commodity Chipkill solutions.

1 Introduction

Security is of utmost importance in modern computing systems. Data confidentiality, authenticity, and integrity are essential, especially in server and cloud systems where multiple mutually distrusted parties share the same hardware. However, only protecting data in DRAM is not sufficient. Memory safety vulnerabilities constantly threaten system security, as security-critical software is predominantly written in memory-unsafe C/C++ code. Traditionally, the security of systems is increased by layering security primitives over each other. This approach may work at the moment, but it ultimately increases system complexity, and the overheads introduced by each new layer accumulate.

At the DRAM level, server-grade systems implement integrity protection. In DRAM chips, memory cells store information as an electrical charge. These cells suffer from leakage currents, causing unwanted data alterations. External disturbances, like radiation or high temperatures, can cause large-scale failures that corrupt multiple bits. Without integrity protection, DRAM errors would cause silent data corruption and, subsequently, erroneous computations or system crashes. Thus, *error-correcting codes* (ECC) are used to detect and correct DRAM errors. An ECC computes and stores a checksum of the stored data. When reading from memory, the checksum can restore the original data if an error is detected. Commodity single-error correction, double-error detection (SEC-DED) codes, for example, can correct one erroneous bit per 64 bits in a cache line. Thus, ECC provides *integrity* for DRAM data.

On top of integrity, keeping data secret and protecting against deliberate data modification is necessary. Memory encryption technologies of major hardware vendors like Intel [22] or AMD [2, 29] provide data confidentiality through encryption. Encryption protects against attacks like bus snooping or cold boot attacks [17, 18]. Moreover, memory encryption provides cryptographic isolation for virtual machines in cloud environments. Encrypting the data of co-located tenants isolates them from each other and protects against a potentially malicious hypervisor. Intel's trust domain technology, Intel TDX [11], provides *authenticated encryption* by extending the encryption with a message authentication code (MAC) based on SHA-3 [15]. A MAC generates a fingerprint of the input data using a secret key. Data modifications are detected by recomputing and comparing the MAC to a stored version.

Only a party possessing the correct key can compute a MAC for a given input. Thus, the MAC provides authenticity and integrity of DRAM data.

While authenticated encryption is a crucial component for safeguarding DRAM data, runtime safety is equally imperative. As data is processed unencrypted at runtime, additional measures must be taken to protect it from vulnerabilities and threats. Studies by Microsoft found that the most prominent sources of security-relevant bugs in their products are memory safety issues [45]. Memory safety violations allow attackers to read or modify allocated data, tamper with heap metadata, or perform other security-critical operations [6, 9, 20, 23, 56]. *Memory tagging* mitigates memory safety issues by associating each allocation with a *tag*. A tag holds metadata for the allocation and is used to enforce a security policy that protects against memory safety violations at runtime. ARM and Oracle provide commercial ISA extensions using tagged memory. ARM MTE [50] and SPARC ADI [51] implement hardware-supported tagging for memory protection. While tagged memory architectures offer strong protection against software-based attackers, they introduce performance and memory overheads since tags must be fetched frequently. Furthermore, tags must be stored in DRAM, thus reducing the amount of usable memory.

Recently, the idea of combined primitives offering a more holistic protection is gaining traction. MACs and ECC, for example, are conceptually similar as they both detect data modifications. However, combining the strong detection capabilities of MACs with the error correction of ECCs is challenging. In 2020, Kounavis et al. proposed `MAGIC` [31], a combined mode for authenticated encryption and error correction. The `MAGIC` mode is a generic construct facilitating authenticated memory encryption while allowing the correction of errors that affect a bounded number of bits in a single granule using a specially tailored MAC function.

In this work, we present `Voodoo`, the first combined scheme for DRAM error detection and correction, authenticated encryption, and memory tagging. Building on `MAGIC`, we develop three novel tag encodings that allow us to seamlessly combine memory tagging with authenticated encryption and error correction. Thus, `Voodoo` overcomes the limitations of existing tagged memory architectures, which incur non-negligible performance and memory overheads. *We can offer up to 36-bit tags without introducing additional memory requests or storage overheads*. We implement our design using gem5 [7] and evaluate its performance. Our results underline the practicability of our design as we reach a performance overhead of 1.4% on average compared to a system without any additional protection. Furthermore, we implement a Monte-Carlo simulation of DRAM errors and benchmark the correction capabilities of our design. *We find that we can reach an error correction rate of* 99% *and an error detection rate of* 100% *for errors confined to a single DRAM chip.* This is a significant improvement compared to SEC-DED, which has a correction rate of approximately 62%.

Contributions. We make the following key contributions:

1. We present `Voodoo`, the first combined primitive for authenticated encryption, DRAM error correction, and memory tagging.

2. We develop three tag encoding schemes, providing up to 36 tag bits while facilitating reliable error detection and correction.

3. We implement a prototype of our design and evaluate the performance using the SPEC CPU 2017 benchmark suite, yielding a geomean overhead of just 1.4%

4. We implement a Monte-Carlo simulation of a DRAM fault model. `Voodoo` reaches a 99% error correction rate for single-chip errors, significantly improving on commodity SEC-DED codes.

Outline. The paper is structured as follows: Section 2 discusses the required background. Section 3 elaborates on combining integrity protection, authenticated encryption, and memory tagging. Section 4 presents our novel tag encodings and their properties. Section 5 discusses and simulates the error detection and correction capabilities of `Voodoo`. Section 6 details our implementation and showcases the advantages of our combined mode through benchmarking. Section 7 discusses related work, and Section 8 summarizes our findings.

2 Background

This section provides background on authenticated encryption, DRAM structure and faults, memory tagging, and `MAGIC`.

2.1 Authenticated Encryption

Encrypting data grants *confidentiality* for the data, as only a party possessing the correct key can encrypt and subsequently read the data. However, an adversary can still modify encrypted data. Altering a single bit of a ciphertext will cause the resulting plaintext to deviate from the originally encrypted plaintext. Even though such an attack cannot change the plaintext precisely, it can still entail security issues [37, 61].

With *authenticated encryption* (AE), unprivileged ciphertext modifications are detected. Authenticated encryption provides *integrity* and *authenticity* through a message authentication code (MAC). A MAC is a mapping $\mathcal{M} : F_2^* \times F_2^k \rightarrow F_2^t$. An arbitrarily sized input and a secret k-bit key map to a t-bit checksum as the output. Only a party possessing the key can compute a correct MAC for a given input. When accessing data, recomputing the MAC and comparing it with a stored version allows for the detection of data modifications.

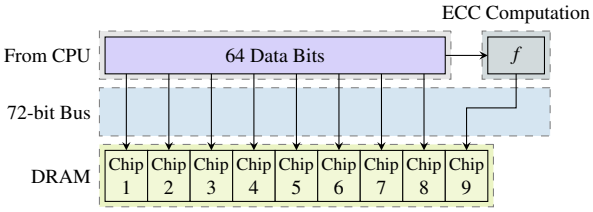

Figure 1: Writing data using an ECC DRAM. The function f computes ECC bits that are stored alongside the data on a separate chip on the DRAM module.

2.2 DRAM Structure and Faults

DRAM modules store data in *memory cells*. Each cell holds one bit in the form of a charged or discharged capacitor. Memory cells are organized in *rows* and *columns*, forming a *memory array*. Multiple (sub-)arrays are combined to *banks*, which are further organized in *bank groups*. Banks operate in parallel, thus improving the performance of the memory. A single DRAM chip can host multiple banks. We distinguish between x4, x8, and x16 DRAM chips [25]. The number defines the amount of data pins of the chip. Multiple DRAM chips form a *rank*, and, in the case of DDR4 DRAM, the overall data bus width is 64 bits. DRAM accesses are performed in *bursts* where each burst yields 512 bits of data. For DDR4 DRAM with a 64-bit bus width, each burst consists of 8 subsequent accesses called *beats*.

Memory cells are inherently error-prone as the stored charges are subject to leakage [24, 46]. Thus, they must be refreshed periodically [25]. Excessive leakage causes the charge to be unrecoverably lost. Hence, the stored data can become faulty. Besides leakage, external disturbances can influence the charge stored in DRAM cells [4, 38]. While single-bit faults are the most common fault, multiple bits read from a single DRAM chip may be erroneous [5, 36, 49, 53].

To mitigate the effects of DRAM faults, error-correcting codes (ECC) are used [14, 24]. An ECC extends the data with redundancy to restore the data in the case of a fault. For DDR4 memory with ECC, each 64-bit memory word is accompanied by 8 ECC bits, resulting in a storage overhead of 12.5%. The redundant data is stored in additional chips on the DRAM module. ECC DRAM modules have a 72-bit wide bus to allow simultaneous fetching of data and redundancy. Figure 1 illustrates how the data and the redundant information is stored to a DRAM module using nine x8 chips. One class of commodity ECC are single-error correction, double-error detection (SEC-DED) codes [19]. With SEC-DED, correcting one and detecting two errors per 64-bit word is possible. Faults affecting more than two bits in a 64-bit word are not guaranteed to be detected. Undetected faults may be miscorrected and cause the system to process faulted data. Chipkill codes offer stronger protection, as they can correct up to a complete chip failure [14].

2.3 Memory Tagging

Tagged memory [26] enforces different security policies for memory safety [50, 51, 58], memory isolation [48, 52, 59, 62, 64], capability systems [8, 63], or dynamic information-flow tracking (DIFT) [13, 28, 54]. Every memory location is associated with metadata, the so-called *memory tag*, which has a specific *tag size* and *tag granularity*. Capability architectures, such as the M-Machine [8] and CHERI [63], use a single-bit tag to mark and protect capabilities in memory. CHERI associates a single-bit tag with every 16 or 32 bytes of memory.

Commercial products like the ARM memory tagging extension (MTE) [50] associate each 16-byte granule with a 4-bit tag [51], allowing fine-grain policies. A pseudorandomly generated tag is encoded into the upper bits of each pointer. The dedicated tag is associated with the corresponding memory location through the tagged memory architecture. Access to the memory location is only granted if the pointer tag matches the tag of the location. Similarly, SPARC application data integrity (ADI) [1] uses a 4-bit memory tag at the granularity of 64 bytes for memory access checks [51].

Memory tagging can also be used for isolation. Mondrian [62] uses 2-bit tags per word, while Loki [64] uses up to 32 bits per word to enforce memory isolation. HDFI [52] enforces data-flow isolation with a single-bit memory tag. Furthermore, memory tagging can be used to design enclave architectures. SPEAR-V [48], for example, uses memory tagging on page granularity to isolate enclave memory. TIMBER-V [59] allows for stack interleaving based on fine-grain memory tagging using 2-bit tags per word.

While tagged memory architectures are versatile and help to improve runtime security, they share common drawbacks if implemented naïvely. Tags require additional storage space that scales with the tag size and granularity. Thus, the size of usable system memory declines. Furthermore, the tags must be fetched and propagated by the tagged memory architecture. This causes additional pressure on the DRAM bus, resulting in a loss of performance [27]. Especially for workloads typically encountered in servers and cloud systems, additional DRAM traffic has a strong performance impact [27, 52].

2.4 The `MAGIC` Mode

In 2020, Kounavis et al. proposed the `MAGIC` mode for authenticated encryption and error correction, bridging the gap between authenticated encryption and DRAM fault protection [31]. `MAGIC` computes an N-bit checksum T over n N-bit ciphertext blocks C_i and an N-bit block of authenticated data D. During the computation, `MAGIC` uses a blinding cipher E_K, where K denotes the key used by the encryption. Similar to `GMAC`, `MAGIC` uses a secret N-bit *hash key* H [43]. The checksum is computed as

$$T = E_K\left(D + \sum_{i=1}^{n} C_i \cdot H^i\right) \quad (1)$$

using finite field arithmetic in GF(2^N). When reading from memory, MAGIC computes an N-bit syndrome S as

$$S = E_K^{-1}(T) + D + \sum_{i=1}^{n} C'_i \cdot H^i$$

where C'_i denotes the ciphertext block read back from DRAM. If one of the ciphertext blocks at index j was modified, then $C_j \neq C'_j$ and the syndrome will evaluate to $S = (C_j + C'_j) \cdot H^j = e_j \cdot H^j$. MAGIC corrects errors with a Hamming weight less than or equal to a chosen threshold T_{th} and confined to a single ciphertext block. T_{th} determines the maximum number of correctable bits. Checksum differences with a Hamming weight below T_{th} are considered to be an error on the checksum and are corrected by replacing the faulted checksum. Values for H are selected such that

$$(\forall e : e \neq 0, \mathrm{HW}(e) \leq T_{th}) \wedge (\forall i \in [1, n-1]) : \\ \mathrm{HW}\left(H^i \cdot e\right) > T_{th}, \mathrm{HW}\left(H^{-i} \cdot e\right) > T_{th} \quad (2)$$

holds. When performing error correction, MAGIC locates the erroneous ciphertext block by computing the *error location indicators* S_i as $S_i = S \cdot H^{-i}$. Equation (2) guarantees that $\mathrm{HW}(S_i) \leq T_{th}$ holds only if i equals the index of the faulted ciphertext block. The error can be corrected by XORing the error location indicator to the faulted block.

The error correction of MAGIC stems from carefully selecting H, which is not randomly drawn but chosen according to Equation (2). This condition limits the number of permissible values of H. Let $\mathcal{H}$ be the set of values H that fulfill Equation (2). The cardinality of $\mathcal{H}$ can be estimated as

$$|\mathcal{H}| \geq 2^N - \frac{n(n-1)}{2} \left(\sum_{t=1}^{T_{th}} \binom{N}{t} \right)^2 . \quad (3)$$

Equation (3) helps to estimate whether some valid H values are guaranteed to exist. A positive result guarantees the existence of permissible values for H. In general, one can find permissible values by sampling a value at random and asserting that Equation (2) holds. With $N = 64$ bits, $n = 8$ bits and $T_{th} = 7$ bits, for example, the set $\mathcal{H}$ contains at least $2^{61.9}$ values.

3 Combining Integrity Protection, Authenticated Encryption, and Memory Tagging

In this section, we detail how Voodoo extends on MAGIC to implement tagged memory through the output produced by the MAC computation. First, we identify the requirements for a combined authenticated encryption, error correction, and memory tagging scheme. Then, we discuss the principle design of Voodoo. We elaborate on the functionality and the involved hardware components that process the data and the memory tag. Finally, we discuss the drawbacks and pitfalls of a naïve memory tagging implementation without sufficient tag encoding.

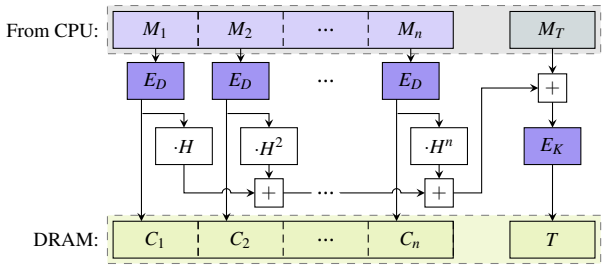

Figure 2: Overview of the Voodoo hardware architecture. The data $M_1, \cdots, M_n$ is first encrypted and then used as the input for the MAC computation. The encoded memory tag M_T is added to $\sum_{i=1}^{n}(C_i \cdot H^i)$, thus forming the intermediate of the MAC computation.

For the sake of clarity we will refer to the output of the MAC computation as the *checksum*. The metadata used for memory tagging is referred to as the *memory tag* or *tag*. When including a memory tag M_T into the checksum T we must consider how the memory tag may interact with the other features of our scheme. We identify the following three requirements that we aim to fulfill.

Accesses with a wrong tag must be detected. Memory tagging aims to improve the runtime security of a system. A fundamental property of tagged memory architectures is that memory accesses with an incorrect tag are detected. Thus, Voodoo must reliably detect tag mismatches. As tagging implements security-critical policies, a tag mismatch will terminate the process that encounters the error.

Error detection and correction are not weakened significantly. Using the checksum T to hold metadata for memory tagging influences error detection and correction. Thus, the encoding must not significantly weaken the error detection and correction abilities.

The memory tag can be read. For certain use cases, such as swapping and process migration, it is necessary to read the tag associated with a memory location. As the memory allocator usually performs tagging, we cannot assume that the operating system has knowledge of which memory is associated with which tag. Thus, we aim to support extracting memory tags from checksums.

3.1 Design Overview

Voodoo consists of two key components. The first component is the hardware architecture depicted in Figure 2. The second component is the *memory tag encoding* discussed in Section 4. The encoding does not necessarily require a hardware building block. Unless stated otherwise, M_T is already encoded when written to memory.

Checksum and Syndrome Computation. In general, we compute the checksum when writing to memory as

$$T = E_K\left(M_T + \sum_{i=1}^{n} C_i \cdot H^i\right) . \quad (4)$$

We denote the value passed to the blinding cipher E_K as the *intermediate*. When reading from memory, we compute the syndrome as

$$S = E_K^{-1}(T) + M'_T + \sum_{i=1}^{n} C'_i \cdot H^i. \tag{5}$$

Here, M'_T denotes the memory tag provided during the read operation, and C'_i represents the ciphertext blocks as read from memory. All operations are performed in $GF(2^N)$.

The checksum computation is depicted in Figure 2. First, the data written to memory is split into n N-bit blocks and encrypted using a data encryption cipher E_D. E_D can be any suitable cipher whose output matches the block size of N bits. The encrypted data C_1 to C_n and the memory tag M_T are then used to generate the intermediate value of the MAC computation. Applying the blinding cipher E_K to the intermediate yields the checksum T. We assume that an ECC DRAM is used. Hence, the ciphertext and the checksum can be stored and fetched within one access. Using a tweakable block ciper such as QARMA [3] for E_D allows to include the physical address as an encryption tweak. Thus, the same data at different locations in memory yields different ciphertexts and different checksums. AMD SEV-SNP, for example, uses this technique to protect againt attacks moving ciphertext in memory [61].

The values of H are secret and must fulfill Equation (2). However, we tighten the condition by requiring the products $e \cdot H^i$ with exponents *up to n* to produce a Hamming weight strictly above T_{th}. The condition is modified to

$$\begin{aligned} &(\forall e : e \neq 0, \mathrm{HW}(e) \leq T_{th}) \wedge (\forall i \in [1,n]) : \\ &\mathrm{HW}\left(H^i \cdot e\right) > T_{th}, \mathrm{HW}\left(H^{-i} \cdot e\right) > T_{th} \end{aligned} \tag{6}$$

The condition used by MAGIC (Equation (2)) does not ensure $\mathrm{HW}(S) > T_{th}$, as i never reaches n. With Equation (6), every syndrome from a correctable error has a Hamming weight above T_{th}.

Error Detection and Correction. When reading from memory, the syndrome is computed as given in Equation (5). A non-zero syndrome indicates a data error or a tag mismatch. In the case of a data error, the error correction procedure is the same as for MAGIC. We compute the error location indicators as $\forall i \in [1,n] : S_i = S \cdot H^{-i}$. An error is deemed correctable *iff* precisely one of the error location indicators has a Hamming weight that is not above T_{th}. Let j denote the index of the erroneous block identified through the error location indicators. The error is fixed by computing $C_j = C'_j + S \cdot H^{-j}$. If more than one error location identifier shows a Hamming weight that is in range, we consider this to be an uncorrectable error. If no index j is found, we also treat the error as an uncorrectable error.

Errors that affect the checksum T can be corrected by computing the Hamming weight of the difference between the fetched and the computed checksum. If the Hamming weight is less than a pre-defined threshold, we assume that the checksum suffered a fault and restore the correct checksum by overwriting it with the computed checksum.

Table 1: The misinterpretation probability of a naïve tag encoding w.r.t. the number of correctable bits. N and T_{th} are given in bits.

N \ T_{th}	1	2	3	4	5	6	7
64	2^{-55}	2^{-49}	2^{-45}	2^{-41}	2^{-38}	2^{-34}	2^{-31}
128	2^{-119}	2^{-112}	2^{-107}	2^{-102}	2^{-97}	2^{-93}	2^{-89}

3.2 Naïve Tag Encoding

In general, MAGIC supports the authentication of additional data when computing T. However, this additional data without any encoding is not suitable for implementing memory tagging. Assume that M_T can be freely selected from $\{0,1\}^N$. We denote this encoding as f-Unbounded. The modified checksum is computed as described in Equation (4). Including the memory tag in the checksum guarantees that an access with a wrong memory tag causes a non-zero syndrome. Assume the case in which we perform an access using a wrong memory tag M'_T. The syndrome will evaluate to $S = M_T + M'_T = e_T$. This value is equal to the *difference between the two memory tags* and will never be zero. Thus, the mismatch is detected. However, the syndrome cannot be distinguished from a syndrome that is due to errors in the ciphertext blocks.

A tag mismatch is identified correctly if $S = e_T$ is not interpreted as a correctable error. An e_T that causes exactly one error location indicator to have a Hamming weight less than or equal to T_{th} will be treated as a correctable error. We denote the case in which a memory tag mismatch causes error correction as a *misinterpretation*. Let $\mathcal{C}_f$ be the set of error location indicators that will be misinterpreted as a correctable error due to their low Hamming weight. Given an N-bit block size, the cardinality of $\mathcal{C}_f$ is given as

$$|\mathcal{C}_f| = \sum_{t=1}^{T_{th}} \binom{N}{t}. \tag{7}$$

For a misinterpretation, exactly one error location identifier must have a Hamming weight less than or equal to T_{th}. Using Equation (7), we can compute the misinterpretation probability. Given a memory tag error, the probability P_{Mis} that the mismatch is interpreted as a correctable error is

$$P_{Mis} = n \cdot \left(\frac{|\mathcal{C}_f|}{2^N}\right) \cdot \left(1 - \frac{|\mathcal{C}_f|}{2^N}\right)^{n-1}. \tag{8}$$

Memory tag errors with a Hamming weight lower than or equal to T_{th} will never be falsely interpreted due to Equation (6). Table 1 lists the misinterpretation probabilities for

Table 2: The aliasing probability of f-Pattern for X tag bits for $N = 64$ bits and $N = 128$ bits, respectively. T_{th} is the Hamming weight threshold in bits.

N	T_{th} \ X	1	2	4	8	16	32
64	7	0	0	0	2^{-63}	2^{-48}	2^{-32}
128	14	0	0	0	0	2^{-123}	2^{-96}

different T_{th}. As the cardinality of $\mathcal{C}_f$ increases, so does the misinterpretation probability. Due to the chance of misinterpretation, this encoding cannot be used for deterministic memory tagging. Even worse, some tag mismatches can cause silent data corruption.

Memory Tag Extraction. In the case that no error occurs in the ciphertext blocks, we can extract the memory tag from the checksum. Let M'_T denote the memory tag that we extract from T. We can compute $M'_T = E_K^{-1}(T) + \sum_{i=1}^{n} C'_i \cdot H^i = M_T$. It is, however, impossible to extract the correct tag in the case that an error occurred. Assume that the ciphertext block with index j is faulty and let e_j denote the error of the block. Performing the above computation will yield $M'_T = M_T + e_j \cdot H^j$. Thus, the extracted memory tag will not equal the previously encoded tag but contain the error as well. As the possible range for memory tags is not constrained, it is impossible to detect this error.

4 Encoding Tags for `Voodoo`

Based on the requirements and architecture given in Section 3, we develop novel memory tag encodings that meet the requirements while avoiding the issues and pitfalls of f-Unbounded. We introduce three novel encoding schemes called *Check Pattern Encoding* (f-Pattern), *Encrypted Tag Encoding* (f-Encrypt), and *Bounded Hamming Weight Encoding* (f-Bounded). For each encoding, we analyze the impact on the error detection and correction of `Voodoo`. Furthermore, we discuss how memory tags can be extracted from the checksum, even in the presence of errors. In the following, we denote the set of possible memory tags as $\mathcal{M}_T$. We denote memory tag differences as e_T and the encoded memory tag as M_T. For tag extraction, we denote the extracted memory tag as M'_T.

4.1 Check Pattern Encoding

In the naïve encoding, tags can be drawn from the full N-bit range. Most tagged memory architectures do not require such a wide range of tags. ARM MTE, for example, uses 16 tag bits for 512 data bits distributed over four 128-bit granules [51]. As our underlying encoding approach allows for N tag bits, 48 bits would remain unused in the case of MTE for $N = 64$ bits. We can use these spare bits to encode a fixed pattern into the memory tag. When accessing data with a wrong tag, the fixed pattern cancels out when computing e_T. Thus, the syndrome S will only be non-zero in the bits that are actually used by the tagged memory architecture.

The pattern does not directly decrease the odds of a misinterpretation. However, we can modify the correction procedure such that a misinterpretation of tag errors is impossible. In the original correction procedure, we search for the error location using the error location indicators. We modify the procedure by initially checking whether the upper bits of the syndrome are zero. If all upper bits (*i.e.*, the unused bits of the tag encoding) are zero, we assume the error to be a memory tag error. Such errors are treated as uncorrectable errors. The modified procedure will never misinterpret a tag mismatch as the error correction is aborted. Thus, a spurious correction of data that did not experience a fault is impossible. However, we experience an increased rate of uncorrectable errors.

Assume an encoding where only X bits out of N bits are used for the actual tag. The remaining bits are set to a fixed pattern. With an X-bit tag, we can express at most 2^X tag differences with a maximum Hamming weight of X. Thus, a syndrome that fulfills $S \geq 2^X$ is never caused by a tag mismatch. Let $\mathcal{U}$ denote the subset of all possible tags with a Hamming weight that is less than or equal to T_{th}. The elements of $\mathcal{U}$ are unproblematic as no correctable error will ever map to this subset due to Equation (6). The cardinality of $\mathcal{U}$ is $|\mathcal{U}| = \sum_{t=0}^{T_{th}} \binom{X}{t}$.

The syndrome produced by a correctable error can be one of $2^N - \sum_{t=0}^{T_{th}} \binom{N}{t}$ possible values, as the syndrome will always have a Hamming weight above T_{th}. Then, the probability P_{alias} that a correctable error maps to one of the remaining (problematic) values can then be given as

$$P_{alias} = \frac{2^X - |\mathcal{U}|}{2^N - \sum_{t=0}^{T_{th}} \binom{N}{t}}. \tag{9}$$

Note that if X is less than T_{th} bits, the aliasing probability becomes 0, as no error will ever map to a valid tag difference. Table 2 lists the aliasing probabilities for $N = 64$ bits and $N = 128$ bits depending on the desired tag size X. The values chosen for T_{th} are the largest possible values for their respective N such that valid H values are guaranteed to exist (c.f. Equation (3)). This encoding allows for deterministic memory tagging *without aliasing* if the chosen tag size is small enough to be covered by the correction threshold. For large tag sizes, however, the encoding may become unsuitable as the probability of uncorrectable errors increases.

Memory Tag Extraction. With f-Pattern, it is possible to extract the memory tag even in the case of a data error that is present in one of the ciphertext blocks. Due to the distinct pattern of valid tags, we can most likely identify faults during the tag-read operation. The probability that a data error has the shape of a valid tag is equal to the aliasing probability defined in Equation (9). If $X \leq T_{th}$, this probability equals 0, indicating that a data error cannot be confused with

a memory tag. If a data error aliases to a valid tag, the tag extraction will produce a faulty memory tag. When a data error is correctly identified as such, we can try to restore the tag and correct the fault. Computing $M'_T = E_K^{-1}(T) + \sum_{i=1}^{n} C'_i \cdot H^i$ yields $M'_T = e_j \cdot H^j + M_T$. The error e_j can be corrected by applying all 2^X possible tag values to this intermediate result and performing the regular error correction procedure. For the correct memory tag, it is guaranteed that the correction procedure will succeed. However, multiple memory tag values may lead to correctable errors. To avoid miscorrection, we always test all possible memory tags and only correct the fault if precisely one of the memory tags leads to a successful error correction. Once the data error is corrected, the memory tag can be extracted by reading out the syndrome.

4.2 Encrypted Tag Encoding

A different approach to improve the shortcomings of the naïve encoding is by applying an additional encryption on the memory tag M_T before encoding it into the checksum T. With f-Encrypt, we encrypt the memory tag using a suitable block cipher, and Equation (4) is transformed to

$$T = E_K\left(E_T(M_T) + \sum_{i=1}^{n} C_i \cdot H^i\right). \tag{10}$$

We eliminate the case of data corruption due to tag mismatches by imposing an additional constraint on how the values of M_T are conditioned. We limit the memory tags only to values that have either low or high Hamming weights. Formally, we specify that $\mathrm{HW}(M_T) \leq L_L \vee \mathrm{HW}(M_T) \geq L_U$ must hold where L_L and L_U denote the lower and upper Hamming weight limits, respectively. The size of the available tag space can be computed as $|\mathcal{M}_T| = \sum_{t=0}^{L_L} \binom{N}{t} + \sum_{t=L_U}^{N} \binom{N}{t}$. Encrypting a memory tag from this tag space will lead to a ciphertext uniformly drawn from $\{0,1\}^N$. In the case of a tag mismatch, the resulting difference will again be uniformly drawn. The probability that such a difference is misinterpreted as a correctable error is the same as for f-Unbounded. However, we can use the fact that actual memory tags have either low or high Hamming weights to distinguish between memory tag mismatches and actual data errors. Assume a tag difference e_T causes an error location indicator to have a Hamming weight less than or equal to T_{th}. We can now compute $M'_T = E_T^{-1}\left(E_K^{-1}(T) + \sum_{i=1}^{n} C'_i \cdot H^i\right)$ in an attempt to restore the memory tag. In the case of an actual data error, the computation will evaluate to $M'_T = E_T^{-1}\left(E_T(M_T) + e_j \cdot H^j\right)$. In the most probable case, the result of this computation has a Hamming weight above L_L and below L_U. The probability P_{HW} that a non-zero syndrome originating from an error in the data maps to a valid tag when decrypted can be given as

$$P_{\mathrm{HW}} = \frac{\left(\sum_{t=0}^{L_L} \binom{N}{t} + \sum_{t=L_U}^{N} \binom{N}{t}\right)}{2^N}. \tag{11}$$

The unlikely case that the result suggests an error due to a tag mismatch is treated as an uncorrectable error. With this modification, it is impossible for a tag mismatch to lead to miscorrection, and every tag mismatch is guaranteed to be detected. As a tradeoff, we increase the probability that a correctable error is interpreted as a tag mismatch and treated as an uncorrectable error. Equation (11) allows us to tune this probability by adjusting L_U and L_L. While the encryption of the memory tag adds additional latency, the actual performance impact is low. Memory tags are encrypted when writing to memory, which can happen parallel to the encryption of the plaintext data. Thus, encrypting the memory tag does not add latencies to the MAC computation. Decrypting the encrypted memory tag is only necessary if the syndrome does not evaluate to zero. No additional latency is introduced for read accesses without tag mismatches or errors, which is the common case.

Memory Tag Extraction. When using f-Encrypt, we compute $M'_T = E_T^{-1}\left(E_K^{-1}(T) + \sum_{i=1}^{n} C'_i \cdot H^i\right)$. In the error-free case, this will always yield the correct tag value. Given that a data error occurred, the result of the outermost decryption will be a uniformly drawn, random value. The probability that this decryption leads to a valid tag is equivalent to the probability given in Equation (11). As with f-Pattern, we can try to correct the error and then restore the memory tag by iteratively searching for the correct memory tag and performing the error correction procedure. If precisely one memory tag leads to a correctable error, we have found the erroneous ciphertext block and can extract the tag.

4.3 Bounded Hamming Weight Encoding

We can completely avoid misinterpretation and aliasing by limiting the values of M_T such that the condition $\mathrm{HW}(e_T) \leq T_{th}$ is fulfilled for all possible memory tag differences e_T. Such memory tags can never alias to correctable errors due to Equation (6). Contrary to f-Pattern and f-Encrypt, we do not need to modify the error correction procedure to distinguish between tag mismatches and data errors. Instead, searching for the error location will yield an inconclusive result as the Hamming weight of e_T is always less than or equal to T_{th}. Legitimate errors in data blocks will always lead to Hamming weights above T_{th}, as the selection of H ensures this property. Thus, by encoding the memory tags such that $\mathrm{HW}(e_T) \leq T_{th}$ is fulfilled for all possible tags, we can deterministically distinguish between memory tag mismatches and actual errors in the ciphertext blocks. However, the encoding limits the possible set of memory tags to guarantee that the difference between two memory tags is always within the threshold.

Assuming that each block in the MAC computation is N bits wide, we can compute the number of possible tag values given the value of T_{th}. Each memory tag may have a maximum Hamming distance of T_{th} to any other memory tag; hence the maximum number of set bits per memory tag equals $\lfloor T_{th}/2 \rfloor$.

Table 3: The available tag space in bits (Equation (12)) for $N = 64$ bits and $N = 128$ bits, respectively, when using f-Bounded. T_{th} is the Hamming weight threshold in bits.

N \ T_{th}	2	4	6	8	10	12	14
64	6	11	**15.4**	-	-	-	-
128	7	13	18.4	23.3	28	32.4	**36.5**

It follows that

$$|\mathcal{M}_\mathcal{T}| = \sum_{t=0}^{\lfloor T_{th}/2 \rfloor} \binom{N}{t}. \tag{12}$$

Table 3 shows how the available tag space increases with an increasing T_{th}. While bounding the Hamming weight limits the tag space, it allows us to encode tags without the chance of misinterpretation or aliasing. Thus, we deterministically detect every tag mismatch without increasing the probability of uncorrectable errors.

Memory Tag Extraction. For f-Bounded, it is impossible that a data error assumes the shape of a tag error. Memory tags have a maximum Hamming weight of $\lfloor T_{th}/2 \rfloor$. According to Equation (6), errors in the ciphertext blocks will always lead to a product with a Hamming weight strictly above T_{th}. When computing $M'_T = M_T + e_j \cdot H^j$ we can always detect the presence of an error. When adding two elements $a, b \in GF(2^N)$ with $\mathrm{HW}(a) > \mathrm{HW}(b)$ the Hamming weight of the result is at least $\mathrm{HW}(a) - \mathrm{HW}(b)$ The resulting Hamming weight of M'_T is, thus, guaranteed to be at least $\lfloor T_{th}/2 \rfloor + 1$. Hence, the result can never have the shape of a valid tag difference. Like f-Pattern, we can recover the tag and correct the error by testing all possible tag values and performing the error correction procedure. If precisely one tag leads to a correctable error, we have successfully restored the tag and corrected the data. If multiple tags would lead to an error correction, we consider the data to be uncorrectable.

Comparison of Encodings. Table 4 summarizes the capabilities of the presented encoding schemes. f-Unbounded is not suitable to implement tagged memory. Memory tag mismatches are not guaranteed to be detected and can cause miscorrection, thus violating data integrity. Furthermore, it is impossible to read the memory tag in the presence of a data error. All other encoding schemes guarantee that tag errors are detected and never cause miscorrection. They each provide a mechanism to read tags, even in the presence of data errors. However, f-Pattern and f-Encrypt may return a faulty tag in the case that a data error is present during tag extraction. With f-Bounded, we reach the strongest capabilities, as this scheme offers determinism in all analyzed aspects. It is impossible that f-Bounded returns a faulty memory tag during tag extraction.

Table 4: A summary of the capabilities of the different encoding schemes and their success probabilities.

Encoding	Detect Mismatch	Correct Error	Read Tag w. Error
f-Unbounded	$P = 1 - P_{mis}$	✓	✗ read wrong tag
f-Pattern	✓	$P = 1 - P_{alias}$	$P = 1 - P_{alias}$
f-Encrypt	✓	$P = 1 - P_{\mathrm{HW}}$	$P = 1 - P_{\mathrm{HW}}$
f-Bounded	✓	✓	✓

$$isTagMismatch(S) = \begin{cases} HW(S) \leq T_{th}, & \text{if } f\text{-Bounded.} \\ S < 2^X, & \text{if } f\text{-Pattern.} \\ HW(E_T^{-1}(S + E_T(M'_T))) \notin]L_L, L_U[, & \text{if } f\text{-Encrypt.} \\ \bot, & \text{if } f\text{-Unbounded.} \end{cases} \tag{13}$$

Figure 3 shows the generic flow of a read operation with Voodoo. Depending on the encoding pattern, Equation (13) decides if a S value looks like a tag, which indicates that a tag mismatch happened, in which case we do not correct the error.

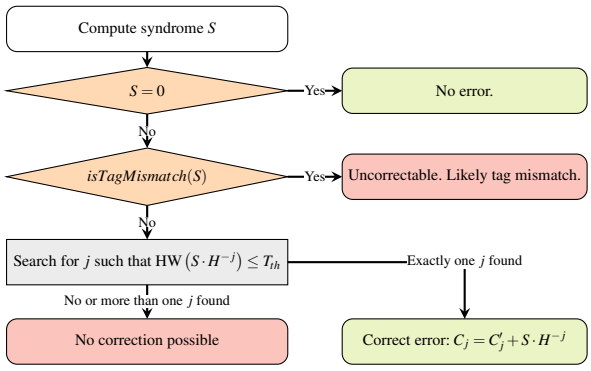

Figure 3: Flow of a DRAM read operation with Voodoo.

4.4 Case Study on Tagged Architectures

In this section, we present a case study that demonstrates Voodoo's applicability. We investigate which tagged memory architectures can be implemented with our encodings. Our findings indicate that Voodoo is suitable for a wide range of academic and commercial tagged architectures. We consider a tag encoding suitable if the available tag space can accommodate the required tag size of the memory tagging scheme. For f-Encrypt, we assume a configuration in which T_{th} is set to the maximum value for the respective block size N. We select L_U and L_L such that the available tag space is minimized but large enough to cover the required tag space. For f-Pattern, we assume that X is chosen to equal the required tag size of the memory tagging scheme. In addition to existing architec-

tures, we analyze models with theoretical tag sizes to show the limitations of our approach.

Supported Tag Sizes. Several architectures, including CHERI [63], DIFT [26], and HDFI [52], implement a single-bit tag per granule. f-Bounded presents an ideal solution for schemes requiring a small tag space. CHERI's 256-bit and 128-bit version yield 2-bit and 4-bit tags per 64 B cache line, respectively. Both variants can be deterministically implemented using f-Bounded. If the parameters are set accordingly, f-Pattern also offers deterministic tagging without aliasing for both granularities. With f-Encrypt, there is always the possibility that data errors alias to tag mismatches. Thus, we can implement both variants but must accept a slight increase in the rate of uncorrectable errors.

Other single-bit memory tagging schemes, such as DIFT or HDFI, operate at a word level of granularity. With 64-bit words, this results in 8-bit memory tags per 64 B cache line. While this tag space is still deterministically covered by f-Bounded, configurations of f-Pattern with $N = 64$ already experience aliasing with a small probability. With f-Encrypt and $N = 64$, we cannot select the threshold values to reach a tag space of exactly 8 bits. Instead, we must use the next larger size of 11 bits. This comes with the downside of an increased rate of uncorrectable errors. For $N = 128$ bits we can select L_U and L_L to reach a tag space of 8.01 bits.

Memory safety countermeasures like ARM MTE [50] and SPARC ADI [1] rely on multi-bit memory tags. MTE and ADI utilize a 4-bit memory tag with a respective granularity of 16 B and 64 B. Thus, SPARC ADI requires four tag bits per cache line, and ARM MTE needs a larger 16-bit tag space. While f-Bounded can cover the tag space of SPARC ADI, it is not possible to provide all tags needed by ARM MTE in the case of $N = 64$ bits. With $N = 128$ bits, both architectures can be implemented deterministically. Also, both architectures can be implemented using f-Pattern and f-Encrypt while offering a reasonably low probability of aliasing.

Some memory isolation schemes [12, 48] require larger memory tags. SPEAR-V [48], for example, uses 24-bit memory tags on page granularity. As our design operates on cache line granularity, we need to encode the memory tag in every cache line, resulting in a tag size of 24 bits. The f-Bounded mode is not applicable here for $N = 64$ bits. However, with $N = 128$ bits we can deterministically encode the tag. With f-Pattern and f-Encrypt, we can encode the complete 24-bit tag but suffer an increased probability of uncorrectable errors.

Both f-Pattern and f-Encrypt offer a tradeoff between deterministic detection of tag mismatches and error correction capabilities. Depending on the expected rate at which data errors occur, a slight increase in uncorrectable errors might be acceptable. However, the encodings may not be suitable for architectures with large tag sizes, as the rate will be too high, and the system will become unreliable.

Supported Architectures. Depending on the tagged memory architecture, memory accesses either carry a tag value that is used for comparison, or the tag value must be extracted from the syndrome. `Voodoo` supports both types of tagged memory architecture, as our encodings allow for tag extraction, even in the presence of errors. However, architectures that do not present a tag on each access (e.g., , DIFT) may suffer from additional latencies when accessing memory locations that suffered a data error. The additional latency is determined by the number of possible memory tags, as they are restored using an iterative approach. For the latency computation, we multiply the size of the tag space with the latency of a single trial computation, which we approximate with 0.44 ns [3]. We find that most tagged architectures are feasible to implement with `Voodoo`. For architectures that use large tags, such as SPEAR-V, the latency can become rather high. As this latency is *only present in the first access to an erroneous data block*, the overall impact is still low. For architectures such as lowRISC or Model 2B, the reconstruction latency is infeasibly high. Thus, architectures with large tags are expected to perform better if the tag is present on each memory access.

Table 5: Case study of our tag encodings. The numbers indicate the probability that a tag mismatch maps to an uncorrectable error. ● indicates deterministic tagging and ○ indicates an impossible configuration. Architectures that present a tag on every access are marked with 🏷, architectures that require tag extraction are marked with 🔍. All block sizes are given in bits. For architectures that do not present a tag on every access, we give the additional latency that occurs when reading the tag from an erroneous location.

Architecture	Tag Bits per 64 B	f-Bounded N=64	f-Bounded N=128	f-Pattern N=64	f-Pattern N=128	f-Encrypt N=64	f-Encrypt N=128	Latency in ns

Table 5 provides a concise case study overview. Tagged memory architectures are sorted according to their tag sizes. All exponents given for the aliasing probabilities are rounded towards higher probabilities. For f-Bounded, a full circle indicates that we can offer deterministic tagging, while an empty circle indicates that the encoding is unsuitable. For f-Pattern and f-Encrypt, we list the corresponding aliasing probabilities for the optimal parameterization described above. As f-Encrypt does not allow us to specify the tag size directly, we must select the parameters such that the available tag space covers the required tag space.

5 DRAM Error Detection and Correction

This section discusses the DRAM error detection and correction of Voodoo. We introduce a fault model based on DRAM faults in DDR4 devices. We then discuss the error detection and correction capabilities for single-block and multi-block errors. By bounding chip errors to single ciphertext blocks, we show how to improve the error correction of Voodoo. Furthermore, we implement a Monte-Carlo simulation to showcase the error detection and correction capabilities. Lastly, we compare the error correction performance to that of commodity and academic error correction schemes.

5.1 Fault Model

We base our fault model on real-world data produced by a large-scale DDR4 fault study of Beigi et al. [5]. Their work identifies sixteen fault modes that affect DDR4 devices. Table 6 lists a coarse-grain overview of the modes we consider in our analysis. The combined fault modes are derived from the fault modes identified by Beigi et al. [5]. We assume that a burst consists of 8 beats where each beat transfers 64 data bits over the bus [25]. We assume that each rank on the DIMM hosts 16 x4 DRAM devices (cf. Section 2) storing data and two x4 DRAM devices for storing redundancy, as this is the setup used in the study of Beigi et al. [5]. Thus, each x4 DRAM device will contribute exactly 32 data bits to the 512 data bits that comprise a cache line. We consolidate modes that will affect the same worst-case number of bits together for simplicity. We identify four fault classes ranked according to the maximum number of affected bits.

Single-Bit Faults. Single-bit faults are the most common faults observed in modern DRAM devices. Here, the content of a single memory cell is corrupted, and only a single bit of the data read from the DRAM device is erroneous.

Multi-Bit Faults. Multi-bit faults affect two to four bits in a single burst. This fault class combines single-word faults and single-column faults.

Subsequent Faults. The class of subsequent faults captures all faults where two of the beats in a burst yield faulted data. The maximum number of faulty bits in this fault mode is 8, as each beat yields 4 bits of data in the case of DRAM chips with four data pins. This fault class consists of two-column faults and single-pin faults.

Large-Scale Faults. Large-scale faults are faults that affect up to 32 bits in the burst. Such faults may be due to full-, half-, and quarter-device faults, all row-related faults, single-bank faults, and single-lane faults.

We compute the expected probability for each class by summing the percentages of the faults. The distribution suggests that 55% of faults are single-bit faults, 4% are multi-bit faults, 4% are subsequent faults, and 37% are large-scale faults.

As we base our fault model on DRAM faults encountered in a production environment, we consider naturally occurring faults to be the main target of the error correction procedure. Rowhammer attacks [30] induce targeted bit flips in DRAM. As shown by Cojocar et al. [10], Rowhammer can bypass and exploit error-correcting codes. Voodoo would also be able to correct Rowhammer-induced errors as long as they are confined to a single block. We expect Voodoo to offer stronger protection than existing linear codes, as they can be reverse engineered and exploited [10]. However, we consider Rowhammer and hardware fault attacks out of scope as they are best mitigated at their source [41, 42].

Table 6: The fault classes that we consider in our analysis. Fault classes are ranked by the maximum number of affected bits per burst. The rate describes the percentage of faults that fall in the given class.

Class	Combined Faults	Bits	Rate
Single-bit	Single-bit	1	55%
Multi-bit	Single-word, Single-column	4	4%
Subsequent	Two-column, Single-Pin	8	4%
Large-scale	Row, Single-bank, Single-lane, Device	32	37%

5.2 Detection and Correction Capabilities

Real-world DRAM errors may violate the assumption that errors are confined to a single ciphertext block. Thus, it is essential to analyze the behavior of Voodoo under such faults.

Detection of Multi-Block Faults. A requirement for our error correction is that only one ciphertext block out of all n input blocks is faulty. However, it is necessary to reason about the behavior of Voodoo in the presence of faults spread over multiple blocks.

Assume the case in which two or more ciphertext blocks experience an error simultaneously. The syndrome will be the sum of all faults multiplied by their respective power of H. During the error correction procedure, we compute n error location indicators. Two critical events can cause data corruption. First, the syndrome may evaluate to 0 as the combined errors cancel each other out. Given that the possible range of products between errors and hash key exponents is $\{0,1\}^N \setminus \{x : \mathrm{HW}(x) \leq T_{th}\}$, the probability of this case is $2^{T_{th}-N}$. Data corruption can also occur when exactly one error location indicator suggests a correctable error. Aliasing occurs when $\mathrm{HW}\left(S \cdot H^{-j}\right) \leq T_{th}$ is fulfilled. The probability for aliasing is, thus, equal to the misinterpretation probability of the f-Unbounded encoding. Table 1 shows how the aliasing probability increases with an increasing number of correctable bits. This type of aliasing is unlikely to occur for a configuration with a block size of 128 bits. Even if $T_{th} = 14$ bits, the theoretical maximum for the given N, the misinterpretation probability is 2^{-65} (cf. Equation (8)). Thus, multi-block errors are likely to be correctly reported as uncorrectable errors.

Error Correction Capabilities. According to the fault model introduced in Section 5, the majority of faults are single-bit

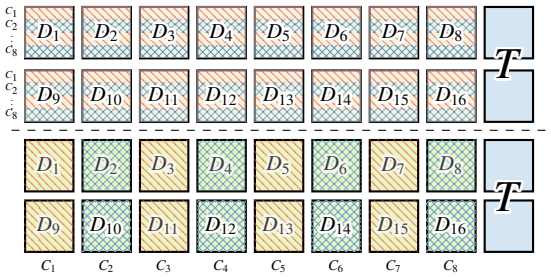

Figure 4: Two variants of how ciphertext blocks are placed in DRAM. Our approach uses the second variant (below).

faults. Every instantiation of Voodoo can handle this fault type, as T_{th} is at least 1. When considering multi-bit faults, T_{th} must be at least 4 to handle all possible faults. The configuration with $N = 64$ bits is not guaranteed to find a suitable hash key H such that Equation (6) is fulfilled for all possible errors. Thus, if we implement the selection of H as described for MAGIC, we are not guaranteed to correct subsequent faults. Even worse, it is improbable that there exists any H that would allow us to correct the large-scale faults as defined in Section 5. However, we find that we can improve the error detection and correction procedure such that some of the subsequent faults and, more importantly, large-scale faults can be detected and corrected.

Bounding Errors to Blocks. Due to Equation (6), we must assume that it is infeasible to search for a H that allows for the guaranteed correction of arbitrary errors with Hamming weights above 7 or 14 bits, depending on N. We can, however, exploit the fact that erroneous bits are usually not arbitrarily distributed. Instead, the physical structure and layout of the memory cause them to follow specific patterns. It is, for example, rather unlikely that two DRAM chips experience a fault at the same time [5, 53]. Thus, we arrange the ciphertext blocks so that one block is confined to two x4 DRAM chips for $N = 64$ bits and four x4 chips for $N = 128$ bits. This ensures that only one ciphertext block is affected even if a complete chip failure occurs.

Figure 4 illustrates two variants of how the ciphertext blocks can be distributed over the DRAM chips. In the first configuration, a single beat transmits a complete ciphertext block. However, the data of a ciphertext is distributed over all DRAM chips. When a chip experiences a subsequent or large-scale fault, multiple ciphertext blocks are affected.

The second configuration solves this by ensuring that even a complete chip fault is bounded to one ciphertext block. Thus, we only experience a multi-block fault if multiple DRAM chips in different blocks experience a fault simultaneously.

Stuck-Pin Correction. Considering the physical structure of DRAM chips for error correction allows us to extend the error detection and correction capabilities. Assume that a chip experiences a single stuck pin. As each DRAM chip is accessed eight times, the maximum number of influenced bits is 8. Thus, a maximum of 8 erroneous bits is found in a single block. For $N = 64$ bits, it is not guaranteed that we find a H with which we can correct 8-bit errors as the maximum T_{th} is limited to 7. However, the eight erroneous bits of a single pin fault are not randomly distributed. Due to the chip's structure, each faulted bit is equally spaced over the 32 bits read from the chip with the broken pin. Hence, instead of increasing T_{th} to 8 bits, it is sufficient to consider $4 \cdot (2^8 - 1) \approx 2^{10}$ error values. Note that a subset of these errors is already contained in the initially considered errors with a Hamming weight less than or equal to T_{th}. For $T_{th} = 7$ bits, there are only four errors where all 8 bits are affected that need to be considered in addition to what is covered by the regular error correction. For two stuck pins, we have $\binom{4}{2}\left(2^8 - 1\right)^2 \approx 2^{18}$ errors that need to be considered. For comparison, the number of errors that must be considered when $N = 64$ and $T_{th} = 7$ is approximately 2^{29}. Let $\mathcal{E}_{SP}$ denote the set of additional errors due to stuck pin faults. The overall set of possible errors is then $\mathcal{E} = \mathcal{E}_{SP} \cup \{e \in \{0,1\}^N : \mathrm{HW}(e) \leq T_{th}\}$. We can adopt Equation (3) to include all possible errors, thus yielding

$$|\mathcal{H}| \geq 2^N - \frac{n(n+1)}{2}(\mathcal{E})^2 .$$

With this estimation, we can determine if there exists a H that is guaranteed to fulfill Equation (6) for all considered errors. We find no significant reduction of the cardinality of $\mathcal{H}$, even when the errors stemming from single- and double-pin faults are included.

Permanent Fault Correction. For larger faults that corrupt even more bits, it is impossible to use a pattern-based approach to include them in $\mathcal{E}$. We can, however, reach Chipkill-level protection for permanent faults. According to Beigi et al. [5], most large-scale faults are permanent or intermittent. Reading from a location with a permanent fault always yields erroneous data. When performing error correction, we first identify the block that needs to be corrected. Initially, this is done by searching for an error with low Hamming weight. However, we can locate a permanently faulted chip without any computation. It is sufficient to perform two additional write and read operations to check if a chip is faulty. We can identify all permanent faults that affect the cache line by writing and reading back a known pattern and the corresponding anti-pattern. Once the faulted block is identified, we can restore the original value, just like in the case of regular error correction.

5.3 Monte-Carlo Simulation

We build a simulation showcasing the error correction and detection performance of Voodoo. Two configurations simulate the fault model defined in Section 5.1.

In the first configuration, all faults are confined to a single chip in one ciphertext block. This mode measures the percentage of correctable, miscorrected, and uncorrectable faults.

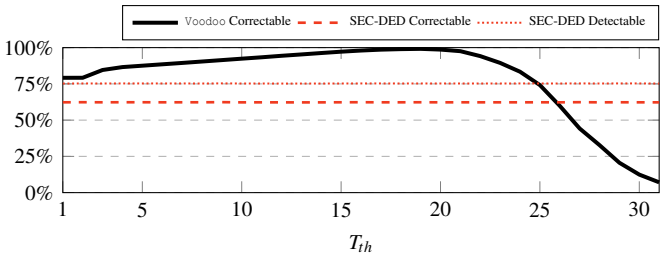

Figure 5: The percentage of correctable errors w.r.t. the threshold T_{th} assuming that a *single block* experiences faults. After an optimum at $T_{th} = 19$, the rate declines drastically.

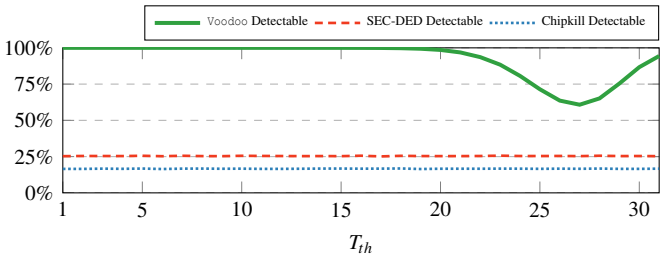

Figure 6: The percentage of detectable errors for faults in *multiple blocks*. Voodoo offers almost 100% error detection.

We compare our results to SEC-DED ECC. With SEC-DED, we consider an error correctable if only one faulted bit per ECC granule is detected. Furthermore, we consider errors as guaranteed SEC-DED detectable if the Hamming weight of the error in the ECC granule does not exceed two. While the ciphertext is confined to two chips, we assume the linear ECC checksum is computed over all 16 chips. Thus, SEC-DED can also correct errors due to single stuck pins and other errors that only affect one bit per granule. We model the distribution of faults according to [5].

The second configuration generates multi-block faults exceeding the corrective capabilities of Voodoo. This configuration measures the detection rate for multi-block faults. We measure detected and miscorrected faults. Our simulation always injects errors in two or more ciphertext blocks. Thus, none of the simulated errors are correctable. The results are compared to SEC-DED ECC and Chipkill. We assume a single-symbol-correction, double-symbol-detection Chipkill code. Hence, an error is considered Chipkill detectable if at most two chips are affected.

Both configurations use a block size of $N = 64$ bits. Furthermore, we assume a cache line size of 512 bits, resulting in $n = 8$ blocks. Each simulated access is erroneous to speed up the simulation. We draw 200 unique values for H and simulate 10 000 errors for each H. According to the data reported by Beigi et al. [5], this approximates 2^{44} years of continuous DRAM operation.

Figure 5 illustrates the percentage of correctable errors w.r.t. the selected threshold value T_{th}. Note that the percentage of correctable errors increases even when exceeding the theoretical maximum of $T_{th} = 7$. This behavior suggests that one error aliasing to another correctable error is very unlikely, even with a high T_{th}. Hence, miscorrections are also extremely rare. We are far more likely to deem an error uncorrectable because the error location is not uniquely identifiable. We find that small values of T_{th} already allow us to surpass the corrective capabilities of SEC-DED ECC. With Voodoo, every error confined to a single block is guaranteed to be detected.

Figure 6 illustrates the detection rate of Voodoo for multi-block errors. Voodoo correctly identifies nearly all multi-block errors as uncorrectable for low values of T_{th}. For $T_{th} = 27$ the miscorrection rate reaches its maximum at 39%. At this optimum, the aliasing probability from multi-block errors to single-block errors is the highest. Further increasing T_{th} will decrease the miscorrection rate, as the likelihood that a multi-block error aliases to two or more single-block errors increases. This behavior is also reflected by Equation (8), which has an optimum at $T_{th} = 27$ bits.

In summary, our Monte-Carlo simulation results underline the applicability of Voodoo for error detection and correction. As expected, the threshold T_{th} strongly influences the corrective capabilities of Voodoo. When setting T_{th} appropriately, we can correct almost all errors produced by the fault model defined in Section 5.1. This strong correction performance is due to most errors being limited in the number of erroneous bits, and the rarity of large-scale errors affecting many bits.

5.4 Error Correction Latency

As Voodoo performs a fixed number of steps on each error correction, we can estimate the time needed for a single correction. The correction latency only depends on the time it takes to correctly identify the faulted block. In a configuration with n N-bit blocks, the number of error location indicators equals n. These error location indicators are computed as $\forall i \in [1,n] : S_i = S \cdot H^{-i}$ and the error correction succeeds if $HW(S_i) \leq T_{th}$ holds for exactly one location indicator. We can consider two approaches for this search. First, we can perform the computation and the check iteratively, resulting in n subsequent computations. Assuming a 0.44 ns latency for each multiplication [3] and $n = 8$ ciphertext blocks, the overall search latency equals 3.52 ns. Contrarily, a fully parallelized search only takes 0.44 ns. Before locating the error, Voodoo decrypts the stored checksum, thus imposing an additional latency of 2.2 ns when using QARMA.

Latency Comparison. We compare our correction latency with the latencies of commodity ECC, HashTag [33], and MUSE ECC [40]. This selection of schemes allows us to gauge the performance of Voodoo compared to commodity error correction, iterative error correction, and correction based on residual codes. According to Cojocar et al. [10] and

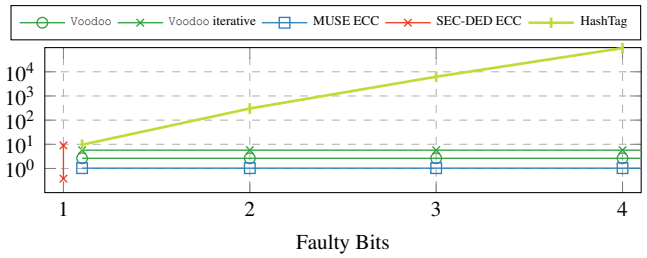

Figure 7: The error correction latencies of different error detection and correction schemes in ns.

Kwong et al. [32], the correction latencies of ECC DDR4 DRAM can range from 0.9 ns to 9 ms. Manzhosov et al. [40] report a correction latency of 0.38 ns for an RS(144,128) code. We use this latency as the lower bound of commodity error correction. For HashTag, we assume that errors are confined to a single 64-bit block and the search is limited to the affected block. We assume that HashTag uses SPEEDY with a latency of 0.3 ns per invocation. For MUSE ECC, we consider a configuration with Chipkill error correction. The error detection and correction latencies of MUSE ECC range from 0.856 ns to 1.179 ns, with the average being 1.03 ns.

Figure 7 shows the error correction latency of Voodoo, MUSE ECC, HashTag, and a commodity ECC solution in direct comparison. The latency of Voodoo is reasonable low at 2.64 ns and 5.72 ns for the parallel and the iterative approach, respectively. This places our latency within the reported range of latencies for commodity ECC [10, 32, 33]. MUSE ECC outperforms Voodoo in terms of correction latency. Note that the main latency of error correction with parallel Voodoo comes from the decryption of the stored checksum. Using a faster block cipher will, thus, result in a lower error correction latency. Both implementations of Voodoo's search outperform the error correction of HashTag. Furthermore, the latency of HashTag grows as the number of faulty bits increases while Voodoo and MUSE ECC offer error correction in a fixed amount of time.

6 Evaluation

In this section, we evaluate Voodoo. While the Monte-Carlo simulation presented in Section 5 allows us to evaluate the error correction performance, we also implement Voodoo using the gem5 full-system simulator [7] to measure the overall performance impact. For comparison, we implement an MTE-like tagged memory architecture that is implemented independently from the authenticated encryption and error correction provided by Voodoo.

6.1 Implementation in gem5

We implement our proof-of-concept prototype using the gem5 system simulator (version 22.1.0.0) to provide an accurate hardware model of our design. Additionally, we implement an authenticated encryption engine based on the structure shown in Figure 2. We implement an MTE-like tagged memory architecture to measure the performance overheads of traditional memory tagging.

Voodoo Mode. We implement Voodoo as described in Section 3.1 as an extension to the gem5 simulator. We include a module with configurable encryption and decryption latencies in our implementation. This allows us to parameterize the model according to the selection of the underlying block ciphers. This model measures the overheads generated by adding the encryption layer and the logic for the MAC computation. We assume that instances of the QARMA block cipher are used for encryption. According to Avanzi [3], the latency of QARMA_x-64 can range from 2.2 ns to 3.6 ns. The delay of a 64-bit GF(2^{64}) multiplication is listed at 0.44 ns. Leander et al. [35], however, list their minimum achieved latency for QARMA_x-64 at approximately 0.4 ns. We make a conservative estimation of the combined forward and backward latencies that we impose on each memory request. When writing to memory, we add a forward latency of 4.04 ns to each write access. This latency is the estimated time it will take to compute the MAC for the provided data. When reading from memory, we impose a 3.6 ns delay, as the checksum is decrypted while the fresh checksum is computed.

Memory Tagging. We implement a memory tagging model that integrates a tagged memory architecture for storing and propagating tags in hardware. We co-locate the tag metadata with the data for every cache line. Additional memory requests are required for every cache miss to fetch the associated tag metadata from a dedicated DRAM region. This mode represents a naïve tagged memory implementation.

Authenticated Encryption and Memory Tagging. This mode implements memory tagging and authenticated encryption as two disjunct system features. Each memory access is delayed, as described above. Additionally, memory accesses trigger additional loads from DRAM.

6.2 Performance Evaluation

We evaluate our hardware models using gem5 and the SPEC CPU2017 benchmark suite running on Linux v5.15. Similar to existing work [33, 40, 58, 60] and to avoid infeasible simulation times, we use the TimingSimpleCPU model at 3 GHz. The cache hierarchy is configured to a private 8-way set associative L1i and L1d cache with 16 kB and 64 kB, respectively. The L1 and L2 access latency is configured to 1 and 10 cycles, respectively. We use a 8 MB shared 16-way set-associative L2 and an 8 GB DDR4 DRAM module.

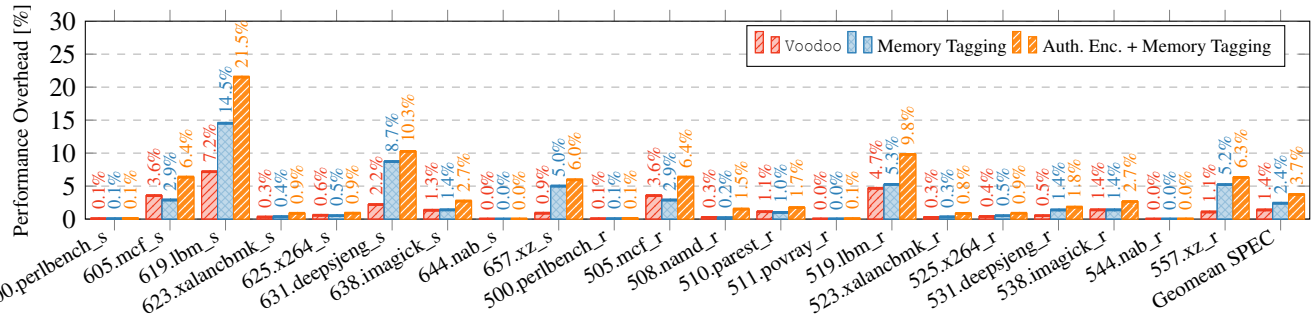

Figure 8: Simulated performance overhead using the SPEC CPU2017 benchmark suite.

Simulation Results. Figure 8 illustrates the simulated performance overhead. The baseline performance is determined by measuring the runtime of the benchmarks on a system that does not implement authenticated encryption or memory tagging. We excluded the benchmarks that encounter toolchain issues, compilation failures, or runtime errors.

The simulated performance results of our design show an overhead of 1.4% compared to the baseline system. The overhead is caused by the delays due to the memory encryption. For traditional memory tagging, we measure an average performance overhead of 2.4%. The additional DRAM requests cause this overhead and it increases for benchmarks with high memory pressure. for the authenticated encryption with separate memory tagging, we find that the geomean of the performance overhead is 3.7%.

Performance Comparison. We compare the performance of `Voodoo` to the reported performance numbers of commodity memory encryption schemes and a commodity tagged memory implementation. We compare `Voodoo` against AMD's memory encryption engine, the memory encryption of Intel TDX, and ARM's MTE implementation. AMD's memory encryption engine uses an optimized AES implementation and imposes a reported geomean performance overhead of 1% across workloads [34]. New and upcoming Intel CPUs incorporate a memory encrpytion engine using AES-XTS with 128-bit keys. The reported maximum performance overhead of Intel TME-MK is given at 2.2% [21]. For ARM MTE, a recent study reports a geomean performance overhead of 1.5% for the SPEC CPU2006 benchmark suite [16]. These results highlight the competitive performance of `Voodoo` compared to other implementations of memory encryption and tagging. Note that the performance given for `Voodoo` in Figure 8 is achieved with an in-order CPU model while the reported performance numbers given above stem from commodity hardware.

6.3 Area Estimation

We estimate the area overhead using the available data for QARMA presented by Avanzi [3]. The area overhead of a single multiplication in $GF(2^{64})$ is listed at 17 kGE ($924.6\,\mu m^2$). Assuming an unoptimized implementation with $n = 8$ message blocks of $N = 64$ bits each, we end up with 8 instances of the 64-bit multipliers, summing up to 136 kGE ($7397\,\mu m^2$). On top of the multiplication, we must also account for the block cipher instances. The choice of the block cipher has a strong impact on the overall area overhead. Assuming a fully-unrolled QARMA-64 with 22kGE ($1238\,\mu m^2$) as the underlying block cipher and no further optimizations, we require 9 instances of the block cipher, resulting in 198kGE ($11\,142\,\mu m^2$). Thus, we reach an overall area overhead of approximately 220kGE ($18\,539\,\mu m^2$) for `Voodoo`. Using the same comparison as [33], we reach a relative overhead of 0.007% when considering the area of a Raptor Lake CPU [57].

7 Related Work

Several academic designs propose using ECC DRAM modules to encode metadata or increase system performance for tagged architectures. However, none of the related research proposes a combined primitive for authenticated encryption, error correction, and memory tagging.

HashTag [33] replaces Hamming codes with truncated hashes and stores the memory tags in free bits of the ECC chip. While this approach eliminates additional fetches, the error correction procedure suffers from increased latencies due to a brute-force search. Furthermore, large tag sizes reduce the error detection and correction capabilities significantly. `Voodoo` offers a larger tag space without compromising on error correction. Furthermore, our error correction approach does not rely on an iterative search.

MUSE ECC [40] uses residue codes to protect DRAM integrity. The unused states of the code provide spare bits that can be used for memory tagging. The number of spare bits depends on the size of the code and the error detection and correction capabilities. Contrary to `Voodoo`, MUSE ECC only protects data integrity.

Implicit Memory Tagging (IMT) [55] uses alias-free tagged ECC for memory tagging, where they integrate the tag metadata within the check bits of the ECC chip. IMT detects tag

mismatches while maintaining single-bit error correction. It is, however, impossible to extract a tag encoded into the tagged ECC. Thus, tag-read operations are not supported.

SYNERGY [47] uses ECC DRAM to co-locate MACs from authenticated encryption with data, effectively removing additional DRAM requests and providing error correction through externally stored redundancy. Thus, SYNERGY does not reduce the memory overhead but eliminates the performance overhead of MAC fetches in the error-free case.

8 Conclusion

In this paper, we present Voodoo, the first combined scheme for authenticated encryption, DRAM integrity protection, and memory tagging. We extend MAGIC and develop three novel encodings for memory tags to allow for memory tagging without additional memory requests or storage requirements. We thus address the limitations of conventional tagged architectures, which incur non-negligible performance and memory overheads. We showcase that a wide variety of existing tagged memory architectures can be realized using our design. Moreover, we analyze our scheme's robustness based on real-life DRAM fault data. Our gem5 prototype implementation demonstrates the advantages of our approach when compared to a conventional tagged memory implementation. Compared to a system without any additional security features, our Voodoo prototype incurs a low performance overhead of 1.4% on average. In addition, our Monte-Carlo simulation shows the advantages of Voodoo over SEC-DED codes as we reach an error correction rate of 99% for single-chip errors. Furthermore, we reach a higher detection rate for multi-block faults than Chipkill.

A.1 DRAM Error Simulation

Table 7 lists the fault types given in Table 6 in more detail. As the study by Beigi et al. measures fault rates for two different DRAM vendors, we average over the reported rates. Our Monte-Carlo simulation samples from the given set of faults. After deciding the fault type, we generate the number of faulted bits depending on the fault type. For single-word and single-column faults, we uniformly draw a number between 1 and 4 deciding how many bits are faulted. We discard zero-bit results. We then sample an error that has the previously sampled number of bits set. For larger faults such as row faults, we draw the number of faulted columns according to the fault type. We then proceed to draw the number of faulted bits per faulted column. The number of faulted columns in the same burst window is decided by computing the probability that we see only one faulted column in the burst and sampling from this distribution. If multiple columns are present, we draw the number of affected columns uniformly and allow for up to 8 faulted columns in the burst window. Thus, row faults that affect multiple columns are slightly exaggerated, as the number of faulted columns per burst window would follow a hypergeometric distribution.

A.2 Glossary of Terms

Table 8 lists the symbols and terms used in this paper.

Table 7: The detailed fault classes that we consider in our analysis.

Class	Fault	Bits	Rate
Single-bit	Single-bit	1	55.06%
Multi-bit	Single-word	4	0.325%
	Single-column	4	3.85%
Subsequent	Two-column	8	2.84%
	Single-pin	8	0.67%
Large-scale	Partial row	32	24.345%
	Single row	32	0.26%
	Single row + single bit	32	0.975%
	Two row	32	4.125%
	Consecutive row	32	0.555%
	Cluster row	32	5.7%
	Single bank	32	0.065%

Abstract

In software development, the prevalence of unsafe languages such as C and C++ introduces potential vulnerabilities, especially within the heap, a pivotal component for dynamic memory allocation. Despite its significance, heap management complexities have made heap corruption pervasive, posing severe threats to system security. While prior solutions aiming for temporal and spatial memory safety exhibit overheads deemed impractical, we present SHADOWBOUND, a unique heap memory protection design. At its core, SHADOWBOUND is an efficient out-of-bounds defense that can work with various use-after-free defenses (e.g. MarkUs, FFMalloc, PUMM) without compatibility constraints. We harness a shadow memory-based metadata management mechanism to store heap chunk boundaries and apply customized compiler optimizations tailored for boundary checking. We implemented SHADOWBOUND atop the LLVM framework and integrated three state-of-the-art use-after-free defenses. Our evaluations show that SHADOWBOUND provides robust heap protection with minimal time and memory overhead, suggesting its effectiveness and efficiency in safeguarding real-world programs against prevalent heap vulnerabilities.

1 Introduction

In the domain of software development, a notable majority of programs are developed using unsafe languages, such as C and C++, which while granting detailed control over low-level operations and memory management, also invariably expose them to a range of vulnerabilities. The heap, acting as a critical component for dynamic memory allocation, assumes an essential role in these programs by managing data objects of sizes that are not fixed or predetermined. However, the complexity of heap management has made it a hotspot for vulnerabilities, with heap corruption emerging as a widespread issue [56, 60]. Not only are heap vulnerabilities prevalent, but they also pose severe threats to system security, as they can be exploited to manipulate data, bypass security defenses, and execute arbitrary code, often having serious consequences for affected systems [30, 68, 74]. Consequently, comprehensive heap memory protection is imperative.

A comprehensive heap memory protection system should encompass both the temporal and spatial memory safety, ensuring that use-after-free and out-of-bound vulnerabilities are rendered completely unexploitable through its protection mechanisms. Numerous prior works [24, 39, 45, 46, 51, 75, 76] target this objective, all of which successfully provide both temporal and spatial memory safety. However, all of them suffer from an overhead exceeding 1.5x, rendering them impractical defenses in real-world programs. Additionally, some of them mainly used for bug detection or debugging, are not robust in terms of security [56]. Although these tools are not efficient, some prior works [17, 70, 71] can provide robust temporal memory safety with a low time overhead. Consequently, we believe it is possible to build a comprehensive memory protection system with them.

Inspired by these observations and thoughts, we propose SHADOWBOUND to provide a comprehensive heap memory protection mechanism. The core of SHADOWBOUND is an efficient out-of-bounds defense, designed to prevent the exploitation of out-of-bounds bugs by instrumenting boundary checks into programs. Moreover, it is capable of seamlessly integrating with various Use-After-Free (UAF) defenses without encountering compatibility issues. While the concept behind SHADOWBOUND is straightforward, developing such an out-of-bounds defense is not straightforward. We pinpoint two challenges that necessitate addressing. Firstly, the challenge lies in minimizing the time overhead of the out-of-bounds defense. Secondly, compatibility issues with UAF defenses present a hurdle. Most state-of-the-art UAF defenses necessitate the introduction of a new allocator. Thus, it is beneficial for the out-of-bounds defense to avoid any requirements for the allocation algorithm, consequently contracting the design space. Almost all previous works [27, 33, 34, 36], which focused on spatial memory safety as discussed in Section 2, encountered similar challenges.

We address these challenges through two perspectives. Initially, we designed a shadow memory-based metadata management mechanism to store the boundary of each pointer's corresponding heap chunk. This strategy ensures that SHADOWBOUND necessitates only a single load instruction and a handful of arithmetic instructions to extract boundaries during checks. Moreover, the shadow memory is orthogonal to the allocation algorithm, thereby enabling its integration with various allocators, specifically those utilized in UAF defense. Such a design lays the foundational framework for constructing an efficient and comprehensive heap memory protection mechanism.

Building upon the established foundation, we deployed a series of customized compiler optimizations, specifically

tailored for boundary checking. Unlike traditional methods, which instrument boundary checking at the point of pointer dereference, SHADOWBOUND instruments these checks at the site of pointer arithmetic, thereby facilitating easier optimization. Generally, a compiler can retrieve more information at the pointer arithmetic site. At the pointer dereference site, the pointer might be passed externally, which hinders the compiler from fetching any of the pointer's properties. Conversely, the compiler can consistently utilize the computing process information at the pointer arithmetic site. We designed five optimizations based on this information, which significantly reduce the time overhead of SHADOWBOUND.

We implemented SHADOWBOUND atop LLVM 15 and integrated it with three state-of-the-art UAF defense mechanisms: PUMM [71], FFMalloc [70], and MarkUs [17]. To understand its security and practicality implications, SHADOWBOUND was applied to common benchmarks and real-world programs. Specifically, we utilized SHADOWBOUND to safeguard 19 programs against 34 exploitable out-of-bound bugs. With the protection provided by SHADOWBOUND, all exploits were successfully mitigated. Additionally, we undertook synthesis vulnerability testing, generating 244 inputs to trigger out-of-bounds bugs in various ways. Furthermore, SHADOWBOUND successfully prevented the triggering of these bugs. For performance evaluation, we assessed SHADOWBOUND using the SPEC CPU2017 and SPEC CPU2006 benchmark suites, as well as three real-world applications: Nginx, Chakra, and Chromium. SHADOWBOUND exhibits a 5.72% and 10.58% time overhead on SPEC CPU2017 and SPEC CPU2006, respectively, and introduces negligible overhead to the tested real-world programs.

In summary, this paper provides the following contributions:

- We introduce SHADOWBOUND, which employs a novel metadata design utilizing a compact method to encode boundary information in shadow memory. This approach enables SHADOWBOUND to quickly fetch the boundaries of a pointer, thereby making it compatible with various Use-After-Free (UAF) defenses and providing both spatial and temporal safety with minimal overhead.
- We propose a series of novel optimization techniques customized for boundary checking at pointer arithmetic sites, significantly reducing time overhead. These optimizations have been implemented in SHADOWBOUND, based on LLVM 15. An ablation study demonstrates their effectiveness in reducing time overhead.
- Through a thorough evaluation, SHADOWBOUND has been proven to offer robust spatial memory protection in various environments. It consistently maintains minimal time and memory overhead across a spectrum of benchmarks and real-world applications, affirming its full compatibility with three state-of-the-art UAF defenses.

	Associated Address	Access	Exp?
S1	Inaccessible	Crash	✖
S2	Accessible & No Overlap	Benign	✖
S3	Accessible & Overlap	Data Leakage or Corruption	✔

Table 1: Consequences of heap out-of-bounds bugs.

2 Background & Design Overview

2.1 Heap Memory Protection

A comprehensive heap memory protection mechanism should ensure both temporal and spatial memory safety for a program. In the realm of temporal memory safety, several Use-After-Free (UAF) defenses stand out for their remarkable performance, notably state-of-the-art solutions such as MarkUs [17], FFMalloc [70], and PUMM [71]. These tools provide full temporal memory safety, setting them apart from partial or probabilistic memory protection methods [43,47,54,55]. Moreover, they outperform many of their predecessors. For instance, MarkUs leverages a garbage collection algorithm to identify live pointers, thereby preventing the creation of dangling pointers and offering improved performance compared to earlier solutions [40,53]. FFMalloc introduces an efficient one-time-allocation (OTA) allocator strategy, surpassing older solutions like Oscar [22] and other OTA allocators [23]. PUMM, in contrast, utilizes static analysis to pinpoint code units in charge of specific tasks, deferring the reallocation of memory freed by the active unit until it finishes its operations.

However, even with these advanced temporal memory protection mechanisms in place, the challenge of developing a comprehensive heap memory protection mechanism persists due to the absence of an adequate spatial memory protection mechanism. For instance, tools like MEMCHECK [46], TAILCHECK [27], ASAN [51] and its variants [75,76] are redzone-based spatial memory error detection systems, which are vulnerable to bypasses [56]. While ESAN [24,36], SoftBound [45], and PACMEM [39] offer robust spatial memory protection, they still suffer from significant time overheads. Moreover, the designs of TAILCHECK, ASAN, and ESAN require a custom allocation algorithm to adjust the heap layout for out-of-bound checking. This can lead to conflicts when UAF defense introduces new allocators, such as MarkUs and FFMalloc. Although tools like DeltaPointer [33] and SGXBound [34] are relatively more efficient in terms of time overhead, they limit memory allocation to 4GB. Considering that UAF defense also amplifies memory overheads, this hinders their utility in large-scale applications.

2.2 Out-Of-Bounds Exploitation

Out-of-bounds vulnerability is a specific manifestation of spatial errors. Depending on the behavior of a program and the logic of the memory allocator, the consequences of a heap out-of-bounds bug can vary significantly. We present a comprehensive summary of these potential consequences in Table

1, where the associated address refers to the memory address involved in an out-of-bounds read or write instruction. If the system has removed permission to access the associated address (S1), the out-of-bounds access will trigger a page fault and result in a crash. Another consequence is when the address remains accessible but still falls within the original heap chunk, without overlapping with other heap chunks or the freed regions (S2). This situation can occur because most allocators align the size of each heap chunk to 8 or 16 bytes, so they allocate more memory space than the program initially requested. Consequently, out-of-bounds access within such a region may happen. In the final scenario, the memory remains accessible, and the associated address may overlap with another region (S3), including other heap chunks, freed regions, or even extending beyond the heap boundary.

The bug in S1 is inherently non-exploitable, as it consistently results in a crash. In S2, despite the presence of an out-of-bounds bug within the logic of the program, such out-of-bounds access will never occur due to the extra space allocated by the allocator. In these instances, we can assume that the allocator "fixes" the bug. Conversely, an out-of-bounds error in S3 is notably susceptible to exploitation. An attacker can strategically manipulate the layout of the heap, causing the associated address to overlap with critical data. This could lead to data leakage, corruption, or even enable privilege escalation, compromising the entire system. To exploit an out-of-bounds bug in S3, the attacker must first create an out-of-bounds pointer and subsequently attempt to trigger a dereference with this pointer. If we can detect or eliminate the creation of out-of-bounds pointers that may be dereferenced later, any exploitation attempt will be rendered ineffective. SHADOWBOUND follows such a line of thought, which can defend against out-of-bounds exploitation by either transferring the S3 to S1/S2 or detecting all S3.

2.3 Design Overview

SHADOWBOUND diligently works to prevent the exploitation of out-of-bounds bugs by instrumenting boundary checks into programs. It encompasses two principal modules: the metadata management module and the compiler module. The metadata management module maintains shadow memory, recording the boundaries of each pointer's corresponding heap chunk within the shadow memory at allocation sites. Concurrently, the compiler module instruments boundary-checking instructions at pointer arithmetic sites, precluding the generation of out-of-bounds pointers. Additionally, optimization is an essential role of the compiler module; it employs a suite of customized optimization techniques, specifically tailored for boundary checking, which ensures SHADOWBOUND incurs very low time overhead. Notably, both modules are meticulously designed to guarantee seamless integration with various UAF defenses, enabling SHADOWBOUND to collaborate with other UAF defenses to provide exhaustive heap protection.

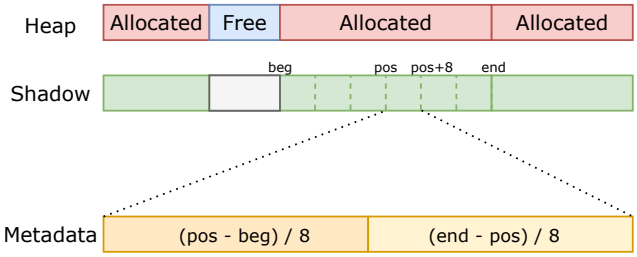

Figure 1: Shadow Memory Mapping and Metadata Layout

3 Threat Model

SHADOWBOUND can be deployed either in conjunction with other UAF defense mechanisms or independently. When deployed alongside other UAF defenses, it is presumed that the target program contains one or more heap out-of-bounds and use-after-free vulnerabilities. If SHADOWBOUND is used independently, the assumption is limited to the presence of heap out-of-bounds vulnerabilities. In this threat model, an attacker can only attempt to exploit these vulnerabilities to potentially escalate privileges. Our goal is to prevent these vulnerabilities to being exploitable.

We assume the shadow memory will not compromise the security for three reasons. First, doing so would require exploiting vulnerabilities in our concise and robust shadow memory management code, which comprises less than 100 lines, giving us confidence in its security. Second, compromising the system in another way would necessitate exploiting a program vulnerability that allows an underflow write, overcoming a substantial 4TB space between the heap and shadow memory. This level of intrusion would require sophisticated exploitation primitives, which SHADOWBOUND is designed to detect and thwart preemptively. Finally, the attacker has no chance to infer the shadow memory addresses of objects. Since the attacker can only exploit vulnerabilities to leak some information, similar to the second reason then exploitation will be detected by SHADOWBOUND.

4 Metadata Management

In this section, we introduce our metadata management design, covering its layout, creation process, and how SHADOWBOUND leverages this metadata to enhance program security. We will also discuss the compatibility of metadata management with various UAF defense mechanisms.

4.1 Shadow Memory Layout

SHADOWBOUND utilizes shadow memory to track the boundaries of each pointer's corresponding heap chunk in the program. As shown in Figure 1, SHADOWBOUND maps each aligned 8 bytes of the program's heap memory into 8 bytes of shadow memory. Within this shadow memory representation, the front 4 bytes are dedicated to storing one-eighth of the length from the aligned 8 bytes to the beginning of the respective heap chunk. Conversely, the back 4 bytes are used

```
1 void foo(void *ptr, int n) {
2     bound_check(ptr, ptr + sizeof(int));
3     int *arr = (int *) ptr;
4
5     for (int i = 0; i < n; ++i) {
6         bound_check(arr, arr + i + 1);
7         other_function(&arr[i]);
8     }
9 }
```

Listing 1: Example: Instrumentation of SHADOWBOUND

```
1 void bound_check(uint64_t old, uint64_t res) {
2     if (!IsHeapAddress(old)) return;
3     uint64_t align = old & ~7;
4     uint64_t shadow = align + OFFSET;
5     uint64_t pack = *(uint64_t*) shadow;
6     uint64_t beg = align - ((pack & 0xffffffff) << 3);
7     uint64_t end = align + ((pack >> 32) << 3);
8     if (res < beg || res >= end)
9         error("Heap out-of-bounds Detected");
10 }
```

Listing 2: Pseudocode for boundary checking

to record one-eighth of the length from the aligned 8 bytes to the end of the corresponding heap chunk. The creation and initialization of shadow memory occur immediately following the allocation operation. The feasibility of this design stems from two fundamental observations.

Firstly, nearly all mainstream allocators, such as ptmalloc [62], tcmalloc [31], and jemalloc [18], default to 8-byte or 16-byte aligned allocations. This intrinsic behavior ensures that any valid 8-byte aligned memory address always belongs to the same memory chunk. Consequently, there is no need to maintain boundary information for every byte; instead, we can efficiently store the boundary information for every 8-byte aligned block. This approach significantly optimizes memory usage. The second observation is that the maximum single-time allocation size for these allocators is limited to 8 GB (2^{33} bits). AddressSanitizer [51]'s default allocator also has such a feature. Building upon the previous observation, we can deduce that the length between any 8-byte aligned block and the beginning or end of the corresponding chunk is always a multiple of 8. Hence, 30 bits are sufficient to store this length information, and we can use 8 bytes or 64 bits to store both length values.

4.2 Boundary Checking

As mentioned in subsection 2.3, unlike traditional checking methods that instrument checking instructions at the pointer dereference site, SHADOWBOUND instruments these checks at the pointer arithmetic site. LLVM provides two types of pointer arithmetic instructions. The `getelementptr` (GEP) instruction takes a base pointer and a set of indices to calculate the result pointer. If these indices are not properly checked, an attacker can exploit a GEP to perform an out-of-bounds access. The `bitcast` instruction (BC) allows the conversion of a base pointer from one type to a result pointer with another type. However, if the pointer cannot sufficiently accommodate the target type, it may potentially result in an overflow issue. Listing 1 provides an example of how SHADOWBOUND checks these two types of instructions. In line 3 of the code, an attempt is made to convert a `void*` pointer to an `int*` pointer. To ensure that the resulting pointer can hold at least one integer, SHADOWBOUND inserts a check at line 2. In line 6, a new pointer is generated, and SHADOWBOUND inserts a check to ensure that the new pointer and the old pointer are located within the same memory chunk.

The pseudocode for the boundary check, as shown in Listing 2, describes a checking function that takes two parameters. The function first checks if the pointer is located in the heap region (Line 2). If so, it aligns the base pointer to an 8-byte boundary and calculates the corresponding shadow memory address (Lines 3-4). It then loads the metadata from the shadow memory (Line 5). The next two lines calculate the boundary. Specifically, for the beginning address, the lower 32 bits of the metadata are taken and shifted left by 3 (effectively multiplying by 8) to get the actual distance from the aligned address to the beginning of the corresponding heap, and then this distance is subtracted from the aligned address to determine the beginning address (Line 6). Conversely, for the end address, the upper 32 bits are taken and shifted left by 3 to get the distance from the aligned address to the end of the corresponding heap, then this distance is added to the aligned address to obtain the end address (Line 7). Finally, the function verifies whether the result pointer falls outside these computed boundaries (Line 8). If the result pointer is less than the starting address or greater than or equal to the ending address, it triggers an error, leading to program termination. Due to the boundary-checking code's reliance on just a single load instruction and a handful of arithmetic operations, the verification process is exceptionally quick, resulting in minimal execution time.

4.3 Compatibility with UAF Defense

SHADOWBOUND introduces continuous memory as shadow memory to track the boundaries of each heap chunk. This technique empowers SHADOWBOUND to seamlessly integrate with virtually all UAF defense. Within the scope of this research paper, we have successfully integrated three state-of-the-art UAF defenses into SHADOWBOUND, MarkUs [17], FFMalloc [70], and PUMM [71]. Each of these defenses implements a secure allocator, which means they need to modify the allocation algorithms, potentially resulting in changes to the heap layout. It's noteworthy that the shadow memory operates independently of the allocation algorithm and heap layout. This ensures that SHADOWBOUND does not conflict with the design of secure allocators.

In addition to secure allocators, some research employs pointer invalidation algorithms for UAF defense [38, 65, 72]. While this approach may not currently provide optimal performance, there is potential for improvement in its effectiveness in the future. Consequently, we also demonstrate SHADOW-

```
1  struct obj {
2      int x, y, z;
3  };
4  void foo() {
5      char *c = malloc(3 * sizeof(int));
6      struct obj* o = malloc(sizeof(struct obj));
7      ...
8  }
9  void bar(char *c) {
10     c[0] = 'x';
11     c[1] = 'y';
12     c[2] = 'z';
13     escape(c + 1);
14 }
15 void zoo(struct obj *o) {
16     o->x = 1;
17     o->y = 2;
18     o->z = 3;
19 }
```

Listing 3: Example of Runtime-Driven Checking Elimination

BOUND's compatibility with these tools. Typically, these approaches involve tracking all pointers to allocated objects and explicitly invalidating them once the referenced objects are freed, requiring program instrumentation. It's worth noting that SHADOWBOUND also necessitates program instrumentation, but there is no conflict because SHADOWBOUND instruments pointer arithmetic instructions, while they only need to instrument dereference instructions.

5 Compiler Optimization

In this section, we introduce the compiler optimization employed by SHADOWBOUND, which play a important role in reducing time overhead while maintaining robust security.

5.1 Runtime-Driven Checking Elimination

This optimization is based on a simple idea: if each heap chunk has infinite space, out-of-bounds access becomes impossible, rendering all boundary checks redundant and eliminable. The core of this concept relies on the runtime environment's ability to provide the compiler with extra information, enabling it to eliminate specific boundary checks that static analysis techniques alone cannot resolve. By leveraging runtime information, certain optimizations become feasible, empowering the compiler to remove unnecessary boundary checks, and significantly enhancing system efficiency. However, it's impractical to allocate infinite or even very large spaces for every chunk due to the potential for high memory overhead. Therefore, SHADOWBOUND chooses an improved approach to balance time overhead and memory overhead. Specifically, SHADOWBOUND reserves a fixed n bytes for every heap chunk, denoted as reserved space. Then, SHADOWBOUND will try to find all eliminable boundary checks using the reserved space provided by the runtime.

As mentioned in subsection 4.2, SHADOWBOUND inserts boundary checks for every pointer arithmetic instruction. Each instruction contains a base pointer argument and generates a result pointer. These two pointers are used as the arguments

```
1  struct obj {
2      int *a;
3      int len;
4  };
5  void foo(struct obj *o, int len) {
6      // initialize the object
7      o->len = len;
8      o->a = malloc(len * sizeof(int));
9      ...
10 void bar(struct obj *o) {
11     for (int i = 0; i < o->len; ++i)
12         o->a[i] = i;
13 }
```

Listing 4: Example of Security Pattern Identification and Directional Boundary Checking Optimization

passed to the boundary checking. Notably, if the offset between the result pointer and base pointer can be confirmed to be less than n bytes at compile time, and the result pointer will never be used as a base pointer in another boundary checking, SHADOWBOUND can safely remove the boundary checking. This is because SHADOWBOUND already reserves n bytes for every heap chunk, ensuring that every live pointer, which may be used as a base pointer in boundary checking, has at least n bytes of space available.

We can use Listing 3 as an example to illustrate how the optimization works. In the function `bar`, the argument `c` generates three pointers in lines 10 to 12, all with offsets less than 8. If we set n to 8, SHADOWBOUND can safely remove these checks. However, we cannot eliminate the check for line 13 because the pointer `c + 1` is passed to another function, indicating that it may potentially be used as a base pointer for boundary checking in that function. If SHADOWBOUND were to eliminate the boundary check for a pointer that has already pointed to the reserved space, it could lead to false negatives due to the elimination in the `escape` function.

Furthermore, the optimization concept can also be applied to eliminate structure member accesses, as demonstrated in the function `zoo` of Listing 3. The object is allocated at line 6, and the return type of the allocation function is `void*`, not `struct obj*`. Consequently, the compiler inserts a type-casting instruction, which prompts SHADOWBOUND to insert a boundary check to ensure that the allocated memory space can accommodate the structure `obj`. This type-casting validation happens in runtime and allows the compiler to confidently determine that the memory space associated with a typed pointer is at least the size of its type. Consequently, the compiler can infer that pointers referring to structure fields are in-bounds. As a result, SHADOWBOUND can safely eliminate the boundary checks for lines 16 to 18.

5.2 Directional Boundary Checking

The boundary checking of SHADOWBOUND consists of two parts: the underflow check ensures that the memory access address is greater than or equal to the lower boundary of the allocated memory chunk, while the overflow check verifies that the address falls within the upper boundary. We can

observe that during boundary checking, the base pointer is always valid. If not, SHADOWBOUND will throw an error when creating the base pointer and the program terminated. So that if we can determine the sign (positive or negative) of the offset between the base pointer and the result pointer, we can optimize by inserting only one side of the checking code. For instance, in line 12 of Listing 4, the offset variable `i` starts from zero, ensuring that it is always positive, eliminating the need to check for potential underflow pointers.

To implement this optimization, SHADOWBOUND leverages LLVM's range analyzer [42], a powerful tool that provides insights into the possible value ranges of variables during program execution. By analyzing the sign of the offset, we can determine which boundary checks cannot be violated. For instance, if range analysis indicates a consistently positive offset, we optimize by focusing solely on the overflow check, thus eliminating the need for underflow verification. It is worth emphasizing that the use of range analysis also ensures that checked arithmetic instructions will not result in integer overflow (or wraparound), thereby maintaining the security assumption of SHADOWBOUND. This approach is particularly beneficial in sections of code that are loop-intensive, as loops tend to undergo multiple iterations with consistent direction.

5.3 Security Pattern Identification

Many programs frequently employ simple code patterns to prevent out-of-bounds, making it unnecessary to validate code that has already been safeguarded by the original program. In this context, SHADOWBOUND focuses on the identification of two primary patterns: Constant Array Argument and Length-Pointer Association.

Constant Array Argument The pattern is used to describe function arguments, where specific function arguments consistently accept constant-length arrays and the access offset for these arguments is always bound by the same constant. These arguments can be either stack arrays, global arrays, heap arrays, or constant-length arrays within a structure. If the arguments always belong to the first two types, we can directly remove the associated checks, as SHADOWBOUND primarily focuses on heap security. To accomplish this, SHADOWBOUND employs whole-program analysis to identify these function arguments and subsequently eliminates the redundant boundary checks associated with them.

The identification algorithm focuses on functions that are not the target of indirect call instructions. This is because if a function can be the target of an indirect call, it becomes challenging to analyze which properties the function's arguments consistently hold, as we may not be able to identify all call sites for this function. To determine if a function is the target of indirect call instructions, SHADOWBOUND examines every instruction in the program and verifies that the function only appears as the called-function argument in call-related instructions. If the function is stored in memory or passed as a function argument, SHADOWBOUND assumes it might become the target of an indirect call.

After identifying eligible functions, SHADOWBOUND inspects the pointer-type arguments of each function. It traverses the entire program to identify all call sites associated with each function. SHADOWBOUND evaluates each call site to determine whether the function's arguments consistently exhibit the characteristics of a constant length. To simplify the analysis, this assessment revolves around two key criteria: firstly, whether the pointer is instantiated within the same function where the call site is located, and secondly, whether the length of the pointer remains constant. If an argument is discovered to be loaded from memory or supplied as a function argument, SHADOWBOUND refrains from engaging in further recursive analysis and instead assumes that it fails to meet the requisite criteria.

If an argument consistently meets the criteria of being a constant-length pointer after assessing all call sites, SHADOWBOUND proceeds to the final step. In this concluding phase, SHADOWBOUND meticulously examines the pointer arithmetic instructions related to the argument within the corresponding function. It leverages the LLVM range analyzer to confirm that the offsets generated by these instructions are strictly bound by the corresponding constant length. For those arguments that successfully pass all verifications, SHADOWBOUND can confidently eliminate the associated checks.

Length-Pointer Association The Length-Pointer Association pattern is a common structural configuration in programs, characterized by two essential members: one representing a pointer and the other indicating the length of the data pointed to. These two members are referred to as the pointer member and the length member in the pattern. This pattern establishes a direct relationship between the pointer member and the corresponding length member. As demonstrated in Listing 4, through the initialization code at lines 7 to 8 for the structure `obj`, we can discern that the structure `obj` exemplifies this pattern, with `a` serving as a pointer to an integer array and `len` denoting the length of that array.

Identifying the Length-Pointer Association pattern is not always straightforward. For example, the modification for the pointer member and length member may not happen in the same scope, which may require heavy dataflow analysis techniques to address it. To simplify the identification process, we have introduced specific constraints that facilitate recognition. Firstly, both members must consistently undergo modifications within the same scope. Secondly, modifications to these two members should exclusively occur at the allocation or deallocation site. This typically means that the pointer is assigned as the return value of an allocation function or as a null pointer. Finally, the length field must precisely match the allocated memory's size at the allocation site. These constraints streamline the pattern identification process.

SHADOWBOUND follows a systematic process to identify the Length-Pointer Association pattern. Initially, it identifies

```
1  void foo(char *p) {
2      char *a = p + 1;
3      char *b = a + 2;
4      char *c, *d;
5      if (random() > 0.5)
6          c = a + 3;
7      else
8          c = b + 4;
9
10     for (d = c; d < p + 100; d++)
11         *d = 'x';
12 }
```

Listing 5: Example of Merge Metadata Extraction

all allocation function call sites and checks if their return values are assigned to structure members. If this condition is met, SHADOWBOUND further verifies if the length argument of the allocation function call is stored in another structure member. If both conditions are satisfied, SHADOWBOUND assumes the potential presence of the pattern. Subsequently, SHADOWBOUND scans the entire program to determine whether the two members of the structure fulfill all the pattern requirements that we mentioned before at all modification sites.

Upon confirming that these two members match the pattern, it means that the length member consistently indicates the length of the pointer member, SHADOWBOUND proceeds to check all pointer arithmetic instructions that utilize the pointer member as the base pointer. If the offset between the base pointer and the result pointer is safeguarded by the length member, SHADOWBOUND confidently removes the corresponding boundary checks. This meticulous process ensures precise optimization based on the Length-Pointer Association pattern.

5.4 Merge Metadata Extraction

Within its boundary-checking process, SHADOWBOUND employs a two-stage approach, which involves an initial *extraction* stage to obtain the base pointer's boundary, followed by a subsequent *checking* stage to validate the result pointer. It's essential to highlight that the extraction stage is notably more time-consuming than the second stage due to the requirement of a load instruction for extracting metadata from the shadow memory. Importantly, the load address is exclusively determined by the base pointer. Consequently, in cases where multiple result pointers are computed from the same base pointer, it becomes possible to optimize by merging the extraction stage of these result pointers' boundary-checking processes, thereby avoiding redundant address loading.

To maximize the merging of extraction stages, SHADOWBOUND employs a backtrace algorithm. Specifically, SHADOWBOUND enumerates all pointer arithmetic instructions and attempts to backtrack their sources. We illustrate how the algorithm works using Listing 5. We start with the pointer `d`, which is initialized with `c` and then self-incremented, making `d` dependent on `c`. While `c` could be computed from either `a` or `b`, it is evident that both `a` and `b` are ultimately derived from `p`. Consequently, all pointers in the function `foo` are generated from `p`, establishing `p` as the source of pointers `a`, `b`, `c`, and `d`. Once all pointer sources are collected, for those pointers sharing the same source, we insert the boundary extraction code after the source. This eliminates the need to extract the boundary again in the subsequent checking.

5.5 Redundant Checking Elimination

In this subsection, we introduce two common techniques employed by SHADOWBOUND to eliminate redundant checks. The first optimization typically occurs when both the allocation and the pointer arithmetic take place within the same scope, or when the base pointer is an array member of a structure. In such cases, the size of the base pointer is inherently determined by its allocation size or type. Consequently, the compiler can optimize this scenario by comparing the allocation size with the offset between the base pointer and the result pointer. If the offset is consistently smaller than the allocation size, SHADOWBOUND can confidently assert that a pointer arithmetic will never result in an out-of-bounds condition. This empowers SHADOWBOUND to eliminate the corresponding checks effectively.

The second technique entails conducting a thorough analysis of the relationships between pointer arithmetic instructions within a program. In particular, it commences by identifying cases where one pointer arithmetic instruction either dominates or post-dominates another instruction, provided that they share the same base pointer. In such instances, SHADOWBOUND will proceed to compare the offsets of these two pointer arithmetic instructions. If it is consistently observed that the dominated computing instruction's offset is greater than that of the other instruction, then the underflow checking for this instruction can be safely eliminated. Conversely, if it is consistently found that the dominated computing instruction's offset is smaller than that of the other instruction, then the overflow checking for this instruction can be safely eliminated.

6 Implementation

In this section, we describe our implementation of the compiler and runtime support for SHADOWBOUND, as well as our integration of state-of-the-art UAF defense mechanisms into the SHADOWBOUND framework.

6.1 Compiler & Runtime Support

SHADOWBOUND is build upon LLVM 15.0.6 framework [37] and consists of two components. The first, known as the function pass, is responsible for the insertion and optimization of checking instructions at the LLVM Intermediate Representation (IR) level. The second component is the runtime module, designed for shadow memory allocation and the management of associated metadata. These two components work seamlessly together, forming the foundational architecture of SHADOWBOUND.

Function Pass. The function pass is implemented as an internal sanitizer within LLVM. Unlike other sanitizers, such as AddressSanitizer [51] or Memory Sanitizer [59], this tool is not designed to detect a specific class of bugs. Instead, it serves as a defense mechanism. Users can enable SHADOWBOUND using the `-fsanitize=overflow-defense` flag. The function pass collects all pointer arithmetic instructions, including `getelementptr` and `bitcast`, and employs optimization algorithms that are mentioned in section 5 to determine which instructions require checking and how they should be checked.

Given that various optimization methods may interact with each other, an improper optimization sequence could potentially hinder both optimization performance and compilation speed. Therefore, we meticulously select the order in which each optimization method is applied, ensuring that our choices result in the best possible outcome. The function pass begins with Runtime-Driven Checking Elimination, as it effectively eliminates a significant number of checking instructions, reducing the burden for subsequent optimizations. Following that, the function pass executes Redundant Checking Elimination, Security Pattern Identification, and Directional Boundary Checking Optimization in sequence. Finally, the function pass concludes with the Merge Metadata Operation.

It is noteworthy that Security Pattern Identification necessitates a whole-program analysis. However, performing a whole program analysis requires access to information from all functions within the program, whereas the LLVM function pass is limited in its scope, and capable of retrieving information only from the currently processed function. To address this challenge, we have implemented an external analyzer similar to KINT [67]. This analyzer is capable of both dumping and analyzing the IR code of each function, subsequently saving the analysis results to a configuration file before compiling the program. The function pass then accesses and utilizes the information stored in this configuration file for its optimization, ensuring a more holistic approach to security pattern identification and mitigation.

Runtime Module. The runtime module of SHADOWBOUND has two primary functions. First, it manages metadata, which includes the allocation of shadow memory. The size of the shadow memory in SHADOWBOUND is equal to that of the original heap, mirroring the configuration of MemorySanitizer. Thus, our implementation closely resembles MemorySanitizer's shadow allocation method. Moreover, we introduce reserve operations at allocation sites, as detailed in Section 5. Second, the runtime module checks the arguments of frequently used libc functions, such as `memset` and `strcpy`, to guard against heap out-of-bounds incidents within these functions. To instrument the necessary checking code for these libc functions, we use a technique similar to AddressSanitizer. This method effectively identifies the functions needing validation and inspects their arguments for potential out-of-bounds access.

Table 2: Heap out-of-bounds Prevention Results for SHADOWBOUND on Real-World Vulnabilities.

6.2 UAF Defense Integration

As discussed in subsection 4.3, SHADOWBOUND theoretically can collaborate with three state-of-the-art UAF defense tools: MarkUs, FFMalloc, and PUMM. In this subsection, we delve into the implementation of each tool and present how we seamlessly integrate them within the SHADOWBOUND framework, showcasing the integration achieved with minimal effort.

Both MarkUs and FFMalloc introduce new allocators. However, we encountered a challenge in which the heap region utilized by these allocators conflicted with our shadow memory region. Specifically, we designate two separate regions for the heap and shadow memory. The original heap memory of FFMalloc and Markus is not allocated within these regions. Therefore, we modify the code to adjust the heap region. It is important to note that we do not alter their allocation algorithm; we merely "shift" the allocated objects. Furthermore, we implemented code to facilitate the allocation and initialization of shadow memory after each allocation function. This adjustment ensured that these allocators gained the ability to allocate shadow memory for each heap chunk and initialize it.

The implementation of PUMM differs from that of MarkUs and FFMalloc. Instead of creating a new allocator, PUMM wraps the original allocator. This wrapping mechanism involves deferring specific deallocation operations based on a policy. PUMM generates this policy through binary-based analysis, which obviates the necessity for many modifications to enable integration. To integrate PUMM, our approach entails compiling the program with SHADOWBOUND and then utilizing PUMM to analyze the binary and generate the policy. Subsequently, PUMM can wrap the program's allocator by the generated policy.

7 Evaluation

In this section, we address three key questions to assess the effectiveness and efficiency of SHADOWBOUND:

1. Does SHADOWBOUND effectively prevent heap out-of-bounds-based exploits?
2. What is the quantitative impact of SHADOWBOUND on both runtime performance and memory utilization?
3. How do individual customized compiler optimization algorithms influence time overhead?

All the experiments were conducted on a bare-metal machine configured with Ubuntu 22.04 system, 12th Gen Intel i7-12700 CPU at 4.9 GHz, 32GB RAM, and 1T SSD storage.

7.1 Security Evaluation

Real-World OOB Prevention To validate SHADOWBOUND's ability to prevent real-world heap out-of-bounds-based exploits, we conducted a comprehensive evaluation. This assessment included 34 real-world vulnerabilities; half of them were collected from previous works [75, 76] and MAGMA [28] dataset, while the others were selected from the CVE database [20, 21, 66] and program-specific issue reports. These vulnerabilities spanned a diverse set of 19 applications, encompassing servers, video encoders, language interpreters, widely adopted libraries, and UNIX utilities. For each case, we collected the corresponding Proof of Concept (PoC) that triggers program crashes. We observed how these programs, when compiled with SHADOWBOUND, prevented the associated exploitation attempts.

In Table 2, we present the evaluation results on vulnerabilities selected by us. The results based on vulnerabilities collected from prior works are shown in Table 7 in the Appendix. SHADOWBOUND successfully prevents all cases, demonstrating its capability to prevent real-world heap out-of-bounds-based exploitation. In each case, we observed the three distinct forms through which SHADOWBOUND effectively prevented vulnerabilities: *OOB Detected*, *Benign Running*, and *Transformation*:

- **OOB Detected (OD)**: SHADOWBOUND successfully detects heap out-of-bounds read or write instructions when an attempt is made to compromise a program used as a proof-of-concept (PoC). In simpler terms, SHADOWBOUND acts as a vigilant guard, spotting and halting any unauthorized attempts to access memory beyond its boundaries.
- **Benign Running (BR)**: In certain scenarios, SHADOWBOUND "fixes" the vulnerability by allocating additional memory space for each memory chunk. This extra space transforms what would otherwise be an unauthorized memory access into a legitimate operation, similar to creating an additional safety buffer. We confirmed this using a semi-automatic gdb script. The script fetched both the original requested size and the actual allocated size to determine the address range of the reserved space, and then checked if the out-of-bounds access fell within this range.
- **Transformation (TF)**: SHADOWBOUND transforms heap out-of-bounds vulnerabilities into alternative, non-exploitable forms. During our manual verification process, we observed instances of null-pointer dereferences in these cases. These dereferences occurred because PoCs attempted to dereference pointers loaded from the reserved memory space created by SHADOWBOUND for each memory chunk, and the reserved space is cleared to zero during allocation. Thus, the null-pointer dereference happened.

Program	#Input	#OD	#BR	#TF
cxxflit	1	1	0	0
libpcap	4	2	2	0
libxml2_reader	127	127	0	0
libxml2_xml	61	46	15	0
proj4	3	0	3	0
zstd	48	45	3	0
Total	244	221	23	0

Table 3: Heap out-of-bounds Prevention Results for SHADOWBOUND on Synthesis Vulnerabilities.

Synthesis Vulnerability Prevention To demonstrate SHADOWBOUND's robustness in security, we conducted an extensive evaluation using the RevBugBench dataset [77]. The dataset was originally designed for fuzzing testing and comprises a series of programs, each of which has been injected with over 1,000 distinct vulnerabilities collected from the real world. We employed AFL++ [26] to fuzz each program for 24 hours, generating numerous inputs capable of triggering program crashes. Subsequently, we assessed the prevention ability by using these inputs. It's essential to clarify that although the vulnerabilities were sourced from real-world cases, they might not appear at the same time in the real world. Therefore, these vulnerabilities triggered by inputs are synthetic but they are very close to real-world vulnerabilities.

Furthermore, recognizing that not all inputs result in heap out-of-bounds errors and certain inputs might execute the same program path, we implemented input refinement using the following methodology. Initially, we employed ASAN to discern inputs that cannot trigger heap out-of-bounds errors. For instance, inputs that solely lead to stack out-of-bounds or null-pointer dereference issues were automatically filtered out. Notably, every input will be considered unique if it has a distinct execution path leading to the final crash site. This is because even if another input results in the same crash site, their execution paths may diverge. Consequently, one of the redundant inputs was removed. The identification of triggered bug sets was facilitated by RevBugBench when provided with the program and inputs.

Following the meticulous cleanup process, we confirmed

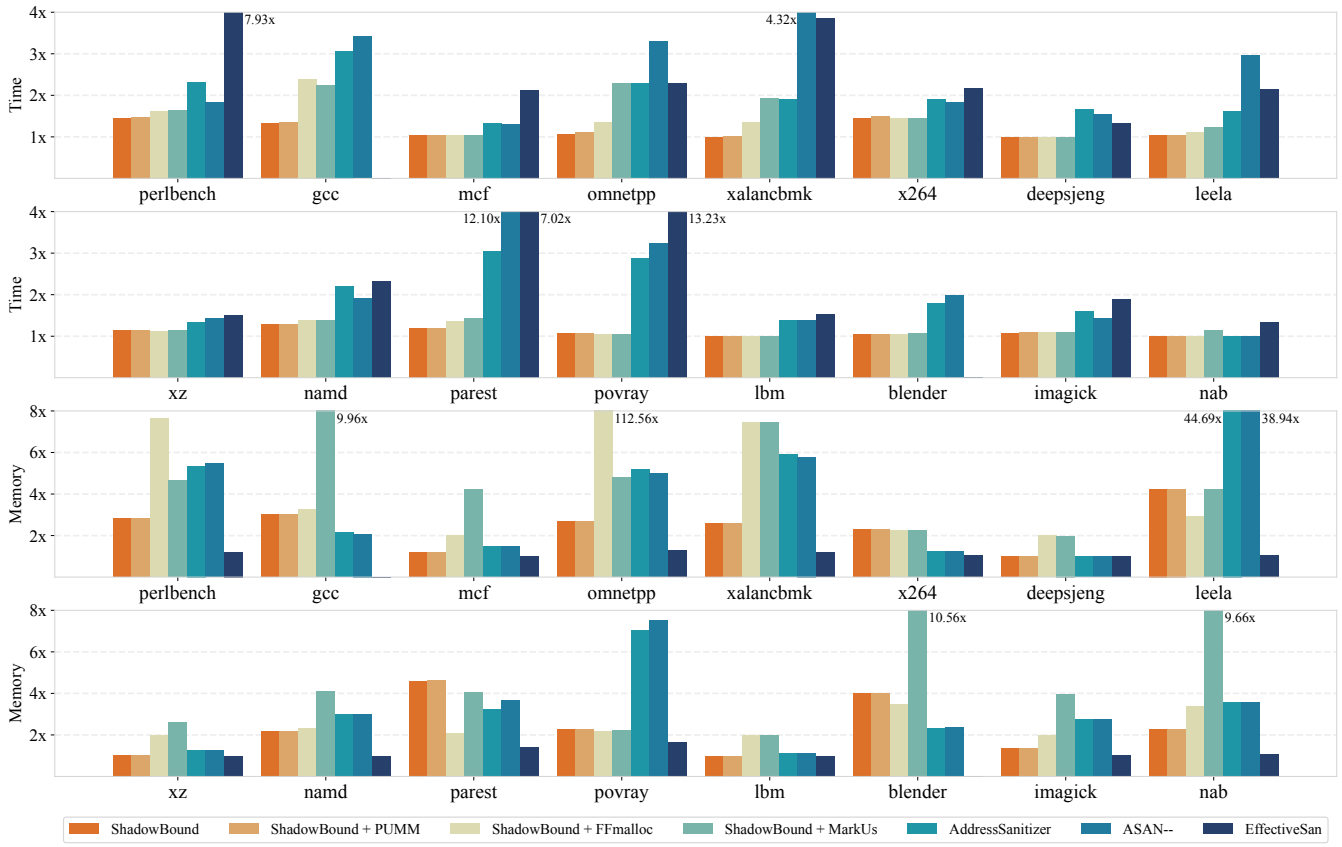

Figure 2: The time and memory overhead of SHADOWBOUND, SHADOWBOUND + PUMM, SHADOWBOUND + FFMalloc, SHADOWBOUND + MarkUs, AddressSanitizer, ASAN−−, ESAN on SPEC CPU2017. The upper two lines represent the results for time overhead, while the lower two outline the results for memory overhead. A value of 1x signifies no overhead. The geomean time overhead of each system is 5.72%, 6.60%, 9.95%, 16.20%, 62.03%, 79.85% and 138.76%. The geomean memory overhead of each system is 54.59%, 55.29%, 218.20%, 302.51%, 116.55%, 112.33%, 2.70%.

that all remaining inputs are indeed able to trigger heap out-of-bounds errors, with each input following a distinct trigger path. Subsequently, we compiled the benchmark programs with SHADOWBOUND and conducted testing using these inputs. The results, as detailed in Table 3, showcased SHADOWBOUND's effective prevention of these errors, with the majority being detected (#OD), while the remaining inputs allowed the program to execute without issues (#BR). All the benign running cases were also confirmed by the gdb script mentioned previously. Unlike our observations in real-world bug evaluations, we did not encounter any instances of *Transformation* (#TF), which we believe is normal given its dependency on the underlying program's logic.

7.2 Performance Comparison

SPEC CPU Benchmark To perform a comparative analysis between SHADOWBOUND and related tools that offer comprehensive heap memory protection, including both out-of-bounds (OOB) and Use-After-Free (UAF) defense, we integrated three state-of-the-art UAF defense tools: PUMM, FFMalloc, and MarkUs with SHADOWBOUND. We then conducted an extensive evaluation, including benchmarking against established tools such as ESAN, AddressSanitizer, MEMCHECK, and ASAN−−, using the SPEC CPU2017 suite [58]. To provide clarity regarding the overhead introduced by SHADOWBOUND itself, we also present results for SHADOWBOUND performance on SPEC CPU2017. Furthermore, we compared SHADOWBOUND with DeltaPointer, the state-of-the-art tool primarily focused on out-of-bounds detection. However, it's worth noting that DeltaPointer exclusively supports SPEC CPU2006 [57], and our attempts to migrate it to SPEC CPU2017 were unsuccessful. Consequently, our comparison between SHADOWBOUND and DeltaPointer is based on SPEC CPU2006. Regrettably, due to code compatibility issues, we had to exclude `471.omnetpp` and `401.bzip2` from the SPEC CPU2006 cases, as LLVM 15 failed to compile these benchmarks due to these codes are too old. To ensure fairness in our comparisons, we configured all tools to disregard detected errors, preventing premature termination. Additionally, we only enabled ASAN−−, ESAN, and AddressSanitizer's heap error detector. In our evaluation, we excluded PACMem and SGXBound due to their reliance on

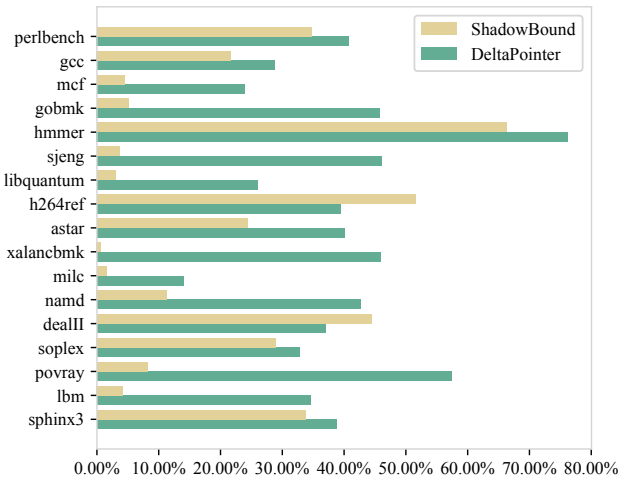

Figure 3: The runtime overhead of SHADOWBOUND and DeltaPointer on SPEC CPU2006, the geometric mean overhead of each system is 10.58% and 37.08%.

specialized hardware for heap memory error detection, as well as the unavailability of their source code. For each tool, we executed the benchmarks ten times and reported the average results to mitigate the impact of randomness.

Figure 2 presents the results obtained from evaluating SPEC CPU2017 benchmarks. Notably, ESAN encountered issues and failed to execute the `gcc` and `blender` benchmarks. As for MEMCHECK, it exhibited a significant performance slowdown of over 4x in every test case, its geomean time and memory overhead is 2426.66% and 92.95%, rendering its results unfit for inclusion in the figure. Furthermore, it is worth highlighting that both ASAN−− and ESAN's results were inferior to AddressSanitizer. This discrepancy is attributed to the fact that AddressSanitizer in LLVM 15 deployed more advanced optimizations, whereas ASAN−− and ESAN are based on older LLVM versions. The time overhead of SHADOWBOUND itself is 5.72%, which demonstrates the efficiency of SHADOWBOUND. All three variants of SHADOWBOUND also performed admirably. In particular, SHADOWBOUND + PUMM demonstrated the lowest average overhead (6.60%), surpassing all tools that provide comprehensive heap memory protection. The memory overhead of SHADOWBOUND itself averaged at 54.59%, and SHADOWBOUND + PUMM also exhibited the best memory overhead among all variants, better than ASAN and ASAN−−. While it is slightly higher than that of ESAN, we believe it is acceptable given the notable performance improvements it offers.

To enhance our understanding of the scalability and performance implications of SHADOWBOUND, we measured several parameters related to heap usage. These include the number of instrumentation points, the number of allocation and deallocation operations per second, the amount of shadow memory allocated for each program, and both heap allocation and access frequencies (see Figure 6 in the Appendix). These measurements were obtained by inserting counting instructions following each load and store operation, as well as allocation and deallocation functions. We conducted linear regression to determine how significantly these parameters affect the performance overhead. We found that performance is most closely related to the frequency of heap access. The regression coefficients for other parameters are close to zero, indicating that they have little or no real relationship with time overhead. Based on the frequency of heap accesses, we used 1GHz, 2GHz, and 3GHz as thresholds to categorize the programs into four groups: *lightweight*, *normal*, *heavy*, and *intensive* heap access. We found the geometric mean time overhead of each group is 2.35%, 3.58%, 6.52%, and 29.66%, respectively. This tiered classification also demonstrates a direct correlation between the intensity of heap access and the performance overhead. Based on the evaluation result, it becomes evident that its adoption is particularly advantageous for lightweight, normal and heavy heap access scenarios, where the method's low to moderate performance overhead can enhance security and monitoring without significantly impacting functionality. On the other hand, for data-intensive and high-performance computing applications, which fall into the intensive heap access categories, the method's higher performance overhead necessitates a more cautious approach.

Figure 3 presents the time overhead of SHADOWBOUND and DeltaPointer on SPEC2006. SHADOWBOUND exhibits lower overhead in nearly all test cases, with the exceptions being `h264ref` and `dealII`. The geometric mean of the time overhead for SHADOWBOUND is also significantly better than that of DeltaPointer. In terms of memory overhead, DeltaPointer achieves an average memory overhead of zero, while SHADOWBOUND incurs an average memory overhead of 68.21%, which is higher than DeltaPointer. It's worth mentioning that while DeltaPointer may have lower memory overhead, it restricts available address space to 4GB, limiting its scalability for large-scale programs. Additionally, DeltaPointer does not provide defense against underflow errors, whereas SHADOWBOUND offers improved security in this regard.

Regarding the variation in time overhead observed in SPEC CPU2006 and SPEC CPU2017, which stand at 10.58% and 5.72% respectively, we have identified the cause. This discrepancy arises from certain test cases within SPEC2006, such as `hmmer`, `dealII`, and `h264ref`, which contain functions exhibiting distinctive patterns that are challenging for SHADOWBOUND to optimize effectively. To exacerbate matters, the test input often leads to these functions consuming over 50% of the program's execution time, amplifying the impact of the instrumentation. However, we believe that these issues are more prevalent in smaller-scale programs. Our subsequent experiments demonstrate that larger-scale programs are less likely to encounter such problems.

NGINX To assess SHADOWBOUND's performance in a real-world, large-scale application, we conducted experiments using Nginx v1.22.1 and the wrk v4.2.0 benchmarking tool. These experiments utilized a configuration of 8 threads, 100

System	Output	Latency (μs)				
	(req/s)	Average	50%	75%	90%	99%

SB + PUMM	79,229	1220	1200	1220	1270	1460

Table 4: Evaluation Results of Native, SHADOWBOUND and its variants: Output and Latency Analysis on Nginx. In the Latency column, Average denotes the average latency of the requested connections, while the remaining values depict latency distribution.

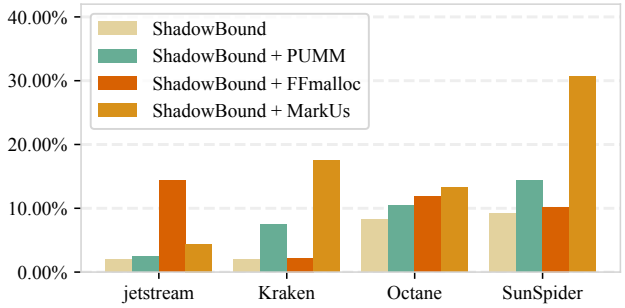

Figure 4: Runtime overhead comparison of SHADOWBOUND and its variants on the Chakra engine: The geometric mean overhead for each system is 4.17%, 7.28%, 7.86%, 13.28%.

connections, and a test duration of 60 seconds. To ensure consistency, we repeated the test 30 times and recorded the average results. The findings are presented in Table 4. SHADOWBOUND experiences 6.47% and 2.54% time overhead for the average and tail (99%) latencies, respectively; these results illustrate SHADOWBOUND's efficiency and practicality in real-world applications. Among variants of SHADOWBOUND, SHADOWBOUND + MarkUs delivers the best performance, experiencing 27.23% and 18.98% time overhead for the average and tail latencies, respectively.

Chakra In addition to Nginx, we also evaluated the performance of SHADOWBOUND, as well as SHADOWBOUND + PUMM, SHADOWBOUND + FFMalloc and SHADOWBOUND + MarkUs on the Chakra. Chakra is a high-performance JavaScript engine developed by Microsoft. Our assessment encompassed four key benchmarks integrated into Chakra: Octane, Kraken, SunSpider, and JetStream. As depicted in Figure 4, our evaluation demonstrates that SHADOWBOUND consistently delivers excellent performance on the Chakra platform. The results indicate that SHADOWBOUND introduces minimal overhead, showcasing its robust compatibility with real-world applications. Particularly noteworthy is the performance of SHADOWBOUND + PUMM and SHADOWBOUND + FFMalloc, which demonstrates exceptional efficiency. These findings underscore SHADOWBOUND's capability to deliver acceptable overheads on large-scale applications.

Table 5: Runtime overhead on Chromium: website loading times and JavaScript benchmarks.

Chromium To assess the performance and compatibility of SHADOWBOUND, we conducted an evaluation using the Chromium browser. Chromium is one of the largest and most widely used software, making it an ideal candidate for showcasing SHADOWBOUND's capabilities. We employed three JavaScript benchmarks, Octane, Kraken, and SunSpider, to test SHADOWBOUND's performance. Additionally, we measured the loading times of the 9 most popular websites according to the Top Websites Ranking [63], a critical metric for enhancing the browsing experience. To ensure accurate loading time measurements, we recorded the average loading time for the nine most popular websites.

It is important to note that during our experiments, we encountered difficulties when attempting to dynamically load the allocators for FFMalloc and MarkUs into Chromium; Chromium immediately raised a segmentation fault upon running the program. According to the stack trace, FFMalloc aborted at the re-allocation function, and MarkUs aborted when creating the new thread. Additionally, PUMM requires fuzzing the program and analyzing the trace files. However, PUMM's analysis algorithm proved to be very slow and memory-consuming in our experiments. We attempted analysis for over 24 hours, yet PUMM still failed to produce results and ran out of memory. Consequently, we are presenting results exclusively for the SHADOWBOUND. Our evaluation includes three benchmarks integrated into Chromium and assesses the access speed of nine popular websites. For each benchmark experiment, we conducted 30 repetitions and calculated the geometric mean values to mitigate the impact of random variations. The results are presented in Table 5.Nearly all website loading time overheads remained below 5%, demonstrating that SHADOWBOUND has minimal influence on the browsing experience for users.

7.3 Ablation Study

In our evaluation of SHADOWBOUND's performance on the SPEC CPU2017 suite, we demonstrate the system's perfor-

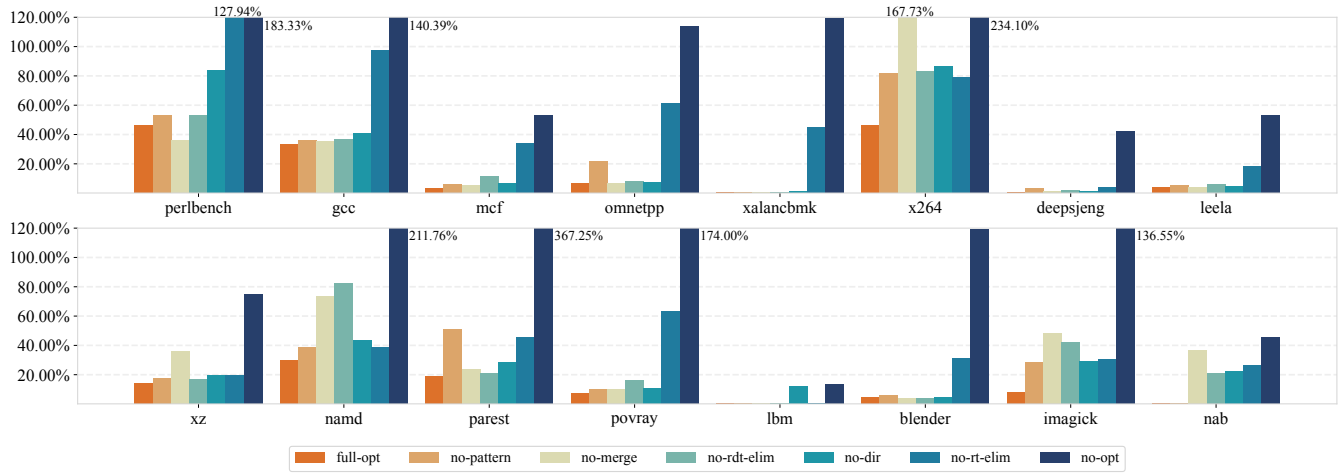

Figure 5: Ablation study result of SHADOWBOUND on SPEC CPU2017. From left to right, the bars show the time overhead of SHADOWBOUND with full optimization, SHADOWBOUND with each optimization disabled, and SHADOWBOUND without optimization. The geomean value of each setting is 5.72%, 9.51%, 11.56%, 11.76% 12.86%, 29.28% and 99.69%.

mance with full optimization enabled. These optimizations include Runtime-Driven Checking Elimination (rt-elim), Directional Boundary Checking (dir), Security Pattern Identification (pattern), Merge Metadata Operation (merge), and Redundant Checking Elimination (rdt-elim). To isolate the effects of each optimization, we conducted an ablation study consisting of seven experiments. Five of these experiments involved disabling one of these optimizations, while two additional experiments enabled or disabled all optimizations together. These experiments provided valuable insights into the system's complete capabilities and its original performance, allowing us to precisely measure the contributions of each optimization to system performance.

The results presented in Figure 5 highlight the significant performance improvements achieved with SHADOWBOUND's optimizations, compared to scenarios without them. The optimization reduces overhead from 99.69% to 5.72%. Among these optimizations, Runtime-Driven Checking Elimination stands out; without it, the overhead increases to 29.28%. Disabling other optimizations, specifically Directional Boundary Checking Optimization, Merge Metadata Extraction, Redundant Checking Elimination, and Security Pattern Identification, results in overheads of 12.86%, 11.76%, 11.56%, and 9.51%, respectively. While the effectiveness of these optimizations may vary across different test cases, each one is essential in the majority of them. These results emphasize the importance of these optimizations in enhancing SHADOWBOUND's performance. Furthermore, the results indicate that moving the checking position from pointer dereference to pointer arithmetic itself does not reduce overhead. As shown in subsection 7.2, the overhead for ASAN is 62.03%, and the overhead for unoptimized SHADOWBOUND is 99.69%. The primary difference between them lies in the checking position. Therefore, performing checks at the point of pointer arithmetic does not lead to a reduction in overhead.

8 Discussion

Intra-Object Out-Of-Bounds As SHADOWBOUND checks at the granularity of heap chunks or objects, which is determined at the time of allocation, it does not provide support for preventing out-of-bounds errors that occur within the same object. For instance, it cannot prevent an out-of-bounds access from one array field to another field within the same structure. Consequently, SHADOWBOUND shares the same weakness as prior works [24, 32, 33, 36, 39, 51]. The boundary within an object's inner fields is not determined by the allocated size but rather by the object's type. If desired, SHADOWBOUND has the capability to relocate shadow memory initialization from the allocation site to the type casting site. We will consider this as a potential area for future work.

Pointer Casting Given that SHADOWBOUND relies on pointers for boundary checking, it's important to note that developers can write code containing implicit type casts and pointer-integer conversions in low-level languages like C/C++. For implicit type casts, although C/C++ allows this practice, a properly configured LLVM always generates an explicit type casting instruction [49]. Therefore, SHADOWBOUND can effectively handle implicit type casts. With regard to the conversion between pointers and integers, there is potential for out-of-bounds issues during integer computation instructions. This vulnerability is also noted in several prior works [24, 36, 45, 73]. However, it's crucial to emphasize that developers typically have benign intentions, and some established C/C++ standards [44, 64] discourage conversions between integers and pointers unless the developers have a comprehensive understanding of the potential consequences. Consequently, occurrences of such errors are exceptionally rare. In fact, during our extensive evaluation, we did not encounter any such cases. Nevertheless, we acknowledge this as a potential source of false negatives.

Stack Protection While the design of SHADOWBOUND does not provide protection against stack out-of-bounds vulnerabilities, it is indeed feasible to enhance SHADOWBOUND's capabilities in this regard. LLVM IR employs explicit instructions for allocating objects on the stack. Consequently, SHADOWBOUND can establish the bounds of stack objects by storing this information in the shadow memory at the time of stack allocation. Alternatively, SHADOWBOUND can be integrated with mature solutions such as shadow memory-based solutions [19, 35], hardware-based solutions (e.g., ARM PA [61]), or hybrid solutions (e.g., Intel CET [52]). Even though these solutions also use shadow memory, SHADOWBOUND was designed with the possibility of integration in mind, so the shadow memory region of the stack is reserved. We believe that these methods are sufficient to protect the stack from attacks such as Return-Oriented Programming (ROP) while providing minimal overhead.

Dynamic Library SHADOWBOUND is capable of safeguarding a dynamic library, provided it has been instrumented by our tool. Should a dynamic library not undergo instrumentation, SHADOWBOUND retains the ability to detect out-of-bounds errors occurring externally. For instance, if a pointer originating within the library triggers an overflow outside of it, SHADOWBOUND can identify such errors. This is due to SHADOWBOUND's comprehensive monitoring of all memory management APIs, enabling precise tracking of every object's boundaries.

Future Optimization SHADOWBOUND still possesses optimization potential in both compiler optimization and metadata management aspects. Regarding compiler optimization, SHADOWBOUND does not fully harness the capabilities of Link-Time Optimization (LTO) [41] and Profile Guided Optimization (PGO) [50]. We believe that boundary checking can be further optimized by leveraging additional interprocedural analysis techniques and profiling feedback data. In terms of metadata management, given that SHADOWBOUND is a pure software solution, metadata extraction can be further enhanced by incorporating certain hardware features to maintain the metadata, such as Intel MPX [48] and CHERI [69].

9 Related Work

Checking Optimization Compiler optimization techniques are commonly employed to optimize out-of-bounds checking. Many previous works [24, 34, 36, 39] have leveraged general optimization techniques to enhance checking performance or eliminate redundant checks. Additionally, there are some works [75, 76] that have designed custom optimization techniques to optimize Address Sanitizer's [51] checking. These optimization techniques can reduce a certain amount of overhead but cannot have an order of magnitude impact. The optimization technology of SHADOWBOUND has significantly reduced overhead and has made SHADOWBOUND practical.

Boundary Annotation LLVM introduced a new feature called `-fbounds-safety` [25]. This feature allows programmers to manually designate length variables for pointers, thereby enabling the compiler to insert boundary checking instructions for these pointers. While a direct performance comparison between SHADOWBOUND and `-fbounds-safety` is not feasible due to the latter's reliance on human annotations, combining `-fbounds-safety` with SHADOWBOUND could be beneficial. This is because neither is consistently superior to the other in all scenarios. For pointers with lengths that are already annotated, the `-fbounds-safety` flag may not require extra instructions to fetch the array length, potentially resulting in better performance. However, `-fbounds-safety` cannot address out-of-bounds errors caused by type downcasting, while SHADOWBOUND can, as it instruments pointer casting instructions. On the other hand, annotating all pointer length variables requires significant human effort and may not always be feasible. In contrast, SHADOWBOUND can manage these cases automatically without the need for human annotation.

Pointer Tagging Pointer Tagging is a common technique for storing the boundary in out-of-bounds detection or defense tools. Some studies [33, 34] store complete boundary information in the high-order bits of the pointer, eliminating the need to retrieve boundary information from memory. However, the available high-order bits are not sufficient to contain all the necessary boundary information. These approaches reduce available memory space, which may lead to potential compatibility issues with large-scale programs. To encode more information in the pointers without shrinking the memory space, other studies [24, 27, 36] have implemented custom allocators that allow the original pointer to convey additional boundary information. PACMem [39] uses ARM PA to generate a key stored in the high-order bits. This key is then used as an index to store the actual boundary information in shadow memory. The complexity of these encoding algorithm usually introduce additional arithmetic and memory operations that could potentially impact performance.

10 Conclusion

This work introduces SHADOWBOUND, an innovative heap memory protection design. SHADOWBOUND utilizes advanced metadata management and customized compiler optimization to provide a robust heap out-of-bound defense. We integrated it with three state-of-the-art use-after-free defenses without compatibility issues. Ensuring both temporal and spatial memory protection, SHADOWBOUND maintains a minimal performance and memory impact. Experimental results demonstrate its effectiveness and efficiency in defending against heap memory vulnerabilities, especially in programs written in unsafe languages.

OPTISAN: Using Multiple Spatial Error Defenses to Optimize Stack Memory Protection within a Budget

Abstract

Spatial memory errors continue to be the cause of many vulnerabilities. While researchers have proposed several defenses to prevent exploitation of spatial memory errors, systems currently rely on defenses that only protect a small fraction of stack data (e.g., return addresses) and leave a window of vulnerability (e.g., by only enforcing on function returns). One proposal to address this problem is to place defenses at the lowest cost locations until a cost budget was met, but this approach only considers a single defense and does not account for the security implications of possible placements. In this paper, we propose the OPTISAN system, which is the first system to apply multiple spatial memory defenses to maximize the number of objects protected from spatial memory errors within a cost budget. OPTISAN analyzes each program to identify the stack objects that may be exploited by spatial memory errors, called *usable targets*, and estimates the overhead for individual defense operations, for both metadata management and spatial checks, to enable flexibility in placement choices. OPTISAN applies this information in a novel Mixed-Integer Non-Linear Programming formulation to generate an optimal placement. We apply OPTISAN to generate placements using a combination of identity-based (i.e., influential BaggyBounds) and location-based (i.e., widely used AddressSanitizer (ASan)) spatial memory defenses, finding that OPTISAN utilizes the more effective Baggy Bounds defense broadly, augmenting it with ASan to increase the number of memory operations with usable targets protected by 18.4% on average across a set of benchmark and server programs. OPTISAN shows that using multiple spatial memory defenses provides valuable flexibility to prevent the exploitation of many spatial memory errors within a cost budget.

1 Introduction

Since the "Anderson report" [7] in 1972, researchers have understood that spatial memory errors, such as buffer overflows [54], could be exploited to compromise process execution. A spatial memory error allows a program instruction to access memory locations outside of the memory region of the intended object. By exploiting spatial memory errors, adversaries may read unauthorized stack data (i.e., stack buffer overread or disclosure attacks) and/or modify unauthorized data (i.e., stack buffer underflow or overflow). Such attacks have been exploited in-the-wild at least since the Morris Worm [58] in 1988 to hijack process execution, and recent vulnerabilities show that such attacks remain a high priority problem even for stack memory (e.g., [9, 47–49, 53]).

Despite broad awareness of spatial memory errors and their impact, only a small fraction of stack data is protected from only a subset of spatial memory errors. First, deployed defenses only check for the modification of return addresses (e.g., due to buffer overflows), traditionally using *stack canaries* [17] and now using *shadow stacks* [2, 15]. However, current defenses do not detect spatial memory attacks that modify local variables without affecting return addresses, nor will they detect illicit reads to stack memory that could lead to *disclosure attacks* [23, 57, 63]. Second, probabilistic defenses, such as ASLR [55] make some attacks more difficult, but adversaries can still exploit objects at relative offsets to perform data-oriented attacks [29, 32]. Third, such defenses only detect illicit stack modification when the vulnerable function returns, leaving a window of opportunity for an adversary to exploit the error fully prior to detection. For example, an adversary could exploit a spatial memory error within the execution of one long-running function to achieve their goals (e.g., perform necessary system calls to modify or leak sensitive data) prior to the vulnerable function returning.

To address the limitations above, researchers have proposed many techniques to detect spatial memory errors more comprehensively. Researchers categorize such defenses [64] into *identity-based defenses* [6, 19, 21, 50, 72], which validate that every memory access is within the expected memory region, and *location-based defenses* [20, 59, 66, 73, 74], which detect memory accesses to invalid memory outside the expected memory region. Despite efforts to improve the performance of both techniques [6, 19, 21, 25, 39, 72–74], their performance overhead still remains too high for broad adoption. A question

is how we can take advantage of such defenses effectively to improve program security.

In this paper, we leverage two insights. First, we find that identity-based and location-based defenses can have significantly different overheads for protecting the same unsafe memory operations due to differences in their implementations. For some operations, location-based defenses may be much more efficient, but for other operations, identity-based defenses may be much more efficient. Thus, a method for placing multiple spatial memory defenses may be beneficial and should account for the performance implications of each defense placement, including the *residual overheads* [38, 69] (e.g., metadata management) of defenses.

Second, even a combination of strong defenses may not be able to prevent all spatial memory errors within a desired performance budget. Thus, we need a technique to determine how to place multiple defenses within a budget. The ASAP system proposed applying individual defenses to operations in increasing order of frequency until an overhead budget is consumed [69]. However, ASAP does not consider the security implications of these choices nor does it account for the residual overheads, acknowledging that the total residual overheads of some programs are greater than the budget. We want to devise a defense placement approach that accounts for performance and security to utilize a combination of location-based and identity-based defenses effectively.

In this paper, we present OPTISAN, which is a tool for generating placements of spatial memory defenses for stack objects that utilizes multiple defenses, where the goal is to maximize the protection of stack memory from spatial memory errors within a cost budget. We develop a tool, OPTISAN, that constructs and solves protection budget problems, which includes: (1) a static analysis to compute which stack objects may be exploited by unsafe memory operations, which we call *usable targets*, to estimate the security impact; (2) a performance model of each defense that captures the costs for the placement of metadata management and bounds checks for each operation to enable flexible selection of placements; and (3) a *mixed-integer non-linear program* (MINLP) formulation to generate an optimal solution for protecting usable targets within a cost budget. While (1) and (2) are customized to protect stack objects, the protection budget formulation (3) is independent of the memory region being protected as long as security impact and defense cost models can be provided.

We apply OPTISAN to SPEC CPU 2006 programs, SPEC CPU 2017 programs and five server programs[1]. First, by applying a combination of Baggy Bounds [6] (i.e., an influential identity-based defense) with AddressSanitizer [59] (ASan) (i.e., a widely used location-based defense), OPTISAN is able to generate placements that cover 18.4% more unsafe operations with usable targets on average than Baggy Bounds alone for the same cost budget. Second, we show that OPTISAN makes placement decisions that account for the number of target objects to increase the protection from each operation defended, when compared to ASAP [69]. Third, we examine nine recent CVEs, finding that these vulnerable unsafe operations are not run frequently, which is consistent with ASAP's hypothesis of most CVEs [69], but nonetheless, OPTISAN places defenses for these unsafe operations earlier than ASAP in six instances and at the same point for the other three, indicating that OPTISAN is able to robustly balance performance and security. Fourth, OPTISAN is also reasonably accurate in predicting the overhead of placements, where the average difference from each budget is 1.47%, enabling us to generate desired placements in three runs or fewer.

This work contributes the following:

- We develop a novel model of spatial error defenses that captures both metadata and check operation costs at the granularity of individual program locations, enabling accurate cost estimates.
- We propose a novel mixed-integer non-linear program (MINLP) formulation to generate solutions that use multiple defenses to maximize the protection of stack objects from spatial errors within a cost budget.
- OPTISAN generates placements for a combination of ASan and Baggy Bounds defenses, increasing the number of unsafe operations protected by 18.5% on average over Baggy Bounds alone, while biasing the protection of stack objects and providing predictable performance.

2 Motivation

2.1 Stack Spatial Memory Errors

A *spatial memory error* occurs when a memory access is performed outside of the memory region of the intended referent, which is possible in programming languages that do not enforce memory safety (C/C++). The *intended referent* [18] of a pointer is the object from whose base address the pointer was derived. Spatial memory errors may either read (e.g., buffer over-read) or write (e.g., buffer overflow) memory illicitly. While spatial memory errors have been known for over 50 years [7], they are difficult to identify, even with automated static and dynamic (e.g., fuzzing) analyses. As a result, programs written in C/C++ often have latent spatial memory errors. For example, over 200 stack buffer overflow vulnerabilities were found in the last three years, 122 of which have a severity rating of at least 7. These include vulnerabilities in Adobe Acrobat Reader (CVE-2023-21610), Adobe Animate (CVE-2023-22243), and OpenSSL (CVE-2022-3786).

Consider Figure 1, which contains code snippets for three stack memory accesses in different functions in the Apache web server (httpd 2.4.32). Researchers have proposed techniques [6, 30] to identify the memory accesses cannot violate spatial memory safety, such as by using value-range analysis [62]. Using such techniques, the stack memory access in

[1] Only five SPEC CPU 2006 and four SPEC CPU 2017 programs run more than 100 stack memory operations that may violate spatial memory safety. We evaluate our approach on these programs only.

```
1 AP_DECLARE(int) ap_parse_form_data(request_rec *r, ap_filter_t *f,
        apr_array_header_t **ptr, apr_size_t num, apr_size_t usize)
2 {
3     ...
4     char buffer[HUGE_STRING_LEN + 1];
5     ...
6     if (offset < HUGE_STRING_LEN) {
7       // Stack memory access 1
8      buffer[offset++] = c;
9     }
10 }
```

Listing 1: Stack Memory Access 1

```
1  static int check_nonce(request_rec *r, digest_header_rec *resp,
2      const digest_config_rec *conf)
3 {
4     apr_time_t dt;
5     char tmp,hash[NONCE_HASH_LEN+1];
6     time_rec nonce_time;
7     .........
8     tmp = resp->nonce[NONCE_TIME_LEN];
9     resp->nonce[NONCE_TIME_LEN] = '\0';
10    // Stack memory access 2
11    apr_base64_decode_binary(nonce_time.arr, resp->nonce);
12    .........
```

Listing 2: Stack Memory Access 2

```
1 static remoteip_parse_status_t remoteip_process_v1_header(conn_rec *c,
2 remoteip_conn_config_t *conn_conf, proxy_header *hdr, apr_size_t len,
3 apr_size_t *hdr_len)
4 {
5     //Local Target
6     char *host;
7     char buf[sizeof(hdr->v1.line)];
8     ...........
9     // Stack memory access 3
10    strcpy(buf, hdr->v1.line);
11    .........
12    // Reachable use  1
13    conn_conf->client_addr = c->client_addr;
14    ...........
15    // Reachable use 2
16    conn_conf->client_ip = apr_pstrdup(c->pool, host);
17    ...........
18 }
```

Listing 3: Stack Memory Access 3

Figure 1: Stack memory accesses in the Apache web server

Line 8 of Listing 1 will always remain within the memory region of the intended referent, buffer. However, the stack memory accesses in Listings 2 and 3 cannot be validated statically to satisfy spatial memory safety. For these operations, developers can either apply defenses proactively to prevent possible spatial memory errors or hope that the stack memory access is actually safe or not exploitable. We find that the Apache web server (httpd 2.4.32) has 2,969 memory operations (i.e., instructions in the LLVM IR) that cannot be proven to be safe from spatial memory errors (called *unsafe operations* in Table 3 in Section 6) via value-range analysis.

Consider the code snippet in Listing 3, which has been reported as a recent vulnerability (CVE-2019-10097 [52]). Listing 3 shows a function named remoteip_process_v1_header that copies a packet header into a stack buffer buf, using strcpy. The function strcpy cannot be proven to comply with the bounds allocated for either the buffer buf or the header hdr, so it may result in a buffer overflow and/or buffer over-read. In this case, adversaries can overflow the buffer buf to overwrite stack objects allocated above buf on the stack. As a result, the local pointer variable host can be modified to point to any desired payload, which can be used to corrupt important fields in the configuration object conn_conf in **line 17**. 14 stack objects may be targeted by this vulnerability.

```
1 ShadowAddr = (Addr >> 3) + Offset;
2 k = *ShadowAddr;
3 if (k != 0 && ((Addr & 7) + AccessSize > k))
4     ReportAndCrash(Addr);
5 // Memory access (store)
6 *Addr=...
```

Listing 4: ASan Check Operation

```
1 // Pointer arithmetic
2 p = baseAddr + offset;
3 k = bounds_table[baseAddr>>slot_size];
4 if ((baseAddr^p) >> k!=0)
5     p = BaggySlowPath(baseAddr,p);
6 .....
7 // Memory access (Store)
8 *p=...
```

Listing 5: Baggy Bounds Check Operation

2.2 Spatial Error Defenses

Programmers currently apply inexpensive, but incomplete and/or probabilistic defenses, such as stack canaries [17] and Address Space Layout Randomization [55] (ASLR). Stack canaries (and shadow stacks [11, 15]) check that the value of the return address at the function's return is the same as when the function was called. However, the function's local variables may be illicitly modified or read without detection. In addition, attacks that complete prior to the function returning and attacks where the adversary controls the offset will also not be detected by these defenses. ASLR randomizes the base location of the stack and code memory segment to prevent attackers from predicting the location of target code or data. However, attacks whose target is at a relative offset from a vulnerable memory region may still be accessed illicitly. For example, the vulnerability in Listing 3 above allows attackers to modify a local variable illicitly that is located at a known offset from the vulnerable buffer buf, but canaries do not prevent illicit access to local variables and ASLR does not prevent targeting objects at known offsets.

As a result, researchers have proposed defenses specifically targeted at preventing spatial memory errors. Researchers recognize two classes of spatial memory defenses, as identity-based and location-based defenses [64]. First, *identity-based defenses* rely on the intended referent of the memory access to determine validity of the access. For example, the SoftBound defense [51] tracks whether a pointer to an intended referent may ever reference memory outside of the bounds of its allocated region. Because identity-based defenses check whether a pointer value is within a memory range, these defenses instrument every pointer arithmetic operation. The Baggy Bounds defense [6] removes instrumentation for memory accesses that can be proven to satisfy spatial safety and reduces the cost of checks by aligning and padding allocations to the next power of two. The Listing 5 shows this efficient check which involves a single memory load (i.e., bounds table lookup), arithmetic operations, and a comparison. Baggy Bounds is currently the most efficient identity-based defense, so we examine its use in this paper.

Alternatively, *location-based defenses* detect spatial memory errors that access an invalid memory region. The idea is to use a metadata store, such as a *shadow memory*, to

Program	*ASan (%)*	*Baggy (%)*	*ASan is Slower (%)*	*Baggy Improves (%)*
httpd	13.15	19.66	2.43	16.76
sqlite3	0.45	0.63	0.84	12.69
sjeng	33.08	53.08	5.45	12.10
povray	5.50	6.63	30.22	49.45
gcc	8.94	14.17	1.02	17.37
perlbench	10.75	20.95	3.05	2.33

The first two columns contain the performance overhead to protect all unsafe operations using ASan and Baggy Bounds, respectively. The third and fourth columns show the percentage of cases where ASan is slower and the percentage reduction in cost if Baggy Bounds is used instead.

Table 1: Performance Trade-offs between ASan and Baggy Bounds

track state for each byte (or a portion) of the usable address space. This metadata store is consulted on each memory access to detect (illegal) accesses to invalid memory. These defenses differ in how they encode invalid memory, as either red-zones [26,27,59,61] around the object encoded in shadow memory or separate unallocated (guard) pages [45,56] outside legitimate memory regions. Address Sanitizer [59] (ASan) is a widely used location-based defense, often used in fuzz testing [46] to detect bugs. For example, ASan has detected more than 10,000 memory bugs [24,68] across various applications including over 3,000 memory bugs in Chrome [24]. It is designed to be more efficient than prior techniques [26,27,61].

ASan employs a directly mapped, compact shadow memory to detect operations that access memory outside the expected bounds using *red-zones*. For stack objects, a red-zone is 32 bytes. Listing 4 shows an ASan check, which involves a single memory load (shadow memory lookup), arithmetic operations, and a comparison. In this paper, we examine the use of the ASan defense[2]. We note that location-based defenses may be bypassed, e.g., by incrementing a pointer beyond an object's red zone , or through an unaligned access that is partially out-of-bounds [60]. Identity-based defenses cannot be bypassed, but may not be applicable to all scenarios (e.g., buffers within objects).

Neither identity-based nor location-based defenses are deployed in production environments because their performance overheads are not yet acceptable. Table 1 shows the overheads of ASan and Baggy Bounds for spatial memory error protection for all unsafe operations (i.e., stack memory accesses that cannot be proven safe by value-range analysis) for a set of programs. For benchmarking these programs, we use the test suite provided with the program such as Apache HTTP Test project [8] for Apache, the TCL test suite [65] for sqlite, and *ref* workload for the SPEC CPU 2006 programs. ASan always has a lower overall performance overhead than Baggy Bounds for these programs, but we observe that ASan may have a higher overhead than Baggy Bounds for some fraction of the unsafe operations in the program (ASan Is Slower column). In these cases, the number of memory accesses (checked by ASan) is greater than the number of pointer arithmetic operations for those objects, leading ASan to incur a higher performance overhead than Baggy Bounds. The fourth column (Baggy Improves column) shows the percent overhead reduction (i.e., relative to the ASan column) if Baggy Bounds is used instead of ASan in those cases only.

[2]ASan– [74] is an optimized version of ASan, but there are implementation issues in applying it incrementally with another defense, so we will explore using it in future work.

2.3 Managing Spatial Defense Performance

Researchers have proposed methods to apply spatial memory defenses in ways that limit their overhead. For example, the ASAP system [69] applies the Address Sanitizer [59] (ASan) spatial memory defense to as many operations as possible within a cost (i.e., performance overhead) budget. ASAP chooses which operations to defend in the order of their expected execution frequency (e.g., from an execution profile), starting with the least frequent operations, until a budget is exhausted. ASAP demonstrates that a significant fraction of memory operations can be defended (87% on average for the programs tested) within a cost budget of 5% for some programs in the SPEC CPU 2006 and Phoronix benchmarks.

While ASAP takes an important first step towards a method to utilize stronger memory defenses wisely, challenges remain. First, ASAP cannot combine multiple defenses, which may be desirable based on their performance trade-offs. As seen in Table 1, in some cases the BaggyBounds defense [6] enforces memory safety more efficiently than ASan, as explained earlier in Section 2.2. ASAP does not account for the frequencies of operations performed by defenses nor their overheads. Second, ASAP does not account for the residual costs [38, 69] of a defense (e.g., ASan's red-zone metadata management), but these costs can be significant. As a result, ASAP cannot generate placements for a desired budget for programs using ASan with high residual costs (i.e., more than the cost budget), such as gcc and perlbench. Third, ASAP does not account for whether a memory operation can actually enable any exploitation. As a result, ASAP may waste the valuable performance budget unnecessarily on operations that cannot be exploited. Fourth, for a desired budget ASAP may choose to protect operations that are inexpensive to protect (low execution frequency), but present fewer risks (e.g., fewer stack objects at risk) than other operations. While vulnerabilities along frequently executed paths appear to be less common, such vulnerabilities have been found in the wild as seen in recent work [74]. Thus, ASAP's approach may lead to such vulnerabilities being left unprotected even when they present a high risk. Instead, we propose that considering multiple defenses (i.e., performance trade-offs), the risk associated with the unsafe operations (i.e., stack objects at risk), and all their costs (i.e., check and residual costs) may enable a protection budget to be used more effectively.

Ultimately, we still lack an effective approach to apply spatial memory defenses to protect the stack. Ideally, we would like to apply the complete identity-based defenses comprehensively, but they are too expensive in many cases. Given

that location-based defenses, even though they are incomplete, would be a significant improvement over the current defenses, we would like to be able to leverage them as well to maximize our protection of stack memory within a cost budget. However, we lack techniques that understand the performance implications of defenses comprehensively (e.g., including metadata) to apply defenses efficiently and predictably (i.e., incur the expected overhead overall after placement). In addition, we lack techniques that can utilize accurate performance modeling to maximize the defense we can obtain with location-based and identity-based defenses in combination. While Baggy Bounds avoids placing defenses when operations are safe from spatial errors, it does not account for whether operations are actually exploitable (i.e., any illicitly accessed target may be used). In addition, while ASAP accounts for cost [69] imprecisely, it does not consider whether a placement of multiple defenses and whether it protects the maximal amount of stack data within a cost budget.

3 System Overview

Threat Model We assume that programs may contain spatial memory errors on accesses to stack data, such as stack buffer under/overflows and buffer over-reads. We assume that adversaries can exploit any spatial memory error to access other objects illicitly in stack memory. We assume that memory accesses that are validated to satisfy memory safety are not exploitable, and that the techniques used to validate memory safety [6, 30, 62] do not misclassify any unsafe accesses as safe (i.e., are *sound*). In addition, we assume that any stack memory modified illicitly must have a *use* (i.e., a memory access to the illicitly modified stack object) after the unsafe operation to be exploitable. We assume any stack data that may be accessed by an illicit read can be exploited (e.g., by using the buffer into which the illicitly accessed data is read). We leave the problem of extending protection to heap and global objects for future work, as discussed in Section 7.

We assume the following defenses are already applied to the program. First, we assume that the program employs a defense to prevent the modification of code and the execution of data, such as Data Execution Prevention [4] (DEP). We assume that these protections cannot be disabled (e.g., no bugs exploit changing memory permissions using `mprotect`). Second, we assume that the ASan and Baggy Bounds defenses prevent illicit modification of their metadata and execute correctly. We assume that no attacks on memory accesses to the heap or globals can access stack memory or can circumvent ASan and Baggy Bounds.

OPTISAN **System** The OPTISAN system is shown in Figure 2. OPTISAN generates a placement of defenses, in this case for the ASan [59] and Baggy Bounds [6] defenses, to maximize the protection of stack objects from spatial memory errors within a cost budget. To do this, OPTISAN first identifies the operations that may violate memory safety (i.e., *unsafe operations*) using known techniques (e.g., value-range analysis [62]) in Step (0). For each unsafe operation, OPTISAN computes the stack objects that may be exploited by spatial memory errors, called *usable targets*, in Step (1), which is described in Section 4.3. Next, OPTISAN estimates the expected cost of defenses at each location where defense code may be placed, called *monitoring points*, both for spatial memory checks and for initialization and cleanup of metadata used by these defenses, using offline profiles in Step (2), as described in Section 4.1. OPTISAN then applies a novel optimization formulation to generate a defense placement that maximizes the protection of stack objects from spatial memory errors within a given performance cost budget in Step (3), as described in Section 4.2. Finally, OPTISAN instruments the program with the computed placement automatically in Step (4), including the incremental metadata support for the limited set of checks placed. The placement of instrumentation utilizes the existing ASan and Baggy Bounds methods, as described in Section 5.

4 OPTISAN Design

In this section, we describe how to develop an accurate and flexible performance model of defenses to enable maximizing the protection of stack objects within a cost budget.

4.1 Modeling Defense Performance Overheads

The goal is to apply defenses within a cost budget in a manner that accounts for the performance overhead of each defense accurately and thus the performance trade-offs between defenses. To estimate the cost of a particular defense placement accurately, we must develop a model of the performance overhead of defenses that is comprehensive (i.e., accounts for all significant costs), fine-grained (i.e., can reason about any placement), and flexible (i.e., can apply either defense to each unsafe operation). The key to achieving this goal is to accurately model the overheads of both check (i.e., prevent accesses that violate spatial memory errors) and metadata operations (i.e., setup and update the state for checks, such as red-zones and bounds). Past work [69] acknowledged that metadata operations could add significant overhead to enforcement due to *residual overheads* [38, 69], which were found to be greater than the placement budget for some programs, such as perlbench and gcc. However, modeling metadata operations presents challenges because metadata operations are associated with objects that may have multiple unsafe operations and require multiple spatial checks. In addition, since OPTISAN considers the placement of multiple defenses with different metadata representations and operations, OPTISAN must reason about the impact of redundant metadata.

OPTISAN is designed to model each check and metadata operation required to account for all defense operations (i.e., be comprehensive) at the granularity of individual defense operations per unsafe operation (i.e., be fine-grained). This enables OPTISAN to choose among multiple defenses for each

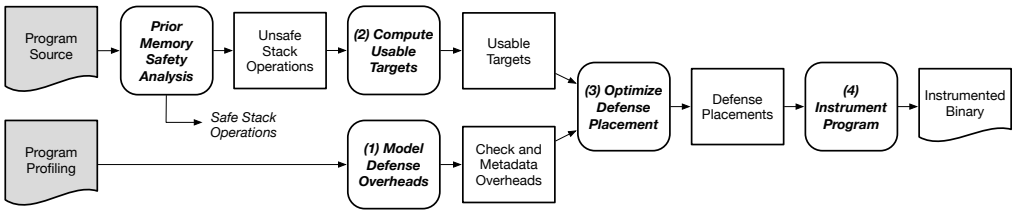

Figure 2: OPTISAN Steps: (1) model the cost of defense operations to assess the impact of their use to prevent spatial errors; (2) compute the target stack objects that may exploited by spatial memory errors in unsafe operations; (3) generate optimal defense placements to maximize prevention of the exploitation of usable targets within a cost budget; (4) instrument the program with the optimal defense placement.

unsafe operation (i.e., be flexible). The key to this approach is to model the check and metadata operations for each defense explicitly through what we call *monitoring points*: the code locations where such operations may be applied. For applying a defense to an unsafe operation, OPTISAN identifies the code locations where its check and metadata operation(s) are required to enforce spatial safety as monitoring points. This enables OPTISAN to determine the cost when a defense is chosen for an unsafe operation based on each of the monitoring points required for the check and metadata operations for that unsafe operation, the cost of each operation individually, and the frequency of execution of each monitoring point used. In addition, monitoring points allow OPTISAN to capture shared operations for each defense, i.e., metadata operations that may be amortized over multiple unsafe operations.

Cost Estimation To estimate the average cost of individual check and metadata operations for each defense, we profile programs to determine the costs attributable to individual check and metadata operations for each defense. We identify check and metadata operations for each defense by matching the IR description of each operation, similar to prior work [69]. We then execute the program instrumented in a variety of ways, similar to recent work [74], to determine the total overhead for all check and metadata operations as separate groups. We execute the program in the following ways for each defense: (1) natively (i.e., without any instrumentation); (2) with full instrumentation; (3) with all metadata operations (including heap), but no checks; and (4) with only stack metadata operations, but without checks. Note that for (2) and (3), we include both heap and stack instrumentation, which is functionally the same for both types of objects, mainly for ease of testing. The total cost of the spatial memory checks (for the heap and stack) is determined by subtracting the runtime of (3) from (2). The total cost of the metadata operations for the stack is determined by subtracting (1) from (4). The average cost for each class of operations is determined by dividing the total cost of each class by the total frequency of the relevant operations obtained using profiling (*gcov*). The costs of any initialization operations for these defenses are built into the metadata costs at present. We then associate the average check and metadata operation costs with the individual, fine-grained operations, *monitoring points*. This fine-grained association of costs with individual monitoring points enables us to estimate the cost of any placement of spatial memory checks and metadata operations of any defense.

One issue that we had to address to apply the performance modeling technique above is to enable the application of metadata operations to individual stack objects as desired. Currently, Baggy Bounds and ASan add stack metadata at the granularity of a function rather than for indivdiual stack objects. That is, should any stack object in a function require a spatial check, then metadata is allocated for all the function's stack objects for both Baggy Bounds and ASan. As we apply defenses for a smaller fraction of objects, many metadata operations may become spurious. In addition, since we may apply multiple defenses to different stack objects in the same function, redundant metadata operations may be created. Thus, we modified ASan and Baggy Bounds to enable the creation of metadata per stack object. We discuss how the metadata can be further improved in Section 7.

4.2 Optimizing Defense Placement

In this section, we formulate a *Mixed Integer Non-Linear Programming* (MINLP) problem to compute optimal defense placements to maximize the protection of the targets of attacks on spatial memory errors from exploitation within a cost budget. Designing this formulation requires us to develop a method to estimate protection from spatial memory errors to compare possible solutions. Then, we integrate the performance modeling from Section 4.1 to determine which solutions are within budget.

Figure 3 shows a view of the intuition behind our proposed method to estimate protection. Given the call graph on the left, unsafe operations are distributed among the program's functions (e.g., Unsafe 1 in Func A). Should an unsafe function have a spatial memory error, this may allow an adversary to illicitly access *targets*, i.e., stack objects other than the intended reference of the operation. Figure 3 shows a mapping between unsafe operations and targets. However, only a subset of the targets that may be illicitly accessed may be used by another instruction after the unsafe operation. We call these *usable targets*, which are associated with unsafe operations by bold edges in Figure 3. The placement of defenses may prevent spatial memory errors, indicated by the **X**s in Figure 3. However, applying a defense for one unsafe operation may

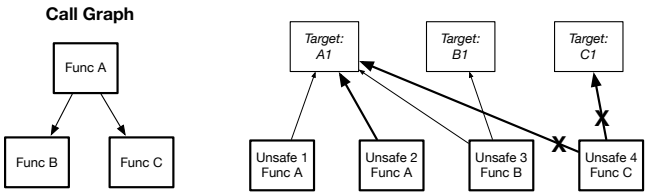

Figure 3: Shows how unsafe operations map to target stack objects in the program represented by the call graph shown. Edges map unsafe operations (e.g., Unsafe 1) to target stack objects (e.g., variable A1 in function A. Bold edges indicate that a target is used in after the unsafe operation (i.e., is a *usable target*). **X**s indicate defenses prevent spatial memory errors. However, target A1 may still be exploited by a spatial memory error from operation Unsafe 2.

Table 2: Definitions and Parameters

$x_{j,p}$	Indicator of defense p at unsafe operation j.
$y_{k,p}$	Indicator of monitoring point k of defense p.
$a_{j,p}$	Accuracy of defense p at unsafe operation j.
T_i	Set of unsafe operations for target i.
$M_{j,p}$	Monitor points of defense p for unsafe operation j.
D_i	Minimum detection accuracy threshold for target i.
f_k	Frequency of monitoring point k.
c_p	Cost of defense p.
g_i	Gain of target i.
B	Monitoring budget.
S_k	Set of unsafe operations for object i.
l	Number of stack objects to be monitored.
n	Number of unsafe operations.
m	Number of targets.
o	Number of sanitizer types, $o \geq 2$.
q	Number of monitor points.

not fully protect a target. While target C1 is fully protected by enforcing spatial memory safety on unsafe operation Unsafe 4, target A1 may still be exploited by an attack on unsafe operation Unsafe 2 followed by its use (i.e., A1 is a usable target of Unsafe 2). In general, for a target to be protected from spatial memory errors a complete defense must guard every unsafe operation in which that target is usable.

We formalize the model shown in Figure 3, based on the parameters definitions in Table 2, as follows. First, any improvement in attack prevention depends on how comprehensively each target is protected from illicit access via unsafe operations. We refer to this as the *gain*, g_i, of target object i. We use the equation below to estimate the gain g_i for each target object, as Constraint (3) in the formulation.

$$g_i = \frac{\sum_{j \in T_i} \sum_{p=1}^{o} g_{i,j,p}}{|T_i|},$$

where: (1) T_i is the set of unsafe operations for target i; o is the number of defense types considered; and $g_{i,j,p}$ is the gain attributable to defending each unsafe operation j with defense p for target object i. For a specific defense p applied to an unsafe operation j for which target i is a usable target, the gain of the said unsafe operation is $g_{i,j,p} = a_{j,p} \cdot x_{j,p}$, where $a_{j,p}$ is the accuracy of the defense p at unsafe operation j and $x_{j,p}$ is a boolean indicating whether defense p is applied at unsafe operation j [3].

A question is how to estimate the impact of defending each unsafe operation individually for each target. For example, the effect of defenses for a target could be the minimum defense applied to any unsafe operation that could illicitly access this target. However, using the minimum defense means that any individual unsafe operations left unprotected by only one unsafe operation may undermine the defense rating overall. Since we have only a limited budget, we assume that some unsafe operations may be unguarded. As a result, we aggregate impact of each unsafe operation by averaging the defense provided, as shown above. Should any or all targets require defense, the formulation includes a threshold constraint to specify the minimum required defense accuracy for each target in a solution, as Constraint (4) in the formulation below.

To model the performance overhead, we utilize the estimates of the overheads of check and metadata operations determined using the methods described in Section 4.1. For each defense, we determine where to place check and metadata operations by computing its *monitoring points* per unsafe operation. We define $y_{k,p}$ to represent whether a monitoring point k of defense p is used.

$$y_{k,p} = \begin{cases} 1, & \text{if monitoring point } k \text{ active for defense } p \\ 0, & \text{otherwise} \end{cases}$$

Constraint (5) of the formulation below ensures that when a defense p is applied for unsafe operation j, all the monitoring points $M_{j,p}$ for that defense are activated.

The overall formulation is shown below. The objective is to maximize the sum of the gain for all of the target objects in Equation 1. The objective value represents the protection of all *usable targets*, aggregating the protection at each relevant unsafe operation for each usable target.

$$\max \sum_{i=1}^{m} g_i \tag{1}$$

Subject to :

$$\sum_{p=1}^{o} x_{j,p} \leq 1, \quad \forall j \in \{1,...,n\} \tag{2}$$

$$\forall i \in \{1,...,m\}, \quad g_i - \frac{\sum_{j \in T_i} \sum_{p=1}^{o} a_{j,p} \cdot x_{j,p}}{|T_i|} = 0 \tag{3}$$

$$g_i \geq D_i, \quad \forall i \in \{1,...,m\}, \tag{4}$$

[3] The accuracy of a defense applied to an unsafe operation is the same for all targets of that operation and dependent on the defense technique chosen, as discussed in Section 6.

Algorithm 1: findUsableTargets(op, OBJs, PDG)

21:    Funcs ← Funcs ∪ FindCaller(F,PDG)
22: end while
23: return U
```

$$x_{j,p} = 1 \Rightarrow y_{k,p} = 1, \quad \forall y_{k,p} \in M_{j,p} \tag{5}$$

$$\sum_{p=1}^{o} c_p \sum_{k=1}^{q} f_k \cdot y_{k,p} \leq B \tag{6}$$

$$x_{j,p} \in \{0,1\} \tag{7}$$

$$y_{k,p} \in \{0,1\} \tag{8}$$

Each unsafe operation can select at most one defense, Constraint (2). Constraint (6) is the budget constraint, which restricts the placement selected to the cost budget.

One issue of the formulation above is that we place defenses at the unsafe operation granularity, rather than stack object granularity. This allows the solver to employ one defense at one unsafe operation and another defense at a different unsafe operation for the same stack object. The use of multiple defenses for the same stack object may be wasteful because the system has to maintain multiple copies of metadata for the same object. We propose an optional constraint to select defenses at the object granularity instead to prevent the creation of redundant metadata. In this case, the unsafe operations of the same object, S_k, are limited to use the same defense by adding the Constraint (9).

$$\sum_{p,q \in \{1,\ldots,o\}, p \neq q} \left(\sum_{j \in S_k} x_{j,p} \cdot \sum_{j \in S_k} x_{j,q} \right) = 0, \quad \forall k \in \{1,\ldots,l\} \tag{9}$$

However, we find that allowing the solver flexibility to choose among defenses, even when accounting for the creation of redundant metadata, results in better solutions in many cases, as discussed in Section 6.

4.3 Computing Usable Targets

In this section, we describe a method to compute the usable targets of an unsafe operation in the stack memory region. Solving this problem consists of two main tasks: (1) collecting the target objects of an unsafe operation and (2) determining whether each target object is usable in an exploit. Algorithm 1 shows this approach, where lines 6-10 collect the targets of an unsafe operation and lines 12-16 determine whether the target is usable. As research in triaging vulnerabilities to determine what exploits may be possible is a nascent and emerging field [14, 32], we propose preliminary, conservative solutions to these two problems. We hope that future work will develop more precise techniques to solve these problems.

Algorithm 1 uses a program dependence graph [34] (PDG), which represents the program's control flows and data flows in one model. We use the PtrSplit [40] PDG representation, which provides a sound alias analysis to ensure an over-approximation of all control and data flows. We apply value-range analysis [62] to the program's PDG representation to identify unsafe operations based on a prior, open-source implementation [30]. Value-range analysis over-approximates unsafe behaviors, classifying an operation as unsafe if it cannot be proven safe. Thus, some operations classified as unsafe operations may not actually be unsafe.

Next, the task is identify all target objects for each unsafe operation. Currently, we take a naive, but conservative, position that any object that could be present on the stack at the time of an unsafe operation may be illicitly accessed by the unsafe operation. Thus, we use the call graph to identify all functions that may be present on the stack for each unsafe operation. The set of stack objects for each of these functions (including the unsafe operation's function) forms the set of target objects.

Recall Figure 3 from Section 4.2. In the given call graph, an unsafe operation in Function A can only illicitly access objects in that function. However, unsafe operations in Functions B and C can both access stack objects of Function A, although not each other's stack objects.

OPTISAN determines whether a target object is a usable target in two ways. For the targets of read operations, we assume that they all have uses (i.e., are all usable targets) since read operations typically aim to use the data read. This assumption is an overapproximation as some data may be read and found not to match a criteria for use, but these criteria are often ad hoc. We will explore more refined interpretations of uses of read operations in future work.

For the targets of write operations, OPTISAN determines whether there are any operations that use the target after it may be illicitly modified. OPTISAN first identifies operations that may perform a memory access to the target. We compute these operations using the intra-procedural data flows (i.e., based on the alias analysis) for the function in which the target object was allocated. We prune operations prior to the unsafe operation using the control flow. In addition, we prune operations that are dominated by a kill operation for the target. We stop the computation at uses that pass a target object to a callee or escape the function through global or heap memory,

declaring the target as usable in those cases.

5 Implementation

We develop a tool, OPTISAN, to automate the proposed approach. It comprises of four key components: (1) LLVM-based [37] static analyses to compute usable target objects for unsafe operations in Step 1 of Figure 2; (2) an LLVM-based static analysis to estimate defense overheads from profiling information, as described in Section 4.1, in Step 2 of Figure 2; (3) a mixed-integer, non-linear program solver [1] to compute the optimal placement within a performance overhead budget for Step 3 of Figure 2; (4) LLVM-based static instrumentation pipeline to instrument the program in Step 4 of Figure 2 using ASan and Baggy Bounds as per the computed placement. OPTISAN's static analyses, performance utility pass, and instrumentation passes are built using LLVM-10.0 in around 5*K* lines of code (LOC). We decouple the LLVM analyses for Step 1 (i.e., computing usable targets) and Step 4 (i.e., placing instrumentation) by using a graph database, Neo4j [3] to store the results of Step 1 to apply the computed placement in Step 4. This enables us to perform the safety analysis [6, 30] and compute usable targets once, and apply the solver (Step 3) to produce solutions that are instrumented (Step 4) independently. Our tool is publicly accessible at `https://github.com/rahultgeorge/OptiSan`.

Modeling Defense Overheads To obtain the defense overheads in Step 1 in Figure 2, we compute the execution profile to enable OPTISAN to estimate the overheads of check and metadata operations for ASan and Baggy Bounds defenses as described in Section 4.1. To obtain the execution profile of the program it is instrumented using *gcov*. The execution profile is stored in a Neo4j graph database [3]. To assign the defense overheads per monitoring point using the profile results, we use an LLVM-based static analysis pass.

Computing Usable Targets In Step 2 of Figure 2, OPTISAN computes the usable targets for unsafe operations. To compute the unsafe operations, OPTISAN leverages the well-known value-range analysis [62] on the program dependence graph (PDG) constructed from prior work [40]. We leverage the SVF [67] points-to analysis to compute the aliases used in the PDG to identify all stack objects that may be referenced by these unsafe operations. To compute the usable targets, we implement the Algorithm 1 described in Section 4.3 using LLVM-based static analyses [37] in around 2K LOC. We rely on LLVM IR to identify stack objects. The passes save the results in a Neo4j graph database.

Optimizing Defense Placements In Step 3 of Figure 2, OPTISAN computes optimal placements using the MNLIP formulation proposed in Section 4.2 implemented using the Gurobi solver [1]. The solver stores the selected placement in the graph database by annotating the specific unsafe operations. The static analysis performed in the Step 1 computes the necessary information needed to instrument any of the unsafe operations with the selected defense.

Instrumenting Defense Placements To instrument a program as per the computed placement, Step 4 of Figure 2, OPTISAN applies the results from the prior steps stored in the Neo4j graph database in LLVM-based static instrumentation passes [37]. The specific unsafe operations and necessary functions are fetched from the database. The pass uses debug information to identify the operations and relevant functions. The functions and unsafe operations are annotated in the IR. This avoids instrumenting unnecessary functions.

The program is instrumented using Baggy Bounds first and then Address Sanitizer as per the computed placement to prevent conflicts. However, there may be redundant checks as each defense is unaware of the specific unsafe operations and instruments each annotated function completely. Subsequently, another instrumentation pass checks for any such redundant checks and removes them using a technique from prior work [69]. The compiler then proceeds as normal and generates the instrumented binary.

6 Evaluation

To demonstrate the efficacy of the proposed placement approach, we attempt to answer the following questions:

- Does OPTISAN's ability to consider multiple defenses protect more unsafe operations? How are the multiple defenses used together?
- Does the security impact of unsafe operations improve the choice of which operations are protected?
- Does considering security impact with cost enable OPTISAN to apply protection for the unsafe operations exploited in real CVEs earlier than prior work?
- Can OPTISAN produce an optimal placement with the desired overhead budget?

We evaluate OPTISAN on the SPEC CPU 2006 programs, SPEC CPU 2017 programs, and seven real-world programs, including five programs from an open-source fuzzing benchmark[4]. We analyze the sixteen C/C++ programs in the SPEC CPU 2017 benchmark (i.e., all the non-Fortran programs). For profiling these programs, we use the test suites provided, such as Apache HTTP Test project [8] for Apache, the TCL test suite [65] for sqlite and the *ref* workloads for the SPEC CPU (2006, 2017) benchmarks [5].

The counts of unsafe operations and targets per program are shown in Table 3. Notably, we find by leveraging value-range analysis [62] that only five of the SPEC CPU 2006 programs, four of the SPEC CPU 2017 programs, and five of the real-world programs have a significant number of unsafe stack

[4]We select all the programs from the Magma benchmark [28] that have a large number of non-free unsafe operations and a test suite.

[5]We modify the Apache HTTP Test to ignore modules without any unsafe operations.

	Name	Unsafe Operations				Usable Targets

Table 3: Counts of Unsafe Operations (relative to spatial memory safety) and Their Usable Target Objects

operations (Table 3 under the column Unsafe Operations, Total). For SPEC CPU 2006 and server programs, Table 3 shows that many have under 100 non-free, unsafe operations. For the SPEC CPU 2017 programs, seven of the sixteen programs do not have any unsafe stack operations and five of the remaining nine programs can be protected with a negligible overhead of 0.30% or less, on average. Furthermore, as identified in prior work [69], a significant number of unsafe operations are never executed in the provided workloads, which can be covered for free (i.e., relative to the workload). For the programs in Table 3, 28% of the unsafe operations on average can be protected for free, leaving the remaining unsafe operations to be consider for protection by OPTISAN, as listed in Table 3 under the column Unsafe Operations, Non-Free.

As described in Section 4.2, the potential security impact of unsafe operations can be characterized through the *usable targets*, also shown in Table 3. Examining the impact of the workload on usable targets, 33% of the usable targets can be protected for free on average (i.e., they may only be accessed by unsafe operations that are not run in the workloads). In the following experiments, we only consider the non-free, unsafe operations and the usable targets accessed by those operations, in the Usable Targets, Non-Free column in Table 3.

ASan Accuracy Recall that unlike Baggy Bounds, in some cases the ASan checks may be circumvented, as described in Section 2.2, so ASan may not prevent all attacks on spatial errors. To account for this, we want to estimate ASan's accuracy of enforcement between 0 (i.e., defense can be bypassed) and 1 (i.e., defense cannot be bypassed). Recent work [74] used the Juliet test suite to validate the correctness of their proposed ASan optimizations, so we use the NIST Juliet C/C++ *v*1.3 test suite [10] to estimate the accuracy of the ASan defense. As shown in Table 4, there are four CWEs [5] relevant to stack spatial memory errors in the test suite. For CWE 126 and CWE 127, we only examine the stack test cases. To estimate the accuracy of ASan, we identify the test cases (i.e., one unsafe operation per test case) for each of these CWEs in the Juliet test suite [10] where ASan can be bypassed. Similar to recent work [74], we estimate accuracy by finding the test cases where ASan may be bypassed because an offset used in the memory access is variable and may be larger than the red-zone size. For example, in several cases offsets are only restricted to be a positive value. We estimate ASan accuracy for each CWE as the fraction of the remaining Juliet test cases that do not exhibit possible bypass as shown in Table 4. We take the average across these four CWEs to obtain an average accuracy of 0.80 for ASan, which we use in this evaluation.

CWE	***Description***	***ASan Accuracy***
CWE 121	Stack Buffer Overflow	0.95
CWE 124	Stack Under-write	0.77
CWE 126	Buffer Overread	0.70
CWE 127	Buffer Underread	0.76

Table 4: ASan accuracy estimates for the NIST Juliet test suite using its bad tests. Bad tests check cases that may bypass red-zones.

Baggy Bounds Accuracy While Baggy Bounds is a complete defense in many cases, it cannot prevent spatial errors in some specific cases identified in Section 2.2. We do not apply Baggy Bounds in cases where it cannot provide an accurate defense (e.g., scalar field within a structure).

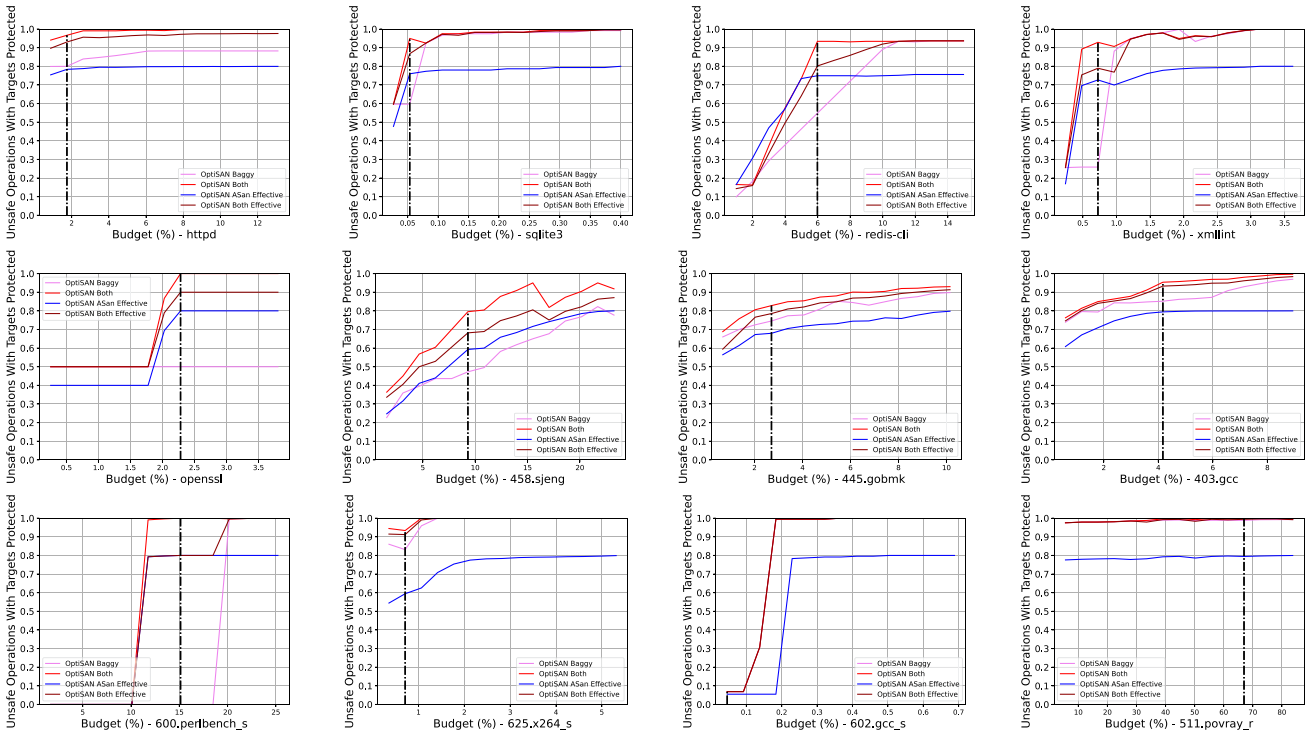

Figure 4: OPTISAN's defense placement solutions: Compare the number of unsafe operations protected by Baggy Bounds alone (OPTISAN Baggy, Pink) to both Baggy and ASan together (OPTISAN Both, Red). The dashed vertical lines show the cost budget where the maximum difference in unsafe operations protected. Also shown are the effective number of unsafe operations protected when accounting for the limited accuracy of ASan for the combination of Baggy Bounds and ASan (OPTISAN Both Effective, Brown) and ASan alone (OPTISAN ASan, Blue).

6.1 Applying Multiple Defenses

The key benefit of applying OPTISAN is to leverage the capabilities of multiple defenses to maximize protection of usable targets. The plots in Figure 5 a) show the measured impact of applying Baggy Bounds and ASan together to protect non-free unsafe operations with usable targets[6]. The OPTISAN Baggy line (Pink) shows the number of unsafe operations that are protected by Baggy Bounds for a budget in the optimal placement using the formulation in Section 4.2. We compare this to the number of unsafe operations that can be protected when both Baggy Bounds and ASan are available in the OPTISAN Both line (Red). In many cases, the combination enables many more unsafe operations to be protected at particular budget levels. The dotted vertical line shows the budget with the greatest improvement by using both defenses over Baggy alone. Note that in some cases, the number of unsafe operations protected decreases as the budget increases, but this is because the formulation is maximizing the gain in protection for usable targets, not the number of unsafe operations.

Figure 4 also accounts for the limited accuracy of ASan in the OPTISAN Both Effective line (Brown). Because ASan may be bypassed in some cases, the effective number of unsafe operations protected is lower than the number in which it and Baggy Bounds are applied. However, even the OPTISAN Both Effective line shows a significant improvement over Baggy Bounds alone in many cases for particular budgets, showing that OPTISAN provides an opportunity to improve security within a budget by combining defenses. Finally, the curve for OPTISAN ASan Effective (Blue) shows the effective protection provided by ASan alone for the unsafe operations. Although ASan is more efficient (performance-wise) overall, its limited accuracy reduces its impact below that of the other options in most cases, which is the common assumption.

We find that OPTISAN Both (Red) protects 18.4% more non-free unsafe operations on average across all fourteen programs for all budgets evaluated, ranging from a minimum of 0% to a maximum of 52%, compared to OPTISAN Baggy (Pink). We note that Baggy Bounds is the more cost efficient choice for all the unsafe stack operations for three programs (i.e., 625.x264_s, 602.gcc_s, and libxml2) [7]. This along with frequency distribution of the unsafe operations for 602.gcc_s leads to only Baggy Bounds being used. When accounting for accuracy, we find that OPTISAN Both Effective (Brown) effectively protects 14% more non-free unsafe operations

[6] Twelve of the fourteen test programs from Table 3 are shown in Figure 4. The remaining two programs, povray and perlbench in SPEC CPU 2006, do not exhibit a significant improvement compared to OPTISAN Baggy alone when applying both defenses.

[7] We note that for 511.povray_r the OPTISAN Both and OPTISAN Baggy lines do not overlap completely i.e., there is minor improvement compared to OPTISAN Baggy alone. ASan is only selected for a maximum of 4.7% of the unsafe operations covered.

across all fourteen programs for all budgets evaluated, ranging from a minimum of 0% to a maximum of 41%, compared to OPTISAN Baggy Effective. Further, we focus on the maximum difference at any budget shown in Figure 4 by the dotted vertical lines. The average maximum difference shown is 51.27% with a minimum of 0% and a maximum of 256%.

Finally, we also evaluate OPTISAN by limiting each unsafe stack object to only one defense to remove all redundant metadata. This restriction causes fewer unsafe operations, 3% on average, to be protected effectively across all programs compared to OPTISAN Both. By allowing the formulation to consider redundant metadata, OPTISAN is able to find more optimal solutions that use multiple defenses for objects used in multiple unsafe operations.

Usage of Defenses We find that when both defenses are considered Baggy Bounds is selected for 86% of the unsafe operations on average across programs for all budgets. In addition to the greater enforcement accuracy, we find two factors that affect Baggy Bound's usage when considering both defenses. First, most programs have a skewed frequency distribution (positively skewed) for the unsafe operations [69], i.e., only a small fraction of operations are really hot and incur majority of the cost to defend, as shown for Apache in Figure 5 a). We find that on average across all the programs evaluated 19% of the non-free, unsafe operations account for 80% of the cost. Intuitively, Baggy Bounds tends to be applied to unsafe operations that have a lower frequency (cost), which is the common case. Second, as shown in Section 2.2 quantitatively, we find that Baggy Bounds can be a more efficient option than ASan in some cases. As shown in Table 1, there is an average overhead reduction of 18% if Baggy Bounds is used in all cases where it is more efficient than ASan. We also note that the Baggy's stack metadata operations can be more cost efficient than ASan's for some programs, such as for 511.povray_r.

6.2 Protecting Usable Targets

Not all unsafe operations have the same security impact. Thus, we want to evaluate whether using multiple defenses can help maximize the security impact within a cost budget. In this paper, we have proposed that the security impact should be measured in terms of usable targets, as explained in Section 4.2.

To better understand the benefit of OPTISAN, we analyze the placements produced by OPTISAN and ASAP for the *Apache* program with a 7% budget in Figure 5b). On the x-axis, we show the check costs (i.e., the operation frequency multiplied by the cost per check) of each non-free unsafe operation for simplicity. However, metadata cost is accounted for when computing the placement. On the y-axis, Figure 5b) shows the effective usable targets protected by covering each unsafe operation. We find that OPTISAN covers at least 7 unsafe operations (i.e., shown as green X's), not covered by ASAP. We find 6 of them to be very important, as they protect more than 10 usable targets each. In addition, we find ASAP covers multiple unsafe operations that have low check costs and protects close to zero usable targets, as can be seen by the orange star in the bottom-left corner. Thus, the OPTISAN formulation biases the choice of unsafe operations to those with more usable targets to increase the stack memory protection.

Program	*CVE (severity)*	*Freq Rank*	*Target Rank*	*Place Rank*	*Total Unsafe*
libtiff	2022-1355 (6.1)	2	4	2	20
openssl	2016-2176 (8.2)	33	5	29	98
	2022-3602 (7.5)	2	2	2	98
	2022-3786 (7.5)	1	1	1	98
libxml2	2017-9047 (7.5)	155	39	149	2,614
	2017-9048 (7.5)	116	39	110	2,614
httpd	2019-10097 (7.2)	1,448	2,869	1,406	2,969
	2020-35452 (7.3)	1,900	2,598	1,831	2,969
readelf	2021-20294 (7.8)	348	356	322	361

The ranks shown are from lowest to highest in the set of all unsafe operations.

Table 5: CVE Analysis - Frequency (Freq) rank and target rank with associated placement (Place) rank for OPTISAN. ASAP places at the frequency rank.

We also measure the number of usable targets protected from all unsafe operations that may access the target for the defense placements produced. Figure 5c) shows the fraction of usable targets protected from all unsafe operations (i.e., using Baggy or ASan) in the placement computed (y-axis) for the three budgets amounting to 25%, 50% and 75% of the budgets necessary to fully protect all unsafe memory operations[8] (x-axis). As Figure 5c) shows, the fraction of usable targets protected can vary significantly at lower budgets (25%), but are approaching full coverage at 75% budget. However, we find that on average only a small fraction of the usable targets (i.e., about 20%) are fully protected for the *povray* program, even at a 75% budget. After investigation, we find that 3% of the unsafe stack operations in povray may access over 70% of the total usable targets. Hence, if only one of these unsafe operations remains unprotected at least (70%) of the usable targets would not be fully protected. Furthermore, we find that 6.56% of these high-impact, unsafe operations account for 99% of the total cost to cover all of them. These high-cost, high-impact unsafe operations remain unprotected even at the 75% budget evaluated. OPTISAN can help programmers identify these high-cost, high-impact operations, providing motivation for code changes to prevent spatial errors.

6.3 Protecting Unsafe Operations for CVEs

To consider the impact of OPTISAN in preventing the exploitation real CVEs, we examine nine CVEs, consisting of six known stack vulnerabilities from an open-source fuzzing dataset [28] and three stack vulnerabilities in other open-source programs - two in Apache and one in the binutils program, readelf. As shown in Table 5, we evaluate whether considering performance (Freq Rank for frequency) and usable targets (Target Rank) enables OPTISAN to prioritize the

[8] The specific budgets at these levels are shown in Table 6.

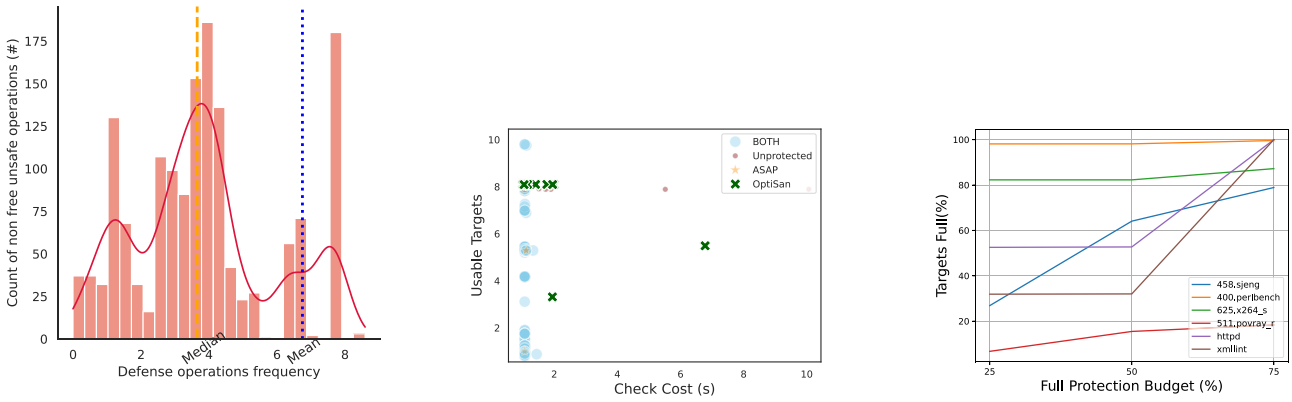

Figure 5: a) Frequency distribution for unsafe operations in Apache b) Distribution of the number of effective usable targets vs. the cost of defending for unsafe operations protected by ASAP, OPTISAN, and both for Apache using ASan. c) Fraction of usable targets protected fully vs. the fraction of the budget to protect all operations.

Program	***Baseline (s)***	***Full Protection Budget (s)***	***25 (%)***			***50 (%)***			***75 (%)***			***Mem (%)***
			Exp (%)	Obs (%)	It	Exp (%)	Obs (%)	It	Exp (%)	Obs (%)	It	
sjeng	400.76	133.71	8.34	6.85	2	16.68	15.32	2	25.02	20.34	3	1.00
perlbench*	243.97	26.52	2.26	1.85	1	3.81	1.87	1	10.27	10.98	2	0.25
httpd	104.44	14.83	3.54	2.63	2	7.09	6.07	1	10.65	7.54	3	0.30
libxml2	74.10	2.53	0.85	0.39	2	1.71	1.78	1	2.70	2.79	1	0.44
625.x264_s	240.65	2.44	0.25	0.40	2	0.50	0.40	1	0.75	0.80	2	0.51
511.povray_r	452.55	383.15	21.17	17.94	1	42.33	42.22	2	63.50	59.61	1	0.13
511.povray_r	452.55	383.15	4.23	2.75	2	8.47	5.01	5	12.70	12.73	1	0.13

Table 6: Performance metrics for programs instrumented with OPTISAN placements and iterations to achieve desired budgets. The columns contain the expected overhead *Exp* , the final observed runtime overhead *Obs* and the number of iterations performed *It* for each budget.
* - For *perlbench*, the budgets at 25, 50, and 75% did not generate distinct placements (see Figure 4), so we chose lower budgets (2.26,3.81 and 10.27 %).

placement of defenses for unsafe operations (Place Rank), before a cost-based heuristic ASAP [70], which only considers performance (Freq Rank).

We find that OPTISAN places defenses for these CVEs prior to ASAP for six of the nine unsafe operations and at the same rank for the other three. The other three cases have low frequencies, so they are prioritized for placement early using the frequency rank alone. While this is not a statistically significant sample and OPTISAN does not guarantees placement prior to ASAP for all CVEs, these results illustrate how at certain budgets ASAP may choose not to protect these vulnerabilities, as it decides solely based on the frequency rank. By considering the usable targets (Target Rank) as well as performance (Freq Rank), OPTISAN protects these vulnerabilities earlier (Place Rank) in these cases.

6.4 Instrumentation Overheads

The practicality of OPTISAN relies on it producing defense placements close to the desired budget. To measure this, we instrument the two SPEC CPU 2006 programs, two SPEC CPU 2017 programs, and two real-world programs as shown in Table 6. We specify three budgets for each program - 25, 50, and 75% of the estimated cost to cover all unsafe operations (*Full Protection Budget*) using *ASan* [59], or Baggy Bounds in cases where it is cheaper (*libxml2 and 625.x264_s*). Since *povray* has a high overhead, we also show that we can generate placements on tighter budgets for programs that are expensive to defend. We also measure the average memory overhead, by measuring the percentage increase in *max RSS (kbytes)*.

On average, the final observed run-time overhead deviates from the specified overhead by 1.47% of the program execution time, or 3.40 seconds, as seen in Table 6. There are 9 cases where we apply OPTISAN iteratively. We change the budget each iteration based on the difference between the expected and observed run-time overhead for each budget evaluated for a program. We find that within two iterations, on average, OPTISAN finds solutions with an average run-time overhead close to the desired budget for each of these programs. There are 5 cases that are slightly over the specified budget on average. Three of the cases are within budget in 3 out of 5 executions and within one standard deviation. The other two cases may be caused by: (1) folding initialization costs in metadata costs which may impact placement at low overheads (*625.x264_s* at 25%) and (2) the step-function effect of perlbench placements (see Figure 4). On average the memory overhead of the defense placement is 0.44%.

7 Discussion

In this section we discuss some current limitations of our approach and possible extensions.

One issue is that OPTISAN considers spatial memory errors with respect to stack memory only. Our approach can be extended to consider global memory, as one can identify *usable targets*, similar to the stack. To extend OPTISAN to the heap requires a reasonable technique to compute usable targets. This is challenging because heap objects may be reallocated to different locations, commonly have many more aliases, and have much larger lifetimes than stack objects.

OPTISAN's use of value range analysis to prune safe operations along with the application of ASan and Baggy Bounds defenses still leaves some operations unprotected at desired budgets, as shown in Figure 4. Ideally, we could integrate other defenses and proposed optimizations [25, 39, 74] to enable the coverage of all unsafe operations using cheaper defenses. In addition, we could use more comprehensive analyses to identify operations that must satisfy spatial safety to reduce checks and isolate usable targets from attack. One possible approach is to apply the recent DataGuard work [30] to identify safe objects using a combination of static analysis and symbolic execution, and isolate the safe stack objects using Safe Stack [16]. We leave this to future work.

OPTISAN currently supports placement using multiple metadata schemes, but this may lead to redundant metadata. However, a single unified and compact metadata scheme could be applied [20] to improve performance [33].

OPTISAN's *Mixed Integer Non-Linear Programming (MINLP)* formulation can be used to include additional defenses such as CFI [44], DFI [13]. They could be modelled as defense options for a group of unsafe operations such as enforcing CFI for a function. We leave this to future work.

8 Related Work

Sanitizer Placement ASAP [69] proposed a greedy approach to sanitize programs. For a given cost level, the most expensive checks are removed until a user-provided cost budget is met. The idea being that a few hot checks account for most of the overhead and that most bugs are along cold paths. Subsequent work [38] extended this idea to runtime partitioning wherein bugs along hot paths are detected probabilistically based on when the sanitized variants of functions are invoked.

Similarly, SanRazor [73] proposes identifying likely redundant checks to improve performance. This approach aims to leverage the execution profile and data flow facts of the checks to eliminate likely redundant checks. However, these approaches aim to improve performance based on heuristics that do not consider the security impact of the elided checks.

Recent work [74] developed multiple optimizations to improve Address Sanitizer [59]'s performance. The first optimization improves the safety analysis employed by identifying safe accesses related to stack and global objects. They remove redundant checks that are dominated by or post-dominated by the other accesses that refer to the same object (including aliases). They merge neighboring checks (memory accesses that access neighboring memory locations). They also optimize checks in loops i.e., loop invariant addresses and memory accesses which monotonically increase or decrease with the loop (change by a constant value).

Optimizing Defense Placements Researchers have long argued for applying systematic techniques based on optimization to make decisions rather than ad hoc heuristics [35]. However, few works consider the problem of optimizing defense placements for security. ProgramMandering [41] (PM) provides a method to generate privilege-separated domains that enables the programmer to optimize one metric while constraining others. The PM system defines four metrics covering security and performance properties that may be impacted by the choice of protection domain boundaries for a privilege-separated domain. PM uses a binary Integer Programming model for the partitioning problem given the metrics, proposing a semi-automated, iterative approach for programmers to determine the code to include in a domain. OPTISAN applies a Mixed-Integer Non-Linear Programming (MINLP) approach to solving a different problem.

Automatic Patch Generation Several approaches [22, 31, 36, 42, 43, 71] have been proposed to automate patch generation for vulnerabilities in programs. These include approaches which generate patches based on fixed patterns [36], such as adding a null check or a memory de-allocation statement to fix memory leaks [22]. Such approaches are not robust as they depend on these fixed patterns. Additional, approaches based on program mutation [71], symbolic execution [43] and machine learning [42] have been proposed.

Recent work [31] proposed using safety properties to automate program repair. The safety properties are manually specified and program-independent. This approach relies on concolic execution [12] to identify the safety property violated. These approaches are limited by their reliance on the knowledge of the vulnerability (i.e., *proof-of-vulnerability*).

9 Conclusions

We present OPTISAN, which is the first system to produce spatial memory defense placements that optimize security and performance within a cost budget. OPTISAN estimates the expected costs of spatial memory defenses, accounting for check and metadata operations and identifies the usable targets that may be exploited. OPTISAN provides an optimization formulation to compute a placement that maximizes the defense of such targets within a prescribed cost budget. Our evaluation shows that OPTISAN can produce placements that protect 18.4% more operations with usable targets using a combination of Baggy Bounds and ASan than Baggy Bounds alone at the same cost budget across fourteen programs. OPTISAN is shown to predict overheads accurately by modeling both metadata costs and bounds checks, making it a practical tool to place defenses.

Abstract

Cryptography serves as the cornerstone of information security and privacy in modern society. While notable progress has been made in the implementation of cryptographic techniques, a substantial portion of research outputs in cryptography, which strive to offer robust security solutions, are either implemented inadequately or not at all. Our study aims to investigate the challenges involved in bringing cryptography innovations from papers to products.

To address this open question, we conducted 21 semi-structured interviews with cryptography experts who possess extensive experience (10+ years) in academia, industry, and nonprofit and governmental organizations. We aimed to gain insights into their experiences with deploying cryptographic research outputs, their perspectives on the process of bringing cryptography to products, and the necessary changes within the cryptography ecosystem to facilitate faster, wider, and more secure adoption.

We identified several challenges including misunderstandings and miscommunication among stakeholders, unclear delineation of responsibilities, misaligned or conflicting incentives, and usability challenges when bringing cryptography from theoretical papers to end user products. Drawing upon our findings, we provide a set of recommendations for cryptography researchers and practitioners. We encourage better supporting cross-disciplinary engagement between cryptographers, standardization organizations, and software developers for increased cryptography adoption.

1 Introduction

Cryptography serves as a fundamental pillar in safeguarding data and information within our modern society. By providing essential elements such as confidentiality, integrity, and authenticity, it plays a pivotal role in securing private data for individuals and organizations. These cryptographic mechanisms are crucial for ensuring secure communications and transactions, defending against a wide range of threats to digital systems.

However, bringing cryptography innovations from papers to products is fraught with numerous challenges. The standardization processes serve as a crucial gateway for these innovations, enabling their integration into cryptographic libraries used by developers. These libraries, in turn, facilitate the implementation of cryptographic products for end-users. However, past research and incidents have highlighted the widespread failures and shortcomings in the successful adoption of cryptographic innovations at various stages of this process.

The widespread use of cryptography in software and hardware products is essential for effective security. While there are increasing threats where cryptographic solutions could help, the full potential of cryptography is often not implemented or deployed. One prominent example is email encryption. PGP [18] and S/MIME [36] have offered end-to-encryption for email since the 1990s. However, past research identified multiple usability problems [19, 39, 41], limited adoption [1, 42], and vulnerable implementations [32, 35].

Our work is furthermore motivated by the long struggle to get secure TLS deployed across the web [5, 28, 29, 34], and the mission statement of the Real World Crypto conference [44]: That the dialogue between cryptography researchers and developers implementing cryptography needs to be strengthened.

We believe that the cryptography and security community would benefit from a clear understanding of the challenges around bringing cryptographic innovations from research papers to products.

In this research, we develop a map of the cryptography ecosystem, understand the relevant stakeholders, processes, and key blockers involved in cryptography adoption, investigate challenges to the effective adoption of cryptography, and identify potential paths to improve future adoption.

We aim to answer the following research questions:

RQ1. *What steps are involved in adopting cryptography, and who are the relevant stakeholders?* Foundational cryptography research on primitives, algorithms, and protocols inform standardization bodies and cryptography product implementa-

tions and deployments. We are interested in the involved steps, stakeholders, and their interaction in adopting cryptography.

RQ2. *What are the key obstacles hindering the widespread adoption and correct use of cryptography?* Previous research and past incidents illustrated a limited and often incorrect use of cryptography. We are interested in the experiences and views of leading cryptography experts on key obstacles in adopting cryptography and their root causes.

RQ3. *What are potential ways to overcome these obstacles?* Increasing the adoption of and correct use of cryptography can lead to stronger security overall. We aim to identify promising paths to help with the more widespread and correct use of cryptography.

To answer our research questions, we conducted 21 semi-structured interviews with leading cryptography experts from academia and industry. Each participant had at least ten years of experience and heavy involvement in the community. We conducted iterative thematic analysis on the interview data to investigate the challenges of secure cryptography adoption.

With this work, we make the following contributions:

Insights from Experienced Cryptography Experts We conduct 21 semi-structured interviews with experienced cryptography experts from academia and industry to collect and report on their insights, opinions, and learnings about secure cryptography adoption.

The Path of Cryptography Adoption We develop and propose a *map* to help make sense of – and argue about – the complex and ever-changing dynamics of secure cryptography adoption. The map is based on the interview data collected and illustrates relevant actors and artifacts in the cryptography adoption ecosystem.

Challenges to Cryptography Adoption We report on the challenges that actors on the path of cryptography adoption face and investigate root causes for the challenges of cryptography adoption, based on our thematic analysis of the expert interviews we conducted.

Path Forward We outline root causes to tackle and recommend actions to take, on both an individual level and a community level, to foster the secure adoption of cryptography – from papers to product.

The rest of the paper is structured as follows: Section 2 summarizes related work on the topics of cryptography adoption and cryptography breakdowns. Section 3 explains the methods we used to gather and analyze data that allows us to address the research questions. Section 4 presents a resulting overview of the path of cryptography adoption. Section 5 reports on the identified challenges to cryptography adoption. Section 6 discusses the results in the context of our initial research questions, and presents recommendations for fostering the secure adoption of cryptography.

2 Related Work

We focus our discussion of related work on research identifying fundamental challenges using cryptography.

Developer Centered Cryptography. In 1993, Anderson discussed the challenges faced by cryptographic system designers due to limited information on system failures [3]. His work revealed that implementation errors and management failures, rather than technical attacks, were the main causes of fraud in retail banking systems, emphasizing the need for a paradigm shift in computer security.

The work of Georgiev et al. exposed significant flaws in SSL certificate validation across various security-critical applications and libraries [20]. The vulnerabilities arose from poorly designed APIs and configurations, making SSL connections vulnerable to man-in-the-middle attacks. The findings emphasize the need for improved API design, comprehensive testing, and enhanced documentation to ensure the security of SSL connections.

In 2018, Haney et al. conducted 21 in-depth interviews of highly experienced individuals from organizations that include cryptography in their products [23]. Within their sample, they found evidence for strong organizational security culture, careful selection of cryptographic resources, and formal, rigorous development and testing practices. Their findings support past studies that suggest that the usability of cryptographic resources may be deficient [2, 21, 33].

Heninger et al. conducted a comprehensive survey of TLS and SSH servers, uncovering widespread key vulnerabilities due to insufficient entropy during generation [24]. Approximately 0.75% of TLS certificates and 1.70% of SSH host keys were at risk of compromise. The study highlights software behaviors, including a Linux random generator flaw, primarily affecting headless or embedded devices.

Fahl et al. investigate the security risks associated with benign Android apps that utilize SSL/TLS protocols to safeguard data during transmission [16]. By analyzing 13,500 popular free apps, the study identified potential vulnerabilities to Man-in-the-Middle (MITM) attacks, with 8.0% of the apps found to be potentially susceptible. Additionally, the research underscores the significance of addressing user misconceptions and inadequate visual indicators for SSL/TLS usage, necessitating the implementation of effective countermeasures.

Cryptographic Libraries. In 2012 Bernstein et al. present NaCl, a cryptographic library that is intended to be securely usable by non-experts, to prevent "cryptographic disasters" that previous, less usable cryptographic libraries had lead to [8]. The 2017 work of Acar et al. presented the first empirical evaluation of cryptographic libraries, examining their impact on code security and functionality [2]. The study found that while simplicity of APIs is important, comprehensive documentation and accessible code examples are crucial

for promoting both secure development and functional correctness. In 2022, Jančár et al. conducted a questionnaire study with 44 developers of cryptography libraries, investigating if and how they ensure that their code is not vulnerable to timing attacks [25]. They found that many developers perceive updating their code to be constant-time as too high of an investment of time and effort to actually tackle it. The authors promote the use and improvement of analysis tools, security-aware compilers, and constant-time cryptographic libraries, which all have the aim of making writing constant-time code easier.

End-to-End Encrypted Email. The seminal paper "Why Johnny can't encrypt" [45] spawned a string of research on the usable security and adoption of email encryption. Even though the problem of ensuring end-to-end-secured email communications seemed to be solved on a technical level by existing implementations of both PGP and S/MIME, the bad usability of these solutions was a major blocker for adoption. In 2019, Ruoti et al. summarize these almost 20 years of "Johnny"-papers on the usability of secure email communication [39]. They recommend tight integration of security tools with users' existing ways of communication, context-sensitive tutorials, and trustworthy design and call for more research into the – to this day – unsolved challenge of usable secure key management for private end users. Stransky et al. analyzed 27 years of email data from a large university and found that only 5.46% of users used S/MIME or PGP, resulting in 0.06% encrypted and 2.8% signed emails [42]. The research reports that key management issues and the use of multiple email clients negatively impact encryption adoption.

Clark et al. investigated email encryption by identifying stakeholders in the current ecosystem of email communication. They infer that the current, less-than-ideal state of end-to-end encryption in email communication stems from the evolution of fragmented secure email solutions created by industry, academia, and independent developers [13]. There are now competing solutions that address different interests of seven stakeholders they identify as Email Service Providers, Enterprise Organisations, Privacy Enthusiasts, Vulnerable Users, Secure Mailbox Providers, and Typical Users. While some enterprise organizations are legally required to be capable of exceptional access to their employees' communications, such exceptional access would be considered a plain backdoor by privacy enthusiasts and vulnerable users. On the other hand, typical users might highly prefer systems that allow server-side processing of their emails by Email Service Providers for, e.g., spam filtering or for reliably pre-sorting email messages into categories.

Standardization Processes. Paterson and van der Merwe present how, for the development of TLS 1.3, the IETF TLS working group was able to move from a *design-release-break-patch* cycle to a *design-break-fix-release* cycle [34]. This means that they were able to involve academia and industry heavily during the design stage of the protocol, instead of relying on the historical way of releasing a standard and then releasing patches after vulnerabilities are found through analysis by academics or through use in the real world. They state that better tools and greater academic community engagement enabled this move. They postulate that a requirements *analysis-design-prove-release* process might have been even better. In 2020, Halpin et al. investigated why attempts to update the OpenPGP standard to a modern security level have failed at the IETF [22]. They find the core reason to be a missing simple AEAD interface, which in turn requires a decentralized public key infrastructure – that does currently not exist.

Also in 2020, Bernstein surveys standardization procedures of past cryptography competitions, and finds performance pressures and limited time for security analysis as sources of security risks, but also possible NSA interference and incentives in academic publishing [7].

3 Methodology

We conducted semi-structured interviews with 21 cryptography experts from academia, industry, and nonprofit and governmental organizations. Our aim was to elicit their personal experiences and reflections on the process of bringing cryptography research output "from paper into practice"—including potentially contentious ones—and to be able to ask follow-up questions. All interviewees had at least ten years of experience researching, designing, standardizing, or implementing cryptography and had high standing and visibility in the cryptography community.

This section provides an overview of our methodology, describing the process of developing the semi-structured interview guide, participant recruitment, interview procedure, the qualitative coding process, and ethical considerations and limitations in this section.

Initial Recruitment and Instrument Development. We initially recruited three participants from our professional networks—researchers with a strong publication record in cryptography and security who had created a cryptographic protocol or application that is widely used today—to scope the problem space. These were in-depth (80–110 min) interviewee-led interviews on their involvement in and experiences with a successful deployment, centered around the question: *What were the obstacles (blockers) they encountered on the adoption path? What did they have to do to overcome them?* We shared the transcripts of those interviews with the interviewees, and asked a number of clarification and follow-up questions. Based on the interviews and their answers, we developed an interview guide for the remaining expert interviews.

Our semi-structured interviews were interviewee-led: Interviews centered around questions that participants answered in-depth, as well as topics and questions they thought would

add to our line of inquiry, which both led to deep insights and helped prioritize and value participants' time. Since we were looking for insights beyond published literature, we asked for their personal assessment and opinions of the causes of problems. Our first three participants had no reservations identifying them, but also qualified that not everyone would agree. We therefore selected such "strong statement" quotes and discussed them at the end of subsequent interviews (see Section 3.1). Expert-led interviews and "feeding forward" quotes for responses by other participants was inspired by the Delphi method [4, 38].

Further Recruitment. In the three initial interviews, interviewees mentioned other academic cryptography researchers, industry-based researchers, or policy experts that would be helpful for investigating the different challenges for effective cryptography.

We wanted to recruit an experienced set of cryptography experts from different parts of the cryptography ecosystem: academic researchers, industry researchers and practitioners, and those working in nonprofit and governmental organisations, and who had been involved with more than one aspect of cryptography research or implementation: experiences ranging from cryptography theory to standardisation to implementing cryptography for expert and non-expert users, and policy work. While we focused on recruiting experts with past successes in getting cryptography adopted, we also aimed for multidisciplinary interviewees to cover a broad set of expertise, experiences, and opinions.

From the recommendations, we invited interviewees who met the eligibility criteria, starting with those mentioned multiple times. We issued 20 invitations in total. 18 accepted; 2 invitees did not respond. See Table 1 for a summary of interviewees' backgrounds and experience. In total, we recruited three interviewees from our professional network and 18 interviewees through snowballing; however, many of the experts suggested by interviewees were also known to us prior to the interviews.

Interview Procedure. All interviews were conducted by one interviewer and one to two additional interviewers, except for P21, where no additional interviewers could be present. The lead interviewer could fully focus on asking questions. The additional interviewers ensured that no questions were left out, could ask follow-up questions that emerged, or take over in case of internet connection issues. We conducted all interviews remotely using a self-hosted Big Blue Button Instance, Zoom, or Google Meet, depending on the interviewees' preferences. We expected the interviews to take 45–90 minutes and scheduled one or two-hour appointments with all interviewees, yielding about 30 hours of interview data. Interviews lasted between 45 and 155 minutes; the median duration was 84 minutes. We based the interviews around non-leading, open questions, allowing interviewees to elaborate on their thoughts and answers.

Positionality. The researchers who carried out the interviews and analysis had a range of disciplinary backgrounds, including psychology, cryptography, and computer science, and a broad range of academic research experience. We made all decisions (study design, interview guide, and results reporting) with reference to published research practices. Nevertheless, decisions on which particular lines of inquiry to pursue, or what to include in the results, are likely to be influenced by the perspectives present and the dynamics between the researchers. Other researchers analyzing our data may have focused on different aspects (though we are confident that on the aspects we are reporting on, they would not have come to radically different results).

3.1 Interview Guide

We describe the semi-structured interviews below and in Figure 1.

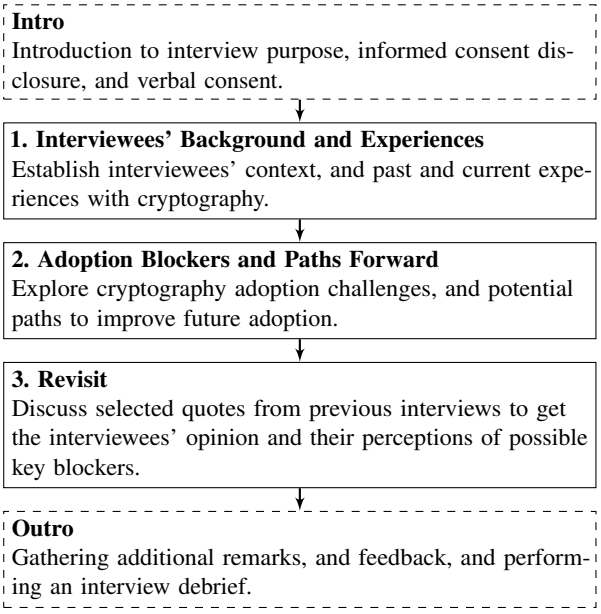

Figure 1: Overview of the interview flow and topics. We followed up the introduction of each section with specific questions (if not already covered). The semi-structured interviews allowed interviewees to diverge from this flow at any time.

We structured the interviews into five main sections, including an introduction, questions about the participant's background and experiences with cryptography, their viewpoints on cryptography adoption blockers and potential paths forward, a discussion of quotes from previous interviews, and a debrief. Each section included opening questions and corresponding follow-up questions and prompts. The full interview guide can be found in Appendix A.1.

At the beginning of each interview, we introduced ourselves, the research project and its goals and provided details

Table 1: Detailed overview of the cryptography experts we interviewed.

[1] Years of experience in relevant fields. [2] Based on self-reported information and internet research.
Column Academic: ●: 7+ years post-PhD in a tenure-track academic position. ○: 1–6 years post-PhD teaching at University
Column Industry: ● 7+ years employment in major tech firms. ○: 1–6 years employment and/or part-time role, e.g. co-founding a start-up.

of the interview process. In particular, we explained that interview participation was voluntary, that interviewees could skip any question and that we would not judge their answers. We guaranteed full de-identification of quotes we might use in a publication and offered them to send a preprint of the paper before publication.

Interviewees could ask questions and we asked them to provide additional verbal consent for interview recording and data processing. We started the recording and began the interviews with the structure below:

Background and Experiences. We first asked interviewees to describe the work or research they primarily do and characterize the cryptography field they work in. This section aimed to connect with the interviewees, ease potentially nervous participants, and establish an initial context about their work.

Adoption Blockers and Paths Forward. We asked interviewees to report on their experiences with blockers for the adoption of cryptography. Specifically, we were interested in experiences related to their work. If available, we asked them to describe some of the work they had hoped would be be adopted but which did not meet their expectations. In the second half of this section, we asked them for the most important factors or steps that led to the adoption of cryptography. At the end of this section, we were interested in our interviewees' views on things that have to improve or change for a better adoption of cryptography.

Revisit. In the final section, we showed participants quotes from previous interviews. We selected quotes based on their significance to be an adoption blocker, to provoke discussion, or to judge expert agreement about a blocker better. For each interview, we selected 5–10 quotes that we knew the respective interviewee to have expertise on. In total, 13 unique quotes where shown across all expert interviews. A list of all discussion quotes is provided in the extended version of this paper.

We did not provide financial compensation to our participants, which, based on our experience with similar expert populations, are often declined; participants supported our research out of the intrinsic motivation to improve the adoption of cryptography.

3.2 Data Analysis

We recorded the audio of all interviews, removed identifying information from the recordings, transcribed them internally and reviewed the transcripts for potential mistakes. We used an iterative semi-open coding approach [12, 15, 43] to perform thematic analysis [14] for all interview transcripts. We stopped interviewing after 21 interviewees, reaching saturation [17].

The main author conducted open coding to develop an initial codebook on all interview transcripts. We additionally followed a deductive approach to code all areas in the cryptographic landscape that participants discussed. In a second coding step, the main author coded all blockers for adopting cryptography using inductive coding. Another co-author independently coded all transcripts. The main author and two other co-authors reviewed both codings, discussed im-

portant insights and identified core topics in multiple affinity diagramming [9] sessions on a whiteboard.

Our approach does not require the reporting of inter-coder agreement. We resolved each conflict when it emerged following established practices in the HCI community [31].

3.3 Ethics and Data Protection

Our institutions did not require formal ethics approval for this type of study. However, we modeled the interview study after the ethical principles for human subjects research involving information and communication technologies outlined in the Menlo report [27]. The research plan, interview procedure, data collection, storage, and analysis, and all involved researchers adhered to the strict German data and privacy protection laws and the GDPR. We provided all interviewees with information about the study procedure and data handling before signing up for the interviews. We encouraged them to get informed before deciding and offered to answer any potentially upcoming questions. We explained to interviewees that they could skip any question for any reason. We sent interviewees a preprint of this paper before publication so they could request changes or correct misunderstandings; following their feedback, we made small changes to Table 1. We did not offer any compensation to our interviewees as they were all highly successful individuals motivated to work on cryptography to make the digital world safer. Personally identifiable information was stored securely and encrypted at rest and in transit, compliant with the GDPR. We removed parts of interviews participants flagged as too sensitive to transcribe and de-identified participants using the identifiers P01–P21 and removed any information that would easily identify our participants from the transcripts. After checking transcripts for correctness, we deleted all audio recordings.

3.4 Limitations

Our research is affected by limitations common to interview studies, including potential over- and under-reporting, self-reporting, recall, social-desirability biases, sampling bias, and limited generalizability [30]. While our sample is a convenience sample that may not represent all cryptography experts, we tried to account for the above biases by interviewing a diverse sample of cryptography experts fitting our recruitment criteria. Our sample includes various academic and industry settings, from leading experts in foundational cryptography research to industry-leading developers of cryptographic products. The interview data imply that our sample is broad and diverse. However, we refrain from making quantitative statements due to the qualitative nature of our research methodology. We conducted 20 interviews in English and one in German.

4 The Path of Cryptography Adoption

In answer to RQ1 *"What steps are involved in bringing cryptography from papers to products, and who are the relevant stakeholders?"*, our participants referred to stakeholders and processes that are part of what we have called "the cryptography adoption path" which is embedded in the cryptography ecosystem. Figure 2 shows a map of that ecosystem, containing entities (actors), activities, and artifacts (products) in the current cryptography ecosystem. Our goal was to create a *simplified* map to help us to make sense of—and to argue about—the cryptography ecosystem as a whole. We are certain that for specific end products, the map can be extended with additional relevant actors and artifacts.

This map helped us to structure the actors and processes involved in bringing cryptography from papers to products. We grouped different stakeholders involved into entities that perform different roles or jobs in the cryptography ecosystem, and which may be performed by a single person or groups of persons. Both the actor entities and the processes were explicitly mentioned by interviewees in the context of turning cryptography research output into products. The path sequence was pieced together from partial descriptions across the interviews—i.e., no single interview described the implementation path as such—and thus should be read as a hypothesis that may change after further evaluation (see Section 7)

Our results reporting follows the path of bringing cryptography theory from papers to end-user products, as supported by our interview data.

Disclaimer. While the cryptography adoption path we illustrate in the map emerged from our interviews, it is a simplification and specific cases might deviate from it.

From left to right, grounded in our results we identify the following areas on the map:

1. Algorithm and Protocol Development
2. Standardization
3. Secure Implementation (Cryptography Libraries)
4. Product Development
5. Adoption and Use of Cryptographic Products

Algorithm and Protocol Development. The (simplified) adoption path starts left on the map, with the design of cryptographic algorithms and protocols. Cryptography researchers create cryptographic algorithms and protocols, which they publish as academic research papers or specification drafts, thus making them available to the community for 1) cryptanalysis, i.e. looking for potential flaws and weaknesses, and 2) security proofs and formal verification, which can show that, under a set of chosen assumptions, a given algorithm or protocol is hard to break. Successful cryptanalysis, security proofs, and formal verification are commonly also published as research papers and inform the design of new or improved cryptographic algorithms and protocols.

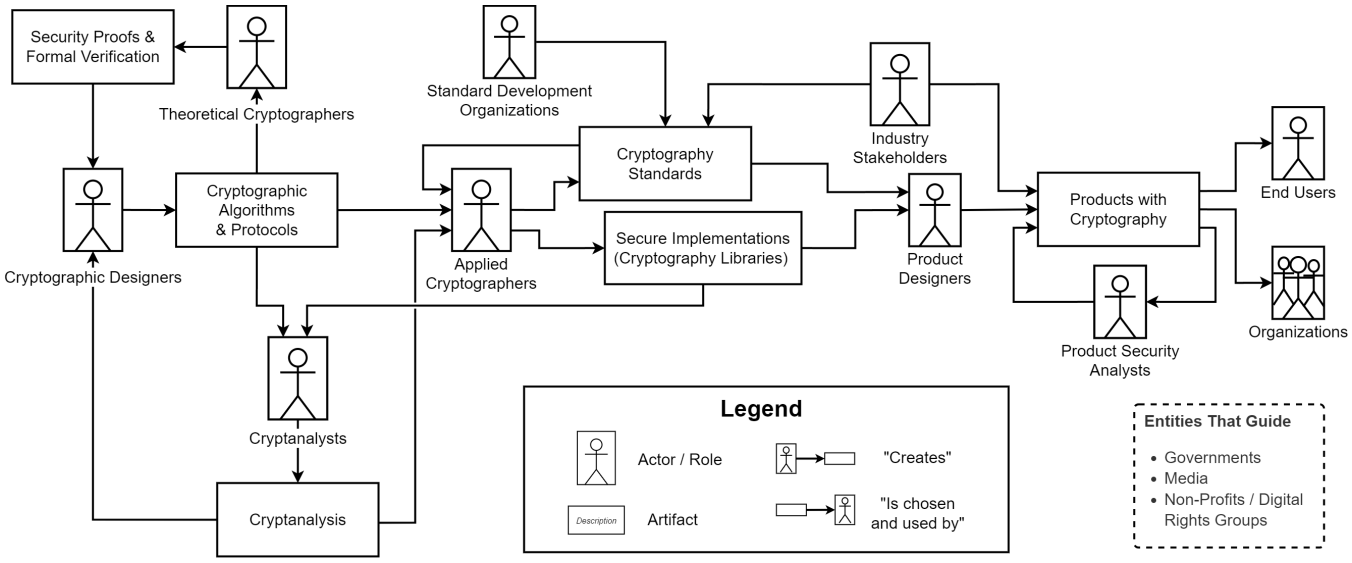

Figure 2: A visualization of the cryptography ecosystem and the path of bringing cryptography from paper to product. This map emerged from our interviews and serves as an abstracted illustration of the complex and ever-changing dynamics of cryptography adoption.

The result is a feedback loop that improves cryptographic designs through academic research.

Standardization. Cryptographic research output that has passed muster with the academic research community might become a standard. Standard Development Organizations (SDOs) can provide a platform and process for cryptography researchers and industry stakeholders to establish consensus and create standard specifications and documentation. This can, e.g., happen in the form of a drafting process of open working groups, as in IETF, or in the form of competitions, as often organized by NIST for cryptographic primitives. Product vendors can choose to put resources into standards development for one of mainly three reasons: They want to be able to interoperate with their or competitor's systems, implement a standard for compliance reasons, or use it as an argument in marketing their product.

Secure Implementation. Cryptographic research papers partially provide proof-of-concept implementations; according to our participants, these are generally not robust enough to be used in a product. Applied cryptographers take the cryptographic research output and turn it into implementations that can be widely used by non-cryptography experts, e.g., software developers. Implementations may be provided in the form of cryptography libraries. Cryptanalysts and security researchers often scrutinize applied cryptographers' output for implementation flaws and feed back the results to improve robustness.

Product Development. Hardware or software vendors and developers may want to protect the data their product is handling. To do that, they select a relevant cryptographic library, which becomes part of the product they create. This product can then again be analyzed by "Product Security Analysts" for security vulnerabilities stemming from, e.g., unintended or unexpected usage of the API of the chosen cryptography library.

Adoption and Use of Products with Cryptography. The last actors on the path of cryptography adoption path are everyday end users and organizations, who choose and use specific cryptographic products. They can choose products that are inherently insecure, or use products in unintended ways and thus potentially risk their privacy or security.

Entities That Guide. The following additional entities are noteworthy. They can influence cryptography adoption in multiple ways.

Governments can create legislation and regulations that impact the funding of research and critical internet infrastructure, impact standards that need to be implemented by certain industries, and specify security and privacy requirements for cryptographic products.

Media outlets can influence public opinion and focus public attention on certain topics.

Consumer advocates and digital rights groups can aid end-user decisions and support the development of secure implementations and infrastructure. For example, the Electronic Frontier Foundation's (EFF) *Certbot*[1] and the *Let's Encrypt* [2] initiative were driving forces for widespread adoption of HTTPS.

5 Challenges of Cryptography Adoption

Our interviews revealed a myriad of challenges that can occur when bringing cryptography from research papers to products. We report on these in the categories 1) misaligned or conflicting incentives in academia, 2) challenges in standardization and 3) challenges in reference implementations, 4) communication gaps and unclear responsibilities, and 5) usability issues, and provide examples from our interviews.

5.1 Misaligned Incentives in Academia

Incentives hold significant sway over the trajectory of human endeavors, both in their presence and absence. When examining the path of cryptography adoption, a central aspect are actors' incentives, as they often do not align perfectly with our overarching goal of secure cryptography adoption.

A frequent pattern we identified is many actors not directly working towards the overarching goal of cryptography adoption because they are not directly incentivized. Additionally, some interviewees illustrated cases where actors partaking in the ecosystem have conflicting incentives and thus actively work against the adoption of secure cryptography.

Many pointed out that the creation and maintenance of production-quality cryptographic code, i.e., code that can be safely used by software developers, is not a primary task of cryptography researchers.

Research is mostly funded through grants. Most interviewees agreed that for many grants, one of the most important metrics is the number of published top-tier research papers. For many researchers, there is not much to gain from putting rigorous amounts of work into usable and secure implementations of their cryptography: "*practical impact does not get you papers at CRYPTO*" (P9). Some interviewees mentioned that some cryptography conferences are starting to reward the "engineering side" of research more. Multiple participants highlighted the effort of the Real World Crypto (RWC) Symposium in this direction. "*Real World Crypto is actually a wonderful place where industry and academia come together. [. . .] The community is growing and a lot of papers that analyse a crypto standard will now actually appear at the security conferences.*" (P3)

But few participants also argued a different way, implying that RWC is not as inclusive as some would want it to be: "*RWC, even by it's name, it conveys what the message is: 'Don't bring your theoretical nonsense here. We don't want to hear about it!'*" (P13). Either way, our participants agree that when designing new cryptography, conferences at most reward proof-of-concept implementations, which may sometimes be labeled as 'reference implementations', but are far from production-ready code. We identify this as a major challenge for cryptography adoption, since almost all our interviewees underlined the importance of providing usable code when working towards adoption of new cryptography.

> "*If you really want people to use it, you have to have code that they can use. To play with. And it has to replicate more than what just the paper does. I think that is what academics don't do enough. It has to be a piece of code that is genuine enough that it can be used to do stuff, that is not just what you have said in the paper, but more general use.*" — P16

Some interviewees expressed favor for the concept of *boring cryptography*, meaning "crypto that simply works, solidly resists attacks, never needs any upgrades" as opposed to "interesting cryptography", which is more complex, or even flawed, and thus offers an opportunity for ample amount of cryptography research. [6]

One participant mentioned a controversial incentive that comes with the concept of boring cryptography: A community incentive for cryptographers themselves to not design secure cryptography, but "*to be exactly at the edge of things being not broken, but, hopefully, some of them do get broken so that you can keep writing papers.*" (P2)

However, when we asked interviewees if cryptography adoption would thrive if we persuaded researchers working on "interesting cryptography" to pay more attention to "boring cryptography", most interviewees refused: "*I don't want to denigrate blue-sky, crazy, research because that is what academia is for. It should be somewhat insulated from the real world.*" (P9)

Some participants shared sentiments that can be summarized as a statement that academia should maintain its ability to explore uncharted territories that may be detached from immediate real-world applications. A participant with industry background noted that it is unreasonable to expect academics, who are not directly compensated by industry, to undertake tasks that primarily benefit industry. "*As an industry person, it feels churlish to complain that these people, who we don't pay for, are not doing our work for us.*" (P9)

Academics possess a diverse skill set that extends beyond their narrow focus; they lack incentives to engage in various activities critical to the overall cryptographic ecosystem. Some participants noted that contributing to standardization efforts and attending standard meetings are essential tasks, but they often receive limited recognition and reward.

> "*Standardization [. . .] is very, very painful. There are people who do that, I mentioned some names in the IETF, they are doing it because they feel it's a socially important thing. . . out of some kind of duty. Social duty. But it's difficult to find those folks.*" — P15

Another participant expanded on this, explaining that "*people won't get that much academic credit for spending like three years flying to IETF meetings and fine-tuning a standard. So, maybe there's an academic incentive problem.*" (P8)

However, some interviewees mentioned that incentives for academics to partake in standardization efforts appear to be growing: "*I would have agreed with this more five years ago, so I think it's going in the right direction. Ten years ago 99% of the community were not interested in standards at all. And this is getting better.*" (P17)

5.2 Standardization

Some interviewees with industry backgrounds mentioned that the IETF standard drafting process has changed over the past 20 years, becoming more cumbersome: "*In practice the IETF-process doesn't work as well as it used to. [...] It discourages participation. We did end up trying to play the IETF-game for [widely adopted cryptographic protocol]. But it was so painful, we all stopped doing it before it was standardized.*" (P4)

Some interviewees suggested to be critical of standardization process participants: "*You'd think the goal is to bring out efficient and secure standards, but of course, companies are also there to protect their own interests. And we know from the Snowden documents that governments send employees there to boycott the process or to make sure that standards are not usable. [...] I think you should understand the game and you should play the game, and you should accept the outcome could never be perfect. [...] It's about everybody protecting their interests and minimizing their losses.*" (P7)

Participants provided examples including the financial industry's resistance to forward secrecy in TLS 1.3, where, near the end of the TLS1.3 drafting process, BITS [10], an organization that at that time represented about 100 of the top 150 US-based financial services, fought to re-add RSA static keys to the standard. Security experts had removed static RSA keys from the draft because static RSA keys break forward secrecy and are perceived as a potential backdoor. BITS argued the need for static RSA keys to be compliant and improve security by monitoring the content of TLS connections cheaply [40].

The above example illustrates that, even in open and transparent cryptography standardization processes, the actors' motivations might not support the most secure outcome possible. They can be about reducing engineering effort and minimizing the cost of updating systems to accommodate new protocols:

> "*I have no idea what to do about the unfortunate influence of industry [in cryptography standards], like: 'We have this system from twenty years ago that is deployed. Our interest is to make sure that it continues to be officially sanctioned.' – It is tough.*" — P9

Different stakeholders with diverging goals. Different actors in standards processes have different goals and incentives.

Academic Researchers According to our interviewees, most researchers will struggle to find funding for putting work into standardization efforts. Standardization work was described as 'tiring', tedious', 'deathly boring', and 'unrewarding' work, that demands long-term commitment—which requires a magnitude of resources that does not fit well into common funding structures in academic research. Our interviewees' collective sentiment towards open standardization processes, like the IETF's Internet Standard Drafting Process [11] and open cryptography competitions run by NIST [7], was positive when compared to more closed standardization processes, like those of the International Organization for Standardization (ISO) or the European Telecommunications Standards Institute (ETSI). At the same time, some interviewees said that NIST processes could be improved, questioning the competition requirements set by the organizers, or being concerned about NIST's collaboration with the NSA.

Industry Stakeholders Some interviewees argued that companies are missing incentives to put resources towards standard development. When creating new standards, companies generally do not gain much from putting more resources into standard development than the bare minimum needed to make it work for themselves. Any resources they spend on making the standard specs and documentation particularly usable (see Section 5.5) reduces the extent of resources their competitors have to invest to implement the standard.

Additionally, our interviewees reported on industry players pushing to have their self-developed protocols standardized for financial gain:

> "*An ISO working group was trying to standardise some smart card based authentication protocol, and some [nationality redacted] guy had invented [a fitting protocol]. He had managed to get it turned into a national standard. And now he was a one-man consulting company and he was trying to get it turned into an ISO standard. And it was complete junk, we broke the protocol, in several different ways. But he still was really, really pushing for this thing to be standardized because, you know, most didn't know what was going on.* " — P3

Misunderstandings in Standardization. A particular challenge for academics and engineers in standardization processes is that, since they have different backgrounds, they have different terminologies, expectations, and ways of looking at things. As one participant highlighted, "*There are a lot of cases where the same words are used to mean different things and different words used to mean the same things*" (P12), making effective communication difficult. Another interviewee cautioned that "*There's not many people sitting in the middle to translate between these worlds. I think there's like half a dozen people who are able to do that*" (P3). And while most participants agreed, some added the correction that there are more people who are able to do that—but don't do it due to conflicting incentives:

> "*There are other people who can do it—but don't do it. [...] They get highly paid to work inside Microsoft or inside Amazon. And they probably look at what happens in the standards world to make sure it's not too crazy, but they don't want to spend too much time. It's very time-consuming, being that person.*" — P15

(see. Section 5.4 "Communication Gaps and Unclear Responsibilities"). The absence of these "translators" can lead to misunderstandings and miscommunication, and result in unsuccessful standards or even security flaws. One of our interviewees reported interactions with the European Telecommunications Standards Institute (ETSI), where academics have not been involved in an early drafting process of a standard as "*I was at some ETSI meetings and [...] we were sitting there with 2 or 3 academics in the back row and our job was just to call 'bullshit!' from time to time when things really clearly went in the wrong direction*" (P5)

According to (P4), *"the people who are involved in standards are inevitably becoming more theory-based"*, suggesting that a better understanding of theoretical cryptography is growing among standard organizations. The same participant went on to remark that *"the people who are involved in actually implementing things are getting less involved in standards because they just can't be bothered with the process"* (P4). This illustrates the division between those involved in setting standards and those implementing them.

Adoption of Standards. Some interviewees reported that many cryptography standards are not adopted because they fail to identify their users and use cases in a meaningful way. Several interviewees agreed that standards go wrong if they misunderstand real-world use cases: "*Often, the standardization process is done in a vacuum, where they don't talk to the potential customers in any meaningful way [...] and then it gets deployed and the customers think that this is not very good, and either the deployers then end up with the bad system or they skip the standard completely.*" (P1). Our interviewees suggest that this tends to happen more often in closed standardization processes, like those of ISO or ETSI, rather than in open standardization processes.

5.3 Reference Implementations

Our interviewees mentioned the important role of reference implementations. Reference implementations occur on different levels: 1) reference implementations of research ideas as part of a research paper; 2) reference implementations of standards; 3) reference implementations for the use of cryptographic library APIs.

Reference implementations provide practical examples that support developers implementing cryptography. They furthermore allow developers to verify the interoperability of their implemented product.

Our participants expressed consensus on the variability of reference implementation quality. "*My reference implementations were never production-ready, they were reference implementations. But this is a problem with code libraries, [...] people just grab them and use them without knowing what they are.*" (P20)

One participant stated, "*reference implementations have a very big role to play in making sure interoperability is there.*" (P17) A distinction was made between reference implementations and optimized implementations. "*You have your reference implementation which is written in the plain scene, no tricks, no optimizations. And then you have the 'weird and whacky' implementation, which gives me my performances.*" (P16) However, there is a tendency for optimized implementations to be considered reference implementations, making them challenging to work with for those lacking specific additional skills. As one participant pointed out, "*There are companies that are selling very large numbers of different [IoT] objects. They're just using reference implementation code off the shelf, putting it into devices, and then we discover a huge number of vulnerabilities. And they just don't have the skill-set in their engineers to check whether the reference that they're using is sound.*" (P15). Other examples of misuse of reference implementations provided by some participants are the copying of hard-coded credentials and insecure configurations.

Additionally, low-quality reference implementations can hinder the adoption of cryptography by rendering them simply unusable. One participant shared their experience with software written by academics:

> "*There is no data abstraction. There is no separation of interface from implementation. Half of them, we looked at the code and we go: "We want to include that in our library." Then we read it and we go: "Eww, no!—We'll write it ourselves." It might be super fast, but it is super fast because it breaks every rule under the sun.*" — P16

To address these challenges, some participants made various suggestions. One suggestion involved labeling proof of concepts to distinguish them from production-ready code. However, many participants were quick to point out the very limited effects that this labeling has: Developers may not fully comprehend or pay attention to the potential risks of copying code. As one participant stated about a university class assignment, where students had to implement an encrypted chat protocol:

> "*People don't really realise the danger of what they're putting out there. I developed a class assignment with my students, where they implemented an encrypted chat protocol. The code is on GitHub, so I tried to put a warning on the front page of the repo: 'Don't actually use this for anything! This is*

just a classroom example.'—But I've thought about that a lot. Any crypto code you put on the web might be used by somebody. A lot of people put stuff up just as a pedagogical example or proof of concept. And then it ends up getting used in real products." — P8

In the context of the NIST Post Quantum competition one participant made a suggestion to reduce these risks: "*The reference implementations of post-quantum are of variable quality. That is a worry. It means the implementation ecosystem is not seeded with the very highest quality things. [. . .] I think the answer is that [. . .] we need to flood the space with high-quality implementations. And if that happens, we will be ok. And if it doesn't, it will be more problematic.*" (P9) By providing high-quality reference implementations, the chances of developers picking up the bad reference implementations are decreased.

Some interviewees pointed out that the skills required for creating high-quality reference implementations differ from those needed to write academic papers. "*The quality is very variable because the skill set of making an implementation is different from the skill set of writing a paper that is accepted at [a crypto conference].*" (P11)

5.4 Communication Gaps and Unclear Responsibilities

Many interviewees reported misunderstandings and miscommunication and unclear responsibilities between the different stakeholders involved in the cryptography ecosystem.

As mentioned by some participants the shortage of "translators" poses a significant challenge in bringing cryptography from research papers to products and can lead to output not being implemented correctly, or not being implemented at all: "*[Engineers] have a system and they want to make it secure. And so you indeed have to translate your scheme and explain them what you want to do, what you want to achieve and why these properties are important.*" (P7)

Cryptography research is evolving rapidly, spans many specialized subjects, and uses highly diverse terminology and different language. For example, experts in symmetric and asymmetric cryptography already speak a very different language.

It is not unusual for theoreticians to view applied aspects of their craft as too difficult, messy, and complicated: One of our interviewees reported a theoretical researcher telling them "*No! I don't want to understand the problem with the application. That's your job! My job is just the design and mathematics!*" (P10)

Fortunately, there is a growing recognition of the value of collaboration and cross-disciplinary learning, despite the inherent difficulties or human cognitive constraints that come with working beyond one area of specialization.

" *I think there is now a) appreciation from both sides and these people are talking. This is fairly new. And b) I think that there is also even an appreciation in the crypto conferences now.*" (P17)

By breaking down barriers and engaging in effective communication, cryptographers can gain a better understanding of the ideas and motivations of their colleagues from different backgrounds leading to more productive and collaborative research.

5.5 Usability Challenges

We frequently spotted usability issues when interviewees reported on challenges to secure the adoption of cryptography. This includes the usability of end-user products, but also the usability of cryptography libraries, reference implementations, standard specifications, and documentation.

Some interviewees reported usability issues (in addition to low quality) with reference implementations. Reference implementations can be difficult to understand because they might include tricks that are unfamiliar to developers who are not well-versed in the particular hardware or software being used. "*[. . .] One trick, for example, is if you got anything that relies on floating point and people want to speed it up, they change it to fixed point. And there are people who don't know about fixed point arithmetic.*" (P15) Helpful reference implementations should prioritize code readability over performance optimizations and adhere to established coding practices.

This is further underlined by an interviewee describing the implementations of new cryptography proposals in a subcommunity of cryptography research, "*Academics, when they write papers, care about speed too much. So they remove everything that does safety: All those array boundary checkings, all that making sure stuff interfaces correctly together and decodes [. . .] Their paper is sold on how fast it is. Therefore they only care for how fast it is. And therefore, all the stuff you need in a proper system is thrown out of the window.*" (P16), referring to safe programming, documentation, and good engineering practices.

Some participants reported usability issues with standard specifications in terms of structure and readability. Our interviewees expressed concerns about the current state of specifications: "*Having specs be large, complicated, and reference implementations that can not be executed is, I think, an issue.*" (P9) The same interviewee mentioned that the expectations of the level of understanding of the specifications being too high:

"*The contributors are all experts, who know what the interpretations of this wording are. They are going to be fine. The spec only needs to be roughly approximate for them because they, basically, have an understanding in their head already. Whereas for*

the world as a whole, maybe you want something like UX researchers?" — P9

Many participants commented on the low usability of non-established cryptographic libraries and tools. They agreed that for new ideas to get adopted, their creators have to provide working and usable code that others can play around with. Our participants reported on usability issues they encountered when setting up such tools:

"*I at some point tried to install Project Everest. And [researcher] told me "Here's a script! You download that script. You run it. And either that just installs everything and everything works, or you're in big, big trouble." I was in big, big trouble so I spent a whole weekend actually not installing Project Everest. I didn't manage in a whole weekend.*" — P5

Our participants agree that, for end users, usability is paramount for adoption. "*Identity is another really good example where there is lots of good cryptography to help [. . .], but almost none deployed. [. . .] the UX is the hard bit.*" (P4). Our participants explain, the adoption of cryptography, such as end-to-end encryption in email, may impede users' desired functionality, leading to justified resistance.

"*Deploying crypto takes away features that people really want. It takes away easy recovery, backups, text search or fancy AI features that people want to do. I've seen that especially with encrypted mail. People don't want encryption, they want easy backups and search over their mail history.*" — P8

Other interviewees agreed that to get cryptography more widely adopted by end users, it is imperative to make sure the proposed system does not worsen the user experience by decreasing performance or sacrificing features in the name of security. Our interviewees note that there is existing research towards implementing features like server-side spam filtering in privacy preserving ways, like in the realm of homomorphic encryption, but that more research is needed to arrive at acceptable solutions: "*There are all kinds of fancy cryptographic proposals for being able to do spam-filtering without being able to see plaintext. They are not deployed. They are not totally reasonable at this time.*" (P11).

6 Discussion

We discuss our results in the context of our research questions and make recommendations to improve the process of bringing cryptography from research paper to product.

The Cryptography Ecosystem. Our participants' descriptions of adoption paths and the ecosystem were diverse. They identified a multitude of actors and activities that may help or hinder the process of bringing cryptography from papers to products (c.f. Section 4). One important insight is that research papers do not make it into practice not because cryptographers do not care, but because they are assessed by how many top-tier scientific articles they produce. Phil Rogaway [37] argued that cryptography researchers should focus more on real-world impact, but the rewards of doing so are much less certain than—assuming you have learned to do so successfully—the rewards for producing yet more papers.

Standardization processes represent an essential part of the adoption path, but this is where cryptography research output meets stakeholders from government and industry, who have goals beyond just selecting the best cryptography—plus there are many misconceptions and misunderstandings. The time and effort investment for cryptography researchers who participate in those processes is significant, and the outcomes are uncertain—so it is not surprising that only a small number take it upon themselves to participate.

There is also a shortage of actors who understand cryptographic research output in sufficient depth to anticipate how it will work at the system level and few cryptography researchers who understand the practices and pitfalls of secure software engineering at a level that would allow them to produce secure and usable crypto libraries by themselves. Due to a shortage of double experts, one way to increase adoption is by further encouraging cross-disciplinary engagement between cryptographers and expert software designers. We find implementers who are either missing the skills or incentives to put the needed amount of rigor, effort, and time into secure cryptography implementations.

Developers are pressured by impending deadlines and are equipped with usually only a little knowledge about security and cryptography. They need to be supported with high-quality crypto APIs to prevent security flaws. We find end users caring about many things, but cryptography is seldom one of them, especially when it introduces friction to their everyday life or takes features away: "*In general users don't care very much: I mean good cryptography is cryptography that users don't see, right?*" (P7).

We hope that clearly identifying the involved roles and the steps that cryptographic innovations have to go through enables parts of the cryptography and security communities to focus future research on better understanding, describing, and overcoming the challenges of bringing cryptography from papers to products.

Challenges of Cryptography Adoption. To achieve wide adoption of cryptography, collaboration and communication are key. It is essential that different clusters of experts communicate with each other and ensure that the needs, requirements, and results of their work are understood. Theoretical cryptographers make assumptions when designing cryptographic algorithms. However, once these algorithms are turned into an end product, the initial assumptions are often lost (see Section 5.4). This can lead to security issues in the adoption

of cryptography. We need to find clear ways to communicate these assumptions to groups of people outside the theoretical landscape, such as developers and users.

Of course, not everyone needs to be an expert in multiple areas. However, our interviews have shown that the role of a translator, "a crypto plumber", or a person in the middle is often poorly rewarded and insufficiently incentivized. Our results suggest that there is certainly a need for people to step into this role. We have also identified as pain points gaps in terminology, documentation that is not understandable by the people using it, and developers having a hard time using reference implementations.

A problem adjacent to communication is unclear responsibilities. Our interviewees observe that, in multiple areas, unusable products of research, reference implementation, or vulnerabilities result from unfinished work. Research ideas end up unmaintained, not "production-ready" (see Section 5.4).

One common challenge that arises across all of the topics discussed in the interviews is the frequent lack of alignment of incentives. This results in the need for people to work on tasks that are crucial for the adoption of cryptography, but require significant effort while offering limited rewards. Examples include members of academia being involved in standard-creating processes, researchers focusing on practical tasks to solve real-world problems, and cross-disciplinary work being challenging or implementations stemming from quality research ending up unusable.

On the other hand, we saw that the cryptography ecosystem is evolving and most of the interviewees reflect that. To give an example of work that we were not aware of at the time of of this study, in 2022, Kannwischer et al. [26] created the PQClean project to improve the quality of reference implementations submitted to the NIST Post Quantum Cryptography competition. They find that properly implemented, a set of guidelines together with a testing framework can increase code quality, reduce efforts, and thus benefit submitters, the community, and the standardization body itself.

6.1 Recommendations

Based on our results we provide recommendations for the academic community, industry and standarization organizations. Table 2 provides an overview of the main challenges and our recommendations in this paper.

Academic community. Section 5.1 describes how existing incentives in cryptography research can either foster or inhibit cryptography adoption. Ideally, more academic funding should not single-handedly rely on publication count when evaluation is due. If grant givers aim to support the adoption of secure cryptography, they might consider funding and rewarding the participation of academics in standardization bodies or secure implementation of cryptography.

There is a lot to gain from funding academics to attend non-free standardization meetings, and there are examples of this funding being beneficial: "*Within my grant there's 10000€ for ETSI membership. What's interesting is, that puts in the whole of [university name] as an ETSI member. (. . .) So now anyone can go to their meetings and call bullshit. So I think it's something that maybe more universities should be doing and then have just academics go there and follow what's going on and see how these standards are being made. It is a very interesting procedure. You learn stuff when you are at these meetings.*" (P5)

Academics should be actively incentivized to engage in standardization processes by participating in drafting committees and providing their expertise—with an appropriate reward. This might help the standards being developed with a better understanding of real-world use cases and requirements.

Our results imply communication challenges between different stakeholders in the cryptography ecosystem. We recommend the cryptography research community try to establish common terminology and language to help cryptographers communicate better. We also identified communication issues between cryptography experts and engineers and recommend developing communication skills that support cross-disciplinary collaboration.

When building reference implementations, cryptographers should mind the difference between proof-of-concept implementations that support results in academic papers, and ones that support re-use by software engineers. We recommend cryptographers clearly mark proof-of-concept implementations on the one hand, but more importantly keep code readability and comprehensible documentation of their code in mind if they want to see it picked up by others. Additionally, we recognize that most cryptographers are not also experts in secure coding, and thus encourage them to reach out to experts from the field of software engineering when implementing protocols and algorithms with the aim of improved implementation quality.

Industry. Our interviews imply that wide cryptography adoption is hindered when goals and requirements do not align. Until regulations catch up, researchers interested in adoption might want to try to identify privacy improvements that benefit not only end users but also service providers, to have them help. If service providers adopt secure solutions, end users are not burdened with the choice between something secure and something (possibly) more usable. The biggest security and privacy gains for end users come from existing products adopting transparent security. There are a few well-known examples: WhatsApp implementing E2EE made a huge difference in end-user security, or Google opting to encrypt all data in transit after the Snowden revelations. Additionally, we encourage companies and organizations to consider investing in core infrastructure maintenance projects like the Open Source Security Foundation (OSSF). We encourage implementers and users of standards to reach out upstream, communicating problems, and needs, or actively contribute

Table 2: Summary of identified challenges and recommendations.

Challenge	Recommendations
Academic Incentives	
Missing incentives to create usable reference implementations	Conferences could try to not only judge contributions by their performance and theoretical security levels, but also by usability.
Missing incentives to participate in Standardization efforts	Standardization Organizations could improve outreach towards academia. Grant givers could reward standards participation more explicitly. Raise community awareness of the importance of standards work.
Missing incentives to create production ready code	Promote collaboration between cryptography experts and software engineering experts.
Standardization	
Misunderstandings between academics and engineers. Things get lost in translation	Standards could be UX tested. Have translators between theoretical researchers and engineers. Make standards machine readable or executable.
Different actors with different interests participate in standardization efforts	Open Standardization process; transparent competition requirements; raising awareness of possible ulterior motives; proper requirement analysis in the beginning.
Fail to identify a standard's users and use cases.	Standardization organisation's working groups need to do proper requirement analysis in the beginning of drafting a standard.
Reference Implementations	
Low quality of reference implementations	Support cross-disciplinary outreach between cryptography experts and software engineers; In competitions, provide practical support via ,e.g., CI, automatic testing, ...
Proofs of Concept mislabeled as "Reference Implementation"	Make sure that PoCs are not mislabelled. Conferences might set formal rules for what may be submitted as a "reference implementation".
Misunderstandings	
Communication challenges	Try to establish common terminology and language to help cryptographers communicate better. Promote collaboration between cryptography experts and software engineering experts.
Usability	
Low usability of Reference Implementations	UX testing, UX research, support cross-disciplinary outreach between cryptography experts and software engineers, In competitions, provide practical support via e.g. CI, automatic testing, ...
Low usability of Standards	UX testing, UX research, have machine redable and executable standards with proper documentation.
Low usability of Crypto Libraries	UX testing, UX research. Grant givers can allocate resources for maintaining infrastructure code.
Low usability of End-User Products	UX testing, UX research. Engage in theoretical research on unsolved root causes like key management.

to open standard development, instead of developing and standardizing cryptographic solutions behind closed doors.

Standardization Organizations. Our results imply issues with the complexity, readability, and actionability of standards. Our experts recommend working towards machine-readable and possibly executable, standard specifications, to support automated security proofs. The inspiration can come from unit tests—made for standards. Multiple interviewees suggested the idea or expressed interest in this area, they also see the way forward in automating code audits, and assigning properties to cryptographic functions. After developers specify what security needs they have, there should be an analysis of how the developer "plumbed" the crypto functions together. Some interviewees criticized the proprietary nature of some standardization organizations. For example, ISO standards are expensive and exclude interested cryptanalysts and developers. We recommend the cryptography community focuses on open standards and standardization organizations to be

more inclusive and support easy access to their specifications. Standardization organizations should make sure they are trustworthy by further engaging with the academic community, emphasizing open communication, and open competitions. A "seal of approval" of a trusted standardization organization is a major driver for cryptography adoption.

7 Conclusion

We investigated key challenges in bringing cryptography research from papers to cryptographic products. Therefore, we conducted 21 semi-structured interviews with cryptography experts with high visibility and standing in the community. Based on our interviews we developed a map of the cryptography ecosystem and illustrated involved actors and stakeholders. The map serves as the foundation to highlight challenges and pain points in the ecosystem and report and discuss further results. We identify five major challenges that hinder the adoption of cryptography and provide opportunities to improve future adoption. Misaligned or conflicting incentives of actors in the ecosystem are a big challenge. For example, cryptography researchers are not incentivized for implementations beyond research publications and may not have strong motivations to write cryptographic code that goes beyond proof-of-concept implementations. We find that cryptography standardization is challenging and that some of the current standardization processes do not support the secure and wide adoption of cryptography. For example, involved stakeholders might have diverging goals, and standard specifications tend to be hard to read or incomplete. Reference implementations are crucial for the adoption of cryptography and often contribute to their limited or insecure adoption. Current reference implementations tend to be buggy, hard to read, or do not focus on meaningful use cases for software developers. We also find communication challenges between actors and unclear responsibilities to be major challenges. For example, cryptographers and software developers use different terminologies and languages, and cryptography researchers tend to not feel responsible for anything more than providing theory background. Hence, developers tend to be overwhelmed and misuse standard specifications or provided implementations. We conclude the paper by discussing our results and making recommendations for academic research, industry, and standards organizations. Overall, we recommend being more transparent and open to better support the cross-disciplinary correct and secure use of cryptography. We hope this can help to bring more cryptography research from academic papers to cryptographic products and improve overall security.

Acknowledgements

We thank our interviewees for their valuable time, their helpful insights, and their openness toward our research methods. We thank Leonie Schaewitz and Nikol Rummel (Ruhr University Bochum), who contributed to the design of the interview guide and the initial coding scheme.

A Appendix

We make our interview guide and our codebook publicly available in this appendix. We make the quotes used in the interview part "revisit", as well as more background information, definitions, and further results available in an extended version of this paper, at https://doi.org/10.5281/zenodo.8404611.

A.1 Interview Guide

This is the interview guide we used for interviews P4–P21.

Start. Hello, thank you very much for allowing us to do this interview.! Thank you for signing the consent form! With your permission we will start the recording now. Are you okay with this? [Start Recording]

Intro to Interview. We work in an interdisciplinary project that is interested in better understanding the ecosystem of cryptography, including the research community, the development of cryptographic algorithms, protocols, standards, as well as the deployment of cryptography in software and the adoption of end user products. Specifically, we want to better understand the blockers and barriers, but also the enablers to the adoption and correct use of cryptographic solutions. What we try to do is to build a map of the ecosystem of cryptography with all the actors and all the processes involved in the adoption and use of cryptography. By this, we try to identify where in this ecosystem there are problems and potential blockers that hinder broad adoption or correct use of cryptography. We try to map all the different stages, from the cryptographic primitives to the use of cryptography in products for end users and their adoption.

Therefore, we conduct interviews with experts from the crypto community.

Warm-Up and Background. To start, we first of all would like to ask you to describe the research/work that you primarily do. What would you say is the major focus of your research/work, how do you characterise your field of work?

Follow-up: Would you say that your research/work is more theoretical or applied?

Do you have an interest in the things you work on being adopted at a large scale in the real world? If so, in which area do you see the greatest potential for the adoption of your work?

Identifying adoption problems. In your opinion, what keeps things you work on regarding cryptography from being adopted in the real world? Can you give an example of a research idea or project that you expected or hoped to be adopted, but which did not meet that expectation?

In general, when you think about the research/work that is done in the crypto community, what would you say are the most central problems when it comes to getting research into practice/application?

In your opinion, what are the greatest challenges that you and the crypto community can do something about?

Identifying possible enablers. What would you say were the most important factors or steps that led to your research/work being successfully adopted in the real world?

What are the main things I should consider if I want my cryptography research/work to be adopted in the real world?

In general, what would have to improve or change so that more research/work from the crypto community is applied and adopted in the real world?

Revisit. In the end, we would like to discuss 3-4 potentially controversial statements about the ecosystem of cryptography with you. We are interested in your opinion on these issues.

[Show + discuss quotes subsequently; read the statement to the person]. How do you understand this statement? What do you think about this statement? Do you agree/disagree with the statement?

End. We are getting to the end of the interview. We have two final questions. Do you have any suggestions for people we should interview for this study? Is there anything you want to add that we have not addressed?

Thank you very much for taking part in this interview!

B Code System

We present our resulting codebook resulting from the merging process described in Section 3.2:

Merged Codebook

1 **Patterns that Lead to Adoption Challenges**
1.1 Misunderstandings / Terminology / Things unsaid
1.2 Crypto is hard
1.3 Not My Job / Resposibility unclear
1.4 Usability/Reference implementations
1.5 Conflicting Incentives/ High effort, low reward
1.6 Examples - Good Examples from the real world
2 **Areas and Actors**
2.1 **Area on Landscape**
2.1.1 Algorithm / Protocol Development / Analysis
2.1.2 Standardization
2.1.3 Crypto Libraries / APIs
2.1.4 Software Development
2.1.5 Adoption, Deployment, and Use of Software w/ Crypto
2.1.6 Policy
2.1.7 Misc
2.2 **Actors**
2.2.1 Cryptographers
2.2.2 Standard Development Organizations (SDOs)
2.2.3 Law Enforcement / Secret Services
2.2.4 Government / Lawmakers
2.2.5 Governmental Organizations
2.2.6 Software Developers
2.2.7 Internet Infrastructure Companies and Browser Vendors
2.2.8 Commercial Companies
2.2.9 Messenger Companies
2.2.10 Media / Marketing
2.2.11 End Users
2.2.12 Misc
3.0 Good Quotes

Why Aren't We Using Passkeys? Obstacles Companies Face Deploying FIDO2 Passwordless Authentication

Leona Lassak*, Elleen Pan†, Blase Ur†, Maximilian Golla‡
* *Ruhr University Bochum,* † *University of Chicago,*
‡ *CISPA Helmholtz Center for Information Security*

Abstract

When adopted by the W3C in 2019, the FIDO2 standard for passwordless authentication was touted as a replacement for passwords on the web. With FIDO2, users leverage passkeys (cryptographic credentials) to authenticate to websites. Even though major operating systems now support passkeys, compatible hardware is now widely available, and some major companies now offer passwordless options, both the deployment and adoption have been slow. As FIDO2 has many security and usability advantages over passwords, we investigate what obstacles hinder companies from large-scale deployment of passwordless authentication. We conducted 28 semi-structured interviews with chief information security officers (CISOs) and authentication managers from both companies that have and have not deployed passwordless authentication, as well as FIDO2 experts. Our results shed light on the current state of deployment and perception. We highlight key barriers to adoption, including account recovery, friction, technical issues, regulatory requirements, and security culture. From the obstacles identified, we make recommendations for increasing the adoption of passwordless authentication.

1 Introduction

On the web, passwords remain the dominant form of user authentication [13, 48]. Unfortunately, phishing and credential-stuffing attacks against passwords continue to cause extensive damage even among well-protected online services [93, 96]. Reinforcing passwords by deploying two-factor authentication [40, 77], risk-based authentication [59, 95], and account-security notifications [41, 58, 87], as well as promoting the use of password managers [60, 73] are incomplete solutions to the security problems of relying on passwords [13, 14, 48].

A decade ago, Grosse and Upadhyay [45] described an internal pilot of a USB hardware token that "protects against phishing" and "makes the server side immune to database theft." Shortly after, the Fast IDentity Online (*FIDO*) Alliance was founded to develop and promote authentication standards that "reduce the world's reliance on passwords."

Building on earlier efforts to enhance multi-factor authentication, the FIDO Alliance's *FIDO2* suite of protocols foregrounds passwordless, single-factor authentication for the web. As detailed in Section 2, a user's *authenticator*—either specialized hardware (e.g., a YubiKey) or software running on an existing device—generates a unique asymmetric cryptographic keypair bound to a particular website. The private key is kept on the user's authenticator; the website holds the public key. To log in, the user authenticates locally to their authenticator (e.g., with a biometric or PIN), which then uses the private key to authenticate to the remote website. Around the time the World Wide Web Consortium (*W3C*) adopted FIDO2 as a web standard in 2019, media coverage focused on how FIDO2 would "kill the password" [39, 64, 74].

Starting in 2021, Apple, Google, Microsoft, and others announced *passkeys*, which are multi-device credentials following the FIDO2 standard. In part, passkeys are a rebranding of the existing FIDO2 approach, though they add features for syncing private keys across a user's devices (to avoid needing to re-register on each device) or using a single existing device (e.g., phone) as the authenticator across all devices. The popular media again heralded passkeys as the technology that would "kill the password" [16, 66, 69, 81].

Today, most major operating systems and browsers support FIDO2-based passwordless authentication [34]. Researchers have analyzed FIDO2's security [9, 11, 46] and usability [27, 28, 55, 57, 70, 71], finding FIDO2 more secure and usable than passwords. The FIDO Alliance and W3C have working groups dedicated to driving FIDO2 adoption [36]. It is thus surprising that, to date, only a few companies have deployed passwordless authentication, widely or at all.

We investigate why we are not using FIDO passwordless authentication by answering the following research questions:

RQ1 *How aware are companies about FIDO?*
RQ2 *What are their experiences deploying FIDO?*
RQ3 *What challenges do companies face deploying FIDO?*
RQ4 *How do companies prioritize certain obstacles?*

To this end, we conducted 28 semi-structured interviews with three types of stakeholders: (1) companies and organiza-

tions with user-facing web properties, including both those that have and have not deployed passwordless authentication; (2) vendors selling passwordless solutions to businesses; and (3) experts contributing to the FIDO2 standard. We recruited participants in a number of ways, including with help from the FIDO Alliance, enabling us to recruit chief information security officers (*CISOs*), security engineers working on authentication, and identity management leaders. Such participants are typically difficult to recruit for academic research.

Our interviews aimed to understand participants' experiences with passwordless authentication in their own organizations, identify obstacles their organizations faced deploying passwordless authentication, and elicit participants' personal opinions about the FIDO2 standard. The protocol included a card-sorting task to rate potential deployment challenges.

Around half of our participants had experience deploying FIDO-based protocols either for passwordless or two-factor authentication (*2FA*). The biggest obstacles to FIDO2 deployment participants reported relate to fallback authentication and recovery options, complexity and friction due to the drastic change, technical issues like browser support and revocation options, regulatory requirements, and security culture. We also identify both concerns and misconceptions regarding passkeys. The results of our card-sorting task reveal a mismatch between what organizations considering deploying FIDO2 believe to be pressing obstacles compared to the beliefs of FIDO experts and identity and access management (*IAM*) vendors. Even though we observe widespread agreement that FIDO2 will play a major role in making passwords obsolete in many web use cases, legacy systems make it impossible to eliminate passwords quickly. Our results suggest that FIDO2 will not eliminate passwords completely, but has the potential to reduce the number of passwords used.

Collectively, our findings provide the first comprehensive examination of obstacles and perceptions related to FIDO-based passwordless authentication. We discuss recommendations for industry and outline future research for increasing the adoption of passwordless authentication.

2 Background

Next, we introduce the FIDO2 standard and explore related work on passwordless authentication and studying CISOs.

2.1 FIDO2, WebAuthn, and Passkeys

The FIDO Alliance is an industry association developing and promoting passwordless authentication based on public-key cryptography. Its earlier Universal 2nd Factor (*U2F*) protocol enables cryptographic two-factor authentication [45]. All of its protocols have advantages over passwords: they are fast when used with biometrics [55], they are phishing resistant [90], and secrets are only stored locally.

The *FIDO2* W3C standard consists of two protocols. Web Authentication (*WebAuthn*) [50] describes a JavaScript interface that allows a *relying party* (e.g., a website) to perform a passwordless challenge-response protocol with a *client* (e.g., a web browser). The companion Client to Authenticator Protocol (*CTAP*) [15] specifies the communication between a cryptographic authenticator (e.g., a hardware security key or smartphone) and a client. In FIDO2, the user authenticates by proving their possession of the private key. Specifically, they create a signature that can be verified using the corresponding public key stored on the server during registration. To prevent unauthorized use, the user authenticates locally to their device (e.g., using a PIN or biometric) before the private key is used for signing. The protocol has been formally verified [9, 11].

FIDO2 differentiates between *platform authenticators* (those integrated with a device) and *roaming authenticators* (those that can be used across multiple devices). Example platform authenticators include *Microsoft's Windows Hello* and *Apple's Touch ID* when used exclusively for authentication on a given device. While roaming authenticators canonically included hardware like USB keys that could be plugged into different devices, recent smartphones can be used as roaming authenticators for cross-device authentication [71, 72]. For security, the private key and biometrics templates should be isolated from the main processor and OS (e.g., on a TPM).

Relying parties can specify authenticator types they support (roaming, platform, or both) and whether to require *user verification* via local authentication (e.g., with a PIN or biometric) or just *user presence* (e.g., pressing a button on the security key). Common use cases for user verification include passwordless authentication as offered by Adobe, eBay, Google, Microsoft, PayPal, or Yahoo [2]. In contrast, user presence is commonly used in 2FA scenarios in which a security key is used in conjunction with a password.

To increase the usability of FIDO2, the FIDO Alliance recently standardized *passkeys* [30]. Passkeys are multi-device FIDO2 credentials that third parties may synchronize over the cloud, removing the burden on the user to register multiple devices to the same website and offering convenient recovery in case of device loss or theft. Apple and Google report that their passkey synchronization is end-to-end encrypted [7, 12].

2.2 Related Work

FIDO2: Prior work on FIDO2 adoption has mainly studied client-side usability challenges. Lyastani et al. randomly assigned 94 participants to configure an account using either a YubiKey or a password [57], finding that participants preferred FIDO2 passwordless authentication over a password. However, several concerns were raised: recovering accounts if the security key is lost, hardware compatibility, and a lack of mental models explaining passwordless authentication. Farke et al. conducted a similar study with a small software company [28]. Nine participants used a YubiKey

during their daily work routine, keeping a diary of when they authenticated. Participants responded positively to security keys, citing ease of use, intuitiveness, and convenience. Some also gave up on using the key, mistakenly thinking it did not provide security benefits or feeling it was slower than using their browser's password manager. Nawrath had 161 participants attempt passwordless registration using devices they already owned, finding a lack of platform/browser support to be a key barrier [65]. Lassak et al. studied user perceptions of biometric WebAuthn [55], finding that 67% of participants mistakenly thought biometric data was stored remotely.

Some work has examined FIDO2 from the developer's perspective, though only on a small scale. Alam et al. [4] briefly outlined some conceptual limitations of developers implementing WebAuthn by analyzing discussions in the WebAuthn developer community. These limitations included a lack of deployment-ready solutions, wrong mental models about WebAuthn, and confusing technical details in the FIDO2 specification. Bicakci and Uzunay [10] briefly discussed potential challenges using FIDO2 as passwordless authentication, such as the lack of a convenient recovery method or support for sharing credentials. Casey et al. proposed a new protocol on top of WebAuthn because businesses may not be able to implement current FIDO2 solutions to comply with their policies [18]. We instead interviewed various FIDO2 stakeholders to gather their perspectives on the current challenges and necessary changes for large-scale deployment of FIDO2.

Studying CISOs: Our methods are also motivated by previous studies interviewing CISOs and security professionals in industry. Reinfelder et al. explored how security managers handle user requirements and behaviors by interviewing seven managers from large German companies [78], utilizing snowball sampling to recruit this hard-to-reach population. Haney et al. interviewed 28 cybersecurity advocates to understand how they overcome negative user perceptions of security and motivate the adoption of best-practice security measures [47]. Hielscher et al. interviewed 30 CISOs to understand whether foundational concepts from human-centered security are used in practice [49], while Ashenden et al. interviewed five CISOs from global companies to understand their approach to security [8]. Wolf et al. interviewed 27 CISOs to identify how to improve security in small businesses [97]. Similar to prior work, we utilized semi-structured interviews and snowball sampling, among other recruitment methods. Doing so enabled us to recruit 32 participants across 28 interviews.

3 Methods

We first describe how we generated a list of potential FIDO2 obstacles based on a literature review. We then outline our interview protocol, recruitment, and participant demographics before presenting limitations and ethical considerations.

Table 1: Potential obstacles based on our literature review.

	ID	Description
Necessity	**N1**	Customers are happy
	N2	Passwords are good enough
	N3	Passwords are not problematic with password managers
	N4	Secure enough with 2FA
	N5	Usability good enough with SSO
Usability	**U1**	No standardized fallback
	U2	Unclear handling of lost or stolen devices
	U3	Unclear handling for new devices
	U4	Unclear handling with multiple devices
	U5	Customers do not use biometrics
	U6	Roaming authenticators are not usable
	U7	Change causes friction
	U8	Customers would not switch
Deployability	**D1**	Libraries and frameworks do not exist
	D2	Libraries and frameworks are incomplete
	D3	Libraries and frameworks are not understandable
	D4	Libraries and frameworks written in wrong language
	D5	Need to support both passwords and FIDO
	D6	Cannot get rid of passwords entirely
	D7	Browsers do not have all functionality
	D8	User interface is OS-dependent
IT Management	**M1**	No need to talk to them
	M2	They do not let us talk
	M3	They do not understand
	M4	Policy forbids open-source software
	M5	Policies do not allow biometrics
	M6	Waiting for peer organizations
Finance	**F1**	Investment is unclear
	F2	Implementing FIDO too expensive
	F3	New communication and interfaces are expensive
Comm.	**C1**	FIDO incompatible with UX guidelines
	C2	Need to brand FIDO2
	C3	Unclear how to communicate about FIDO2
	C4	Design questions are hard

3.1 List of Potential Obstacles

Between January and May of 2022, we compiled a list of obstacles to FIDO2 deployment discussed in prior work and artifacts from the W3C and FIDO Alliance's working group meetings, as detailed below. Table 1 presents the resultant list, which we used as part of our card-sorting task.

Prior Papers: Using search terms like "FIDO," "FIDO2," "passkeys," and "WebAuthn" on Google Scholar, we collected potentially related scientific papers. From this list, we identified papers that covered security aspects of FIDO2 [5, 90], implementation issues [4, 75], deployments [70], user experiences [20, 23, 55, 57, 65, 89], roaming authenticators [28, 71, 72], and fallback solutions [54, 85]. Work about security proofs [9, 19] was out of scope. We also looked at non-FIDO2 work about the adoption of other security mechanisms, such as HTTPs [53, 88], 2FA [21, 80], and password managers [60].

Online Resources: We also analyzed online resources, such as articles and blog posts from IAMs like Okta [84] and services like Microsoft [61] and eBay [52] that had already

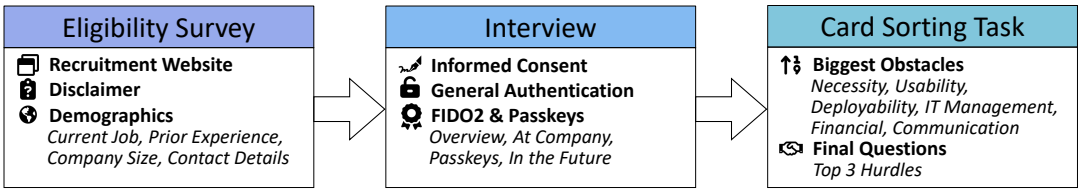

Figure 1: Prospective participants provided demographics and contact details in an eligibility survey. Selected participants were invited to a 45-minute interview about FIDO2 that included a card-sorting task about potential deployment obstacles.

deployed FIDO. We also examined case studies published by the FIDO Alliance covering deployments at services like login.gov, Visa, and NTT [31] from 2017 to 2021.

W3C and FIDO Working Group Resources: Artifacts produced by W3C and FIDO working groups, especially those dealing with adoption (e.g., the user experience working group) [36], also contributed to our list of potential obstacles. We focused on the W3C Web Authentication WG and WebAuthn Adoption CG's open GitHub issues [99], mailing list, and meeting minutes [98, 100], and the official "FIDO Dev" mailing list [33]. We decided against including highly specific issues as our target interviewees would most likely not be deeply versed in the protocols' implementation details.

Two researchers coded all resources in an open-coding process resulting in the first version of what we call our "list of potential obstacles." These coders had backgrounds in cybersecurity and deep familiarity with the FIDO standards and ecosystem. In cooperation with the entire research team, we categorized and refined the list through multiple discussion sessions. We also sought input from external practitioners working at IAMs, as well as FIDO experts with whom we are in personal contact. The final list can be seen in Table 1. In the text, we refer to specific obstacles with their identifier (e.g., N1 = "Customers are happy").

3.2 Interview Structure

Figure 1 summarizes the interview structure. Our extended version [56] contains the full interview script. Questions differed slightly across our three stakeholder groups: (1) "Organizations," or companies deploying FIDO for their employees or customers; (2) "IAMs," or companies that sell authentication solutions to other companies; and (3) "FIDO experts," or participants in FIDO Alliance working groups [36].

Interviews began with the moderator asking participants whether they had any questions about the consent form, which we shared via email prior to the interview. After the participant consented, we started an audio recording. We reassured participants that no identifiable information—particularly company names—would be disclosed outside the research team. We then asked participants about their company and role, as well as their experience in the field of authentication.

The interview's main section began with a discussion of the general authentication infrastructure in the participant's organization for both employees and customers. When not mentioned explicitly, we prompted for specific features (e.g., 2FA) to ensure a comprehensive overview. We also instructed participants to share their positive and negative experiences about authentication at their organization. Aside from FIDO experts, we then assessed participants' knowledge of FIDO and answered any questions they raised about FIDO protocols. Next, we directed the conversation toward the use of FIDO in their organization. For participants whose organizations had already adopted any FIDO authentication options (termed *adopters*), we asked about their experience with deployment, feedback they had received, and what the biggest obstacles had been to date. We also discussed the decisions that had led to the deployment. For the others (*non-adopters*), we asked whether there had been any internal discussions about adoption and what they felt were the key arguments in favor of, and against, FIDO. We explicitly asked what it would take for their organization to adopt it. If participants did not bring up passkeys specifically, we solicited their opinion on them.

In an interactive card-sorting task on a digital whiteboard (see extended version [56]), 18 participants then rated our list of potential obstacles (Table 1) by perceived severity. We asked them to narrate their thought process in a "think-aloud" manner. They could rate obstacles as *major* ("a deal-breaker almost on its own"), *minor* ("in conjunction with other minor obstacles impedes the deployment"), or *not an obstacle*. The remaining participants ran out of time for this activity.

3.3 Recruitment / Participant Demographics

Apart from FIDO experts, our target participant group was CISOs. We also accepted security engineers and developers with extensive experience in authentication alongside decision-making responsibility in their organization. We emphasized that no specialized knowledge about FIDO was required to participate as we were particularly interested in the perspectives of organizations that had not yet adopted FIDO. As we had a very specific, hard-to-reach target group, we used a variety of recruitment strategies. First, we created a recruitment website that summarized the study, addressed concerns about privacy and confidentiality, and linked to the eligibility survey. We posted on social media, including LinkedIn and Twitter, and we also directly contacted people from our personal networks. We also reached out to the FIDO Al-

Table 2: Summary of participants and their organizations. For anonymity, numbers are binned and some fields are blinded. "FIDO Experts" contributed to FIDO development. "IAM" participants sell identity and access management solutions.

		FIDO		Participant		Organization

Depl.: ● = deployed FIDO2, ○ = has not deployed FIDO2, N/A = not applicable.
Expert.: Participant's FIDO expertise (based on moderator's subjective judgment), ⋆ = knows from media, ⋆⋆ = helped deploy, ⋆⋆⋆ = involved with FIDO design.
Years: Number of years of experience within the job (self-reported).

liance to distribute our recruitment text. Furthermore, the lead researcher attended the Authenticate conference in October 2022 to recruit and connect with the community. We also reached out to organizations like the German Federal Office for Information Security (BSI), asking them to distribute our recruitment text via their mailing lists. We conducted interviews between November 2022 and April 2023.

Table 2 summarizes our participants. We conducted 28 interviews in total, encompassing 6 with "*FIDO experts*," 4 with "*IAM*" vendors, and 18 with "*Organizations*" (companies, governments, NGOs) representing a wealth of different industries. Throughout this paper, we reference participants from these three groups with the respective prefixes "E" (for experts), "A" (for authentication vendors), and "O" (for organizations). All interviews involved a single participant except for O18, which included five individuals from different divisions of the same company; we report their collective opinions as one. Thus, 32 individuals were interviewed. We reached saturation (no longer learning new information) after 25 interviews.

Our participants were mostly CISOs or security engineers working in IAM. We also interviewed consultants and individuals in management positions related to security.We had representatives of one start-up (<10 employees), three small businesses (10-49), four medium-sized organizations (50-250), and 20 large organizations (>250). Among large organizations, eight had under 10,000 employees, six had 10,000–100,000, two had 100,000 to 200,000, and four had over 200,000. Participants' organizations were based primarily in Germany (16) or the U.S. (8). The remaining four came from Norway, the Netherlands, Australia, and Switzerland.

[1] Interview O18 included five people from the same organization.

3.4 Analysis

We transcribed our audio recordings, storing files locally. Two researchers then performed independent qualitative coding following a thematic inductive coding approach. We decided not to use our obstacles list for deductive coding as our main aim was to identify as many previously unknown obstacles as possible. In weekly meetings, the full research team refined the codebook and discussed recent interviews. Subsequently, we clustered codes into high-level categories following an affinity diagramming process. As the codebook and themes were developed jointly and iteratively, we decided against calculating intercoder reliability metrics.

3.5 Limitations

Like many qualitative studies, we report on a small sample of 32 individuals across 28 interviews. While the number of people overall is small, we interviewed hard-to-recruit individuals who are key decision-makers in the deployment of FIDO within their organization or in the development of FIDO standards themselves. They also conveyed knowledge they accumulated from discussions with professional colleagues. Thus, our sample size is commensurate with other qualitative studies of hard-to-reach groups. We do not claim to provide a complete overview of all FIDO2 deployment obstacles, but have likely identified those most inhibiting widespread adoption. Most of our participants work at organizations based in the U.S. or Germany; our findings may not generalize to organizations from different parts of the world.

3.6 Ethical Considerations

All data was collected by individuals at an institution that does not have an Institutional Review Board (IRB) or similar ethics review board. However, we followed key principles of the Menlo Report [91]—"respect for persons," "beneficence," and "justice"—in designing our protocol. While we collected no personal identifiers beyond participants' email addresses and full names for correspondence, the ethical treatment of information shared with us about company internal details was a key focus. Protecting the confidentiality of participants' companies and their inner workings, especially when discussing issues in their security infrastructure, was of paramount importance. Voice recordings were immediately transcribed

after the interview to minimize the storage of potentially identifiable information. Transcripts were stored pseudonymously in case of unintentional information leaks. All data was stored and processed in accordance with the GDPR.

We described the study procedure carefully, including all risks, and asked participants for their consent. Participants could stop the interview at any point, which nobody did. As our participants were typically highly compensated tech experts and executives, we expected that participants gaining insight into FIDO2 would be the primary value of participating. Thus, we did not offer monetary compensation, instead offering our own FIDO expertise and feedback in follow-up meetings to participants who desired them.

4 Results: Experiences Deploying FIDO2

This section and the two that follow present our main findings from the interviews. We start by summarizing participants' experiences deploying FIDO. We distinguish between FIDO being used for two-factor authentication *(U2F)* and the more recent proposals for FIDO2-based *passwordless* authentication. As U2F is older and more widely deployed, some participants' responses referenced concrete U2F experiences (instead of passwordless). They did, however, indicate these experiences and opinions to be applicable to passwordless deployments concomitantly. Overall, 13 participants reported that their companies had already rolled out or are currently in the process of rolling out FIDO in some way, such as via Windows Hello or YubiKeys (see "Depl." in Table 2). Seven participants reported that their organization had deployed passwordless authentication, while the remaining six reported that FIDO was being used for multi-factor authentication *(U2F)*. All four IAM vendors offered passwordless authentication solutions for business customers. All organizations refrained from in-house developments and instead used an IAM vendor or the built-in functionalities of their Microsoft Azure ID instances. In contrast, thirteen organizations have not yet rolled out any FIDO solution. The remaining two participants ("N/A" in Table 2) worked in contexts (e.g., as a consultant) where FIDO deployment was not relevant. Except for one company currently in the process of preparing a passwordless rollout, none of the organizations offered FIDO-based passwordless authentication for end users. Instead, passwordless authentication was for employees.

Reasons for Deploying: The 13 participants who had deployed FIDO gave various motivations for doing so. The majority (n = 7) brought up security as the main reason for deployment. Some talked about getting rid of passwords (O6, O16) or switching to a phishing-resistant 2FA solution (O4, O5). Others focused on the ability to create unique identities in warehouse or factory settings (O10, O12). One pointed out that increasing "cloudification" made measures like location-based authentication harder to implement (O15). Three participants brought up usability concerns of passwords, including the toll of frequent password resets (O15). O6 felt passwords are cumbersome even with password managers, and E5 liked FIDO's open standardization.

Reasons Against Deploying: Participants whose organizations had not yet deployed FIDO can be categorized into the following three subgroups: "talked about, but decided against" (*reject*, n = 6), "currently talking about" (*consider*, n = 3), and "never talked about" (*unaware*, n = 4). We represent the groups by adding r (reject), c (consider), or u (unaware) to their identifiers. As arguments and concerns partially overlap between these groups, we report their results collectively.

No Need. Most commonly, participants were uncertain whether they would need FIDO. Some said they already felt sufficiently secure ($O1_r$, $O3_u$, $O11_u$, $O17_c$, $O18_r$). According to $O18_r$, "*attack vectors that FIDO would protect against are rarely seen in real life*" and are already handled by measures like risk-based authentication (*RBA*). Others argued that there is no demand for FIDO from customers ($O1_r$, $O18_r$) or employees who use trusted intranet services ($E3_r$).

Costs. Unsurprisingly, many participants brought up deployment costs ($O11_u$, $O14_c$, $O17_c$, $O18_r$). $O11_u$ said that for them to even consider FIDO, they could not have any increased expenses. The cost of security keys also came up. Even some participants who had already deployed FIDO felt that cost was one of the main obstacles.

Change Too Big. Some argued deploying FIDO would require too much refactoring in their IT infrastructure ($O3_u$, $O11_u$). Others focused on the consumer side, claiming that end users would be unhappy or overwhelmed with such a change ($O8_r$, $O14_r$). $O8_r$ argued that their company had to "*be very conservative with the technology [they] employ*" as their customers are very non-technical.

Non-Universality. Three participants felt FIDO would be less universal than their current methods. For example, $O17_c$'s current smartcard-based authentication covers other use cases like printing and access to buildings that no currently available FIDO-based solution offers. A3 and $O9_u$ pointed out regulatory differences across countries that make it particularly complicated to deploy FIDO in international corporations.

Additional concerns included past negative experiences with alternative (biometric-based) solutions ($O9_u$, $O13_u$) and struggling to convince executives of FIDO's value ($O11_r$).

4.1 Experience with Deployments

Participants whose organizations had already deployed FIDO reported relatively positive experiences overall. O12 and O15 reported surprisingly positive feedback from their workforce: "*our satisfaction ratings increased to the ones we last had 10 years ago*" (O12). O7 reported that their rollout initially had a relatively low acceptance and adoption rate. After a

few weeks of acclimatization, their workforce became more satisfied with the new mechanism. While O2 was satisfied overall with their deployment, they reported that a certain cohort of people was "*just not using it*" and could not be convinced until the company made security keys mandatory.

O4 reported a relatively unsatisfying deployment experience. Uptake did not exceed 65% even after a year. The adoption of biometric-based methods was even lower, stagnating at 15-20%. They attributed their experience to various factors, including mistrust towards the (government-affiliated) employer and technical issues that caused some employees to be locked out of accounts during the initial rollout. Participants also reported both temporary obstacles and persistent issues during and after their deployments. For example, O12 reported that onboarding security keys in Microsoft Azure self-service accounts was relatively complex, requiring a lot of assistance from their IT department. Three participants reported technical issues that required fixes from providers (in their case Microsoft and Apple). A4 felt changing the Active Directory structure was their biggest obstacle during deployment. Furthermore, O7 and O10 emphasized their struggles in convincing management, while O15 and O16 pointed out struggles incorporating legacy software into FIDO-based flows. A1, working in finance, brought up legal issues they encountered after the release of passkeys, causing their deployment to be put on hold entirely. As O2 pointed out, especially in global organizations, physically distributing security keys can become very challenging.

4.2 Consumer-Facing Authentication

Most participants' organizations did not have immediate plans to roll out FIDO for consumer-facing authentication. Only A1 (already in the process of deploying consumer-facing FIDO2), O13, and O15 expressed interest in doing so soon.

As a company, the number of customers is critical. O15 argued that it is good to offer many authentication options to accommodate as many customers' desires as possible. However, three other participants argued that introducing anything that may exclude potential customers (e.g., those whose phones lack FIDO2 support) would be harmful to the business (A3, O14, O15). According to O14, in sectors like health services, it is reasonable to prioritize availability over security and usability. Thus, for these businesses, mandatory FIDO deployment is out of the question. Surprisingly, three participants expressed that the security of individual accounts (which consumer-facing FIDO would protect) is of little value and not a priority (A3, O15, O18). According to O18, account security is the customer's responsibility: "*Everybody knows they should not write down or share [passwords]. They act against better knowledge by contravening it.*" Thus, unless accounts can be compromised at scale, there is little incentive for those companies to protect individual user accounts. As many app-centered services use long-lived access tokens and already offer biometric-based local authentication, O14 found FIDO2's usability advantages unconvincing. O13 and O14 mentioned that supporting security keys would be unnecessary as their user bases are small.

5 Results: Perceptions of FIDO

All participants agreed that the FIDO ecosystem has passed its inflection point and is here to stay. For example, E4 said, "*FIDO is the technology with the [greatest] potential to replace passwords.*" Nevertheless, others felt adoption was much slower than expected and that, even with passkeys, some key issues remain unsolved or are entirely "unsolvable."

Awareness: The vast majority of participants had at least some level of awareness of the FIDO standards prior to the interview. While this can be attributed in part to our recruitment process, about half of the participants were recruited from outside "the FIDO community." Participants from IAM providers and consulting firms consistently reported similar impressions from their work with business customers (A3, E6, O10, O16). E5 said, "*Awareness is there; people want to implement it!*"

Some participants (e.g., O2) reported that the mindset of passwords being "good enough" is not an obstacle in their organization. A2 pointed out that enterprises especially are considering FIDO2 rollouts, but not yet committing. In contrast, others felt that the FIDO standard remains unfamiliar, particularly among people in IT management; at best, they may recognize it as "*logging in with biometrics*" (A3). From the IAM vendors' perspective, E4 noted that business customers usually do not come asking for FIDO, but instead are happy if it is included by default in the package offered to them. O9 similarly said that, despite awareness of FIDO, deploying it is not really a priority for many companies.

While most participants were familiar with FIDO, the nuance between FIDO as an additional authentication factor (U2F) and single-factor, passwordless FIDO2 was frequently lost. When talking about "FIDO," most non-expert interviewees primarily discussed FIDO as a means of 2FA, not a means of replacing passwords entirely.

Misconceptions: Adding to findings about wrong mental models [4], our participants also expressed a variety of misconceptions related to the complexity of the FIDO ecosystem [4, 6]. Many non-experts appeared to have a mental model of FIDO focusing on roaming authenticators; three explicitly expressed this misconception. Such a misconception is particularly undesirable with regards to consumer-facing authentication as participants worried they would burden customers with purchasing extra devices if they deployed FIDO.

O8 expected that FIDO2 required the user to install an extra app, which then securely stores the private key. Similarly, O3 thought passkeys would only work with a central trusted entity

similar to a public key infrastructure (PKI). O5 was not aware that roaming authenticators can require "user verification" (e.g., entering a PIN) and incorrectly feared that unfettered access to accounts would always be possible if someone got hold of the security key. O18 also reported the mistaken belief that security keys could just be erased and used for storage like a USB flash drive and that one could simply order untrustworthy security keys online, creating security threats. These assertions suggested an unawareness of the FIDO Alliance's authenticator certification program [37].

Passkeys: As passkeys were a recent development when we conducted the interviews (November 2022 through April 2023), there was lower awareness than for FIDO2 overall. Note that, especially in early interviews, we did not use the explicit term "passkeys" with every participant. While some participants had spent time learning about passkeys, others requested that we explain the concept during the interviews. Opinions about passkeys were split, with 10 participants fully in favor and 8 expressing criticism. The remainder indicated no clear positive or negative attitude.

Apart from high-level judgments like "*it's a fantastic step forward*" (O6, O12), some participants felt that passkeys are what will give FIDO2 the momentum to replace passwords in the long run (E4, O4). Several explicitly said passkeys solve what they felt was FIDO's biggest issue, account recovery (A2, E1, E4, E5, O4). Despite generally being in favor, O15 hoped that passkeys would continue to follow FIDO's standards-based approach to ensure that "*Apple doesn't turn right while Google turns left.*" In contrast, A1 was skeptical about passkeys' ability to replace passwords, expecting they would be useful only for "low-value accounts."

Some participants arguing against passkeys were passionate in their criticism. They considered the hardware binding of keys to be FIDO's very heart, and they felt passkeys lacked this binding (A1, O7). For example, A1 said that "*passkeys is essentially a really good password manager.*" A4 and O17 were similarly concerned about synchronization to the cloud. E6, who is involved in standards developments in the FIDO Alliance, admitted that passkeys were not the first choice from a security standpoint, yet were the only solution that could adequately address the issue of transferability. They felt that transferability constituted FIDO2's most fundamental drawback at the time of passkeys' development.

Some participants did not trust Apple and Google's ability to securely store the private keys. O13 disagreed with this concern, pointing out that when currently using *Apple's iCloud Keychain* or *Google Chrome's built-in password manager*, users already trust these services to store login credentials. In that case, however, users are currently given the choice of whether to use password managers and their cloud-based synchronization functions. In the case of passkeys, they must trust the service. Thus, as A2 pointed out, passkeys may exclude users concerned about privacy as they would not trust Apple or Google. E1 and E6 both raised concerns about the usability of passkeys in a cross-ecosystem context. While there is a QR code-based solution for transferring passkeys (e.g., from an Apple iPhone to a Microsoft Windows PC), this process may be confusing and error-prone for users. More generally, A1 and E5 argued that unless the ecosystems (Apple, Google, and Microsoft) themselves are completely passwordless, one cannot really claim a security enhancement as security overall boils down to the security of the passwords used to protect those cloud-based accounts.

6 Results: Deployment Obstacles

Next, we report on the deployment obstacles participants expressed during the interviews. The full codebook can be found in the extended version [56]. Obstacles only relevant to company-internal deployments are marked with "***(W)***." Consumer-deployment obstacles are marked with "***(C)***." Unmarked sections apply to both. In this section, we refrain from subjective judgment, revisiting the matter in Section 7.

6.1 Regulation and Requirements

Regulatory requirements—both in terms of national laws and companies' internal policies—were the obstacle to FIDO2 deployment discussed most frequently in our study. Participants reported various concerns that FIDO would collide with their internal compliance and existing regulatory frameworks.

Non-Compliant Policies (W). O1, O3, and O8 pointed out policies requiring them to practice "digital sovereignty," or not to rely on a single vendor for their IT infrastructure. For a FIDO deployment, this not only runs up the bill, but also requires in-house expertise to ensure interoperability, making it hard to commit to drastic changes in authentication infrastructure. For example, O1 noted that if passwordless FIDO were deployed, regulations like password-composition requirements would need to be suspended. O9 mentioned that some security policies demand two completely separate factors for authentication. Others shared that occupational safety regulations hinder the applicability of using biometrics.

eIDAS (C). Participants working in finance shared that a severe obstacle from a federal regulatory perspective originated with Apple's decision to synchronize all passkeys automatically, leaving no option for device-bound credentials [51]. According to the European "Electronic Identification, Authentication, and Trust Services" (eIDAS) regulation, an individual's identity must be bound to a specific hardware device. Thus, credentials stored on a hardware device cannot be easily transferred or replicated.[2] This issue is particularly relevant for all organizations involved in the payment industry. E4 said that "*no serious bank will use [FIDO].*" A1's organization had prepared a consumer-facing rollout of passwordless

[2] See Annex 2.2.1 of the regulation EU 2015/1502 [25].

FIDO authentication for their app in September 2022. Upon Apple's release of their passkey implementation, these developments had to be stopped entirely. They now implement hardware binding in-house, independent of FIDO, considering this to be their only compliant option for passwordless authentication. A1 was particularly frustrated, saying, "*Apple has taken a big dump on FIDO!*" FIDO experts reported being aware of these issues and are currently talking to European regulators (E1, E6). They felt the main challenge would be convincing legislators that passkeys are sufficiently secure.

PSD2 (C). While the FIDO Alliance claims [35] to comply with PSD2,[3] banks struggle with its requirements. While the FIDO standards cover the requirement of *Dynamic Linking*[4] in the form of transaction confirmation displays [22], it is not enforced that all available FIDO-compliant authenticators implement the necessary functionalities. O18 explained that since they have no influence on how security key vendors implement transaction-confirmation displays, O18's organization cannot offer FIDO in a PSD2-compliant manner.

Further Legislation (W). A3 pointed out that in U.S. states like California [44], employers must indemnify expenditures incurred in direct consequence of their employees' duties (e.g., reimbursing cellular plans when prompting employees to use private phones at work). As this requires processing reimbursements, A3 suggested it may deter companies from using biometric FIDO authentication in workplaces.

6.2 Usability Challenges

Complexity and Friction. Nine interviews highlighted the challenges of explaining FIDO to users and non-technical stakeholders, such as management. Participants reported comparing security keys to physical keys as an analogue for non-technical individuals. However, as security keys may be protected by a PIN, sharing them with others does not automatically enable access. Explaining this difference to non-technical people was challenging (E2). As passwordless FIDO authentication requires both possession of the device storing the private key and knowledge of the PIN, some might consider it 2FA, causing confusion (E6). E4 expressed difficulties conveying recommendations for everyone to possess multiple security keys in case of loss or destruction. E6 pointed out the challenge of differentiating proprietary (server-side) biometric authentication solutions from FIDO **(W)**. A3 and O12 reported the onboarding process for security keys to be convoluted, with employees having trouble navigating menus to enroll their key **(W)**. Expert participants who developed FIDO reported difficulty explaining key concepts to UX designers, leading to poorly designed user interfaces (E6, O7).

Consumer aspects played only a minor role. Some participants expressed fears that FIDO2 is not necessarily easy to understand. E6 explained that, in practice, user experience is one of the concerns companies considering consumer-facing, passwordless FIDO2 most frequently raise **(C)**. E1 and O13 emphasized that operating systems and browsers' different approaches displaying FIDO interface elements make it hard for users to recognize it as the same login mechanism across devices **(C)**. E1 extended this criticism to online services putting minimal effort into clear interface design and ignoring the FIDO Alliance's UX guidelines [38]. O18 pointed out that users might mistakenly believe they are more secure with passwords as they are more aware of the risks.

Recovery and Fallback. Opinions were mixed on the degree to which the lack of standardized recovery remains an obstacle. A2, E1, and E5 felt that passkeys fully allay concerns about account recovery. In contrast, A1 and E4 stated that passkeys depend on an individual platform, almost in a "proprietary manner" (despite the technology itself being open), meaning that recovery has not been solved. Several participants reported that questions around fallback authentication are still among the most common concerns when talking to prospective customers. E1, E5, and O6 argued that the options for setting up fallback mechanisms for security keys remain convoluted, while E3 thought that setting up a second security key is a trivial and effective solution. This is also the strategy the FIDO Alliance recommends [42]. E5, however, disagreed: "*That's not really a great user experience, it's a practical solution... In an enterprise [or for] high-value transaction cases that level of inconvenience might be okay. But for the broad consumer, not at all.*"

6.3 Technical Challenges

Overall, participants felt the technical aspects of FIDO appear to be mostly sorted. A2 even pointed out that there is a Conformance Test Tool available for FIDO2 [29]. Supporting both FIDO and passwords alongside each other was only considered a small issue. The biggest concern among participants was that libraries and standards are not easily understandable.

Complex for Developers. As addressed by prior work [4], in contrast to passwords, FIDO protocols are complex and not meant to be implemented by non-specialist developers. Participants familiar with implementing FIDO2 agreed that it is difficult to implement and mentioned a lack of documentation. In fact, E6 recommended that companies should not attempt to implement FIDO in-house as the complexity poses the potential for insecure implementations and misconfigurations. E5, who implemented FIDO for a well-known IAM vendor, shared this view, saying that in the API there are numerous "*options that are not obvious and combinations that don't make sense or offer the protection you think.*" E4 claimed that implementing FIDO increases the "*complexity of the authentication stack by a factor of 10.*" Nonetheless,

[3] The "Payment Services Directive 2" (PSD2) regulates payment services in the European Economic Area. It introduced regulations on strong customer authentication (e.g., via mandatory 2FA) and enforces secure open standards.

[4] *Dynamic Linking* demands that "the payer is made aware of the amount of the payment transaction and of the payee" [26].

E6 does not consider this complexity a major hurdle because they think vendors already offer sufficient solutions.

Specific Technical Issues. Not all browsers, especially in the mobile domain, are yet fully supported. In the past, certain built-in browsers (e.g., Samsung Internet Browser) lacked FIDO support. At the time of conducting the interviews, FIDO2 worked on 95% of mobile browsers [24], with Mozilla Firefox being a prominent exception as it only partially supported FIDO2 (Touch ID and PIN entry were not supported on certain operating systems). Similarly, for passkeys, browser support was very limited [17]. On certain OS and browser configurations, device-bound FIDO credentials and autofill UI were not supported. Participants argued that this impedes the universality, especially keeping consumers in mind **(C)**. O4 pointed out that if a company primarily uses Microsoft, it is not trivial to also handle authentication from Google or Apple devices uniformly. Additionally, O12 mentioned that Windows Hello for Business is limited to ten local identities, which makes it unsuitable for settings like reception workstations where more than ten people share a device **(W)** [63].

Legacy Software (W). While issues with legacy software are well-known in the security community, they play a particularly crucial role in FIDO2 adoption. Eight participants specifically mentioned such issues. As mentioned above, FIDO is rarely implemented in-house. Existing FIDO2 solutions offered by IAM vendors are usually closely integrated with cloud-based services like Azure Active Directory. However, such cloud-based solutions are usually not supported by old applications like process controllers for industrial machines or warehouse software. Some participants viewed this as a justification for not implementing FIDO2 at all to avoid a heterogeneous authentication infrastructure (O12, O18). Others felt that tooling to circumvent such challenges should be made available by IAM vendors, which is not yet the case (O2).

End-of-Life Systems. From a consumer perspective, participants pointed out that supporting old operating systems and browsers is crucial (O1, E5, A2). Web services have to be mindful that many organizations still run on Windows versions that do not support passkeys or other FIDO protocols. A2 voiced that you cannot tell consumers that they can "*only access the website using a specific OS version.*" This argument becomes particularly evident with services that target non-tech-savvy demographics or must be available for the entire population (e.g., digital government services) **(C)**.

6.4 Lack of Universality

One strength of passwords is their near-universal applicability, independent of the devices and environments where they are used. FIDO2 cannot live up to this universality.

Production Environments (W). In environments such as production sites, biometric authentication is often not well-suited as workers wear gloves, masks, or have dirty hands, preventing reliable usage of biometric sensors (A3, O9, O11).

Buried Entry (W). O6, a small-business CISO, highlighted that certain software licensing systems restrict access to important security features, like SSO integration with Microsoft Azure, to larger teams. This practice of hiding security functionalities behind paywalls disadvantages smaller businesses.

Exclusion of User Groups (C). From an ethical perspective, A1 and E2 pointed out that FIDO excludes users who do not have the financial means of purchasing mobile phones or security keys, or even just users who struggle with technology. This is particularly critical for services like bank accounts. If a service is entirely passwordless, in the worst case some user groups would be completely excluded. A3 supported this argument when pointing out that, in lower-income countries, people often have older phones that do not support FIDO protocols or share devices with family members [3, 82]. From an accessibility standpoint, A3 and O1 argued that sharing passwords is often the only means of interacting with web services for some people (e.g., the elderly).

Biometrics (W). Contrary to our expectations [55], concerns about where the biometric data is stored with FIDO2 were not universal and were only raised by European workers' councils in France and Germany (O7, O10). Some participants who had negative experiences with proprietary biometric-based solutions raised concerns about biometric FIDO2, projecting their prior negative experiences (O6, O11). O18 raised concerns about the limited value of FIDO for mobile apps that already offer local biometric authentication **(C)**.

6.5 Organizational Challenges

Manageability and Logistics. While measures for centralized management of username/password credentials have long been available and standardized, the management possibilities for FIDO credentials are still in their infancy.

On- and Off-boarding (W). O12 considered it problematic that the FIDO onboarding process is unnecessarily complex due to its device-centric nature. They criticized that FIDO credentials cannot be managed centrally by IT departments for non-technical employees who struggle to register credentials. A3 and O2 referenced similar experiences. Some participants did not like that security keys would need to be recalled when a customer closes an account (O18) or an employee leaves a company (E11). While employee accounts can be closed centrally regardless of whether they use security keys or passwords, an organization might still want to physically retrieve security keys for asset management and cost control (A3, O1).

Credential Sharing (W). Scenarios like showcasing, exhibitions, or temporary accounts can only be effectively handled with shareable credentials (A1, O1). Despite the security challenges, these cases form a substantial portion of the workflow for businesses like small companies and start-ups.

Passkey Management (C). E5 pointed out an issue that might emerge once passkeys are common. As the number of accounts users have is huge, the number of passkeys a user

Table 3: This table shows how the 18 interviewees who completed the card-sorting task rated potential obstacles.

	Customers happy	Pwd good	Pwd managers	2FA secure enough	SSO usable enough	No std fallback	Stolen unclear	New dev unclear	Multiple unclear	Wouldn't use bio	Roaming auth	Friction	Used to pwd	Libs don't exist	Libs incomplete	Libs not understand	Libs wrong language	Issue support both	Can't get rid entirely	Browser support	Unified experience	No need	Won't allow	Don't understand	No open-source	Bio forbidden	Peer organizations	Why invest	Impl. costs	New comm costs	Incompatible w/ UX	Can't brand	Can't communicate	Color, icons hard

must manage will be, too. This raises the challenge of user-friendly management and revocation of FIDO credentials.

Stakeholders with Power. FIDO at its core is built as an open standard and has always valued its cooperative decision-making processes. Nevertheless, a number of participants pointed out that a few powerful stakeholders are most influential in the FIDO realm. This makes it substantially different from passwords, which cannot be influenced by a corporation.

Solo Efforts. This hurdle has become particularly evident when passkeys were first released by Apple despite them being a joint endeavor of many FIDO affiliates (E4, E5). E5 fears that the companies, being as big as they are, have the power to block the development of FIDO if it does not fit their company-internal agenda. E5 explained, "*If Google has objections, and they do not implement [a feature] in Chrome, it'll never gain adoption.*" As one example of this, device-bound FIDO credentials are not supported by Apple. One can see from that example that FIDO's success is partially dependent on the cooperation of all stakeholders.

Conflict of Interest. Other participants speculated about potential reasons for FIDO2's slow adoption. For some companies involved, a conflict of interest may have emerged since the focus of FIDO shifted from roaming authenticators to platform authenticators. Security key vendors like Yubico have an interest in maintaining their market (E6, O11, O12).

6.6 Prioritization of Obstacles

With our card-sorting task, we aimed to learn more about participants' views of the relative severity of obstacles to FIDO deployment. As Table 3 shows, there was no particular consensus obstacle. FIDO and IAM experts overall were more concerned than representatives from organizations. In Table 3, we calculate participants' mean severity per obstacle, artificially weighing "major" as 2, "minor" as 1, and "no obstacle" as 0 to indicate and reflect trends.

Necessity. Overall, participants confirmed that FIDO is "necessary." They agreed that customers overall are not satisfied (N1), that passwords should be replaced (N2), and that password managers do not sufficiently solve the problem (N3). A more salient obstacle is that existing 2FA solutions are already considered to be secure enough by about half of the organizations (N4). The same applies to single sign-on (SSO), which is considered to be usable enough (N4).

Usability. The most pressing usability obstacle is the lack of a standardized fallback procedure (U1), one of the three biggest obstacles identified overall. Device theft and handling multiple (or new) devices (U2-U4) was rated at least a minor obstacle by most. Some, however, considered these issues to be solved with passkeys. Participants overall did not think that roaming authenticators should be considered unusable (U6). Change causing friction and users being habituated to passwords were considered bigger obstacles; the complexity of change (U7-U8) may outweigh FIDO's advantages.

Deployability. Most participants considered deployability (D1-D4) not to be an issue. The most pressing concern among experts was that libraries are not easily understandable (D3). The lack of full support by mobile browsers (D7) was considered a major obstacle by experts and also raised as a minor concern by representatives of organizations.

IT Management. Three participants rated all management-specific hurdles as major (M1-M3). However, they generally expressed how management can severely impede deployments while emphasizing this not being the case for FIDO in reality. All others rated these issues to be minor at worst. Open-source software (M4) or biometrics being not allowed (M5) do not appear to be obstacles. Some participants in larger companies reported waiting for peer organizations. However, participants also pointed out that being innovative can be an asset and thus not necessarily a hurdle to FIDO (M6). Generally, FIDO and IAM experts rated these aspects much worse than organizations. As organizations have better insights here, this indicates that management is likely not a blocker in reality.

Financial. Most participants rated all financial concerns (F1-F3) as at least minor obstacles. To them, it all boils down to a cost-benefit analysis. Thus, it appears that FIDO's value proposition is not yet entirely clear or it does not solve concerns that are urgent and worth investing in.

Communication. Figuring out how to properly communicate FIDO to the user (C3) was a minor obstacle for most. The other categories (C1, C2, C4) were not considered obstacles.

In summary, the worst-rated obstacles were increased friction for users (U7), the lack of universal support in mobile browsers (D7), and the lack of a standardized fallback (U1).

6.7 Distinguishing Stakeholders Views

Experts and IAM vendors sometimes judge the severity of obstacles differently than organizations. Only experts and IAM vendors raised concerns regarding FIDO being hard to explain and understand. Practitioners might be more oblivious to the challenging task of communicating FIDO's functionality. It could also indicate that in practice the technical functionalities are actually easier to convey than experts think. Shortcomings in support and issues with legacy software were raised by seven organizational representatives, but only one FIDO expert. This might hint at how experts sometimes disregard concerns surrounding this topic as insignificant and easy to fix. However, these pieces of software often comprise a major part of the core business infrastructure. Similarly, only organizations addressed the lack of universal applicability for "non-desk" staff (e.g., in healthcare). Only experts and IAM vendors discussed ethical concerns with FIDO surrounding universal accessibility independent of socioeconomic status and abilities. The experts may take a more idealistic viewpoint on the "purpose" of authentication, whereas organizations apply a pure "business lens."

7 Discussion

Next, we discuss our thoughts on the future of passwordless authentication, give recommendations for industry, and outline important avenues for future research.

7.1 A Passwordless Future

Will We Get Rid of Passwords? According to our findings, not in the near future. However, there is agreement that FIDO2 will play a major role in making the password obsolete in many cases. E5 said that the term "passwordless" should not be understood as eliminating passwords, but rather as having "less passwords [sic]." With legacy software that is often commissioned for over 30 years and written in languages few still understand today, it is unlikely that FIDO will be implemented in such cases (O10). Even once FIDO is deployed, it is still a long way before its security benefits can flourish [90]. FIDO-protected accounts only fully benefit from being more secure if they are used without a password. However, especially for the consumer case, the password will most likely remain the primary fallback. So far, only Microsoft offers "password-free accounts" [92], allowing users to delete the password after enrollment into their authenticator app. This was also mentioned by interviewees who criticize Apple's and Google's passkey implementation, arguing that they themselves must be passwordless before passkeys can offer their full security advantage. While this is technically true, it should not be used as an argument against FIDO as these major services are known for paying very close attention to account protection (e.g., Apple enforces 2FA for all accounts attempting to use passkeys [7]). FIDO also offers a variety of usability advantages over passwords. The same cannot necessarily be said about all other services on the web.

FIDO as a Convenience Feature. FIDO, often perceived primarily as a security technology, should also be recognized for its convenience. When pitching FIDO, it is crucial to emphasize the convenience it brings (E4). In fact, according to some, overall usability will likely be a stronger motivating factor for adoption than security alone (O1). To broaden its appeal, the security community should adopt a narrative that highlights how FIDO makes logins easier and faster, in turn increasing customer/employee satisfaction. Shifting the focus to the seamless user experience could help persuade those who are currently hesitant due to misconceptions, such as believing that current 2FA systems are "secure enough."

7.2 Top 5 Obstacles

No Standardized Fallback. Confirming Bicakci et al. [10], one of the biggest obstacles we observed was the lack of a standardized fallback. While the FIDO Alliance gives recommendations for handling fallback in different scenarios (e.g., having two security keys) [42], these can neither be consid-

ered universally applicable nor are they usable and secure. Some fallback procedures described by our participants involved having a one-time code sent to a predefined colleague who would then share the code in a personal conversation or over the phone. Apart from availability issues (person receiving the code not being available), such measures can involve fear and shame of admitting the loss to superiors [79] and be susceptible to social engineering attacks.

Complexity and Friction. Introducing any new technology will temporarily lead to confusion, resistance, and friction for users and stakeholders. At all times during deployments, it is important to inform, educate, and communicate with all parties involved. To convince management, a clear communication plan emphasizing FIDO's usability, user experience, and security benefits is crucial. It is vital not to disregard these stakeholders. A successful and secure deployment will partially depend on factors that are independent of FIDO's theoretical security. Highlighting success stories or case studies from other organizations could help. FIDO will most likely not integrate seamlessly with existing systems. Thorough testing and engaging with all IT teams are thus indispensable for proper integration with existing infrastructure (A4). Our results echo previously raised concerns about FIDO documentation being confusing [4]. Developers should be assisted with training sessions, clear explanations, and good documentation [17, 43, 76, 101] to help them understand how FIDO and especially its security work (E5). If the user interface or onboarding process for FIDO are poorly designed or difficult to navigate, it will create frustration and resistance. To ensure intuitive and user-friendly interfaces that foster adoption, educated UX designers need to be involved from the early stages of the deployment process. Usability testing with different user groups, not only technical staff, is key (O4).

Technical Issues. While prior work identified a lack of deployment-ready solutions [4], this was of little concern in our sample. However, participants described various examples of technical problems, with incompatible legacy systems and incompatible browser and OS configurations being most common, confirming findings from Nawrath concerning a lack of platform support [65]. As end-of-life systems are a reality in industry and frequently encountered when it comes to consumers, the FIDO Alliance must develop guidelines and propose alternative solutions for such systems. Similarly, the current situation surrounding the support of device-bound credentials or Mozilla Firefox's lack of support for user verification are harmful to a smooth user experience. Note that Mozilla added support with Firefox 114 in June 2023 and announced it will support passkeys with Firefox 120 in November 2023 [68].

Regulatory Requirements. Another frequently named obstacle was regulatory requirements like the payment directive PSD2 and European eIDAS regulation. Members of the FIDO Alliance explained working on convincing legislators that passkeys are compliant with the regulations. Other entities like the U.S. National Institute of Standards and Technology (NIST) are actively asking whether passkeys and FIDO2 are sufficiently addressed in their newest revision of the digital identity guidelines SP 800-63-4 (Draft) [86]. Participants also reported various concerns that FIDO conflicts with internal rules and existing policies and will ultimately require new policies and best practices.

Security Culture. Even 24 years after a canonical paper exhorted that "users are not the enemy" [1], we found that this mindset still has not entirely vanished. Some interviewees felt that security should be pushed on the workforce if the "experts" think a specific security measure is relevant [83]. For example, one company was unsure how to define a policy for handling the security key and whether it could be left in the computer or if it should be securely stored in a locker. Deciding on the latter, they found that most people disregarded the policy as ignoring it allowed for more flexibility.

When talking about reasons for and against deploying consumer-facing FIDO, participants elicited a mindset that taking care of account security is the responsibility of the customer. For FIDO deployments, this mindset may become an issue as those companies likely have little to no intent for changing the authentication landscape for their customers. The compromise of single accounts often causes companies little harm. At worst, they need to reimburse the owner. They follow the idea that telling customers how to behave "correctly" is sufficient and that it is governments' task to properly educate citizens about digital safeguards.

7.3 Recommendations for Industry

Prepare Smooth Deployment. To ensure a smooth deployment process, O10 emphasized the importance of adapting security policies right from the beginning. This is also recommended in the "enterprise journey" resources of the FIDO Alliance [32]. To handle the distribution of security keys in international corporations, O2 recommended using a security key distribution service like YubiEnterprise Delivery [102]. O4, who had a relatively unsuccessful deployment, self-reflected saying that others should not be "the typical tech guy." O4 reported only having piloted FIDO deployment with peers from the tech department. However, as their experience and opinions are not representative of the entire workforce, they should not be used as a reference.

Increase Acceptance in Workforce. To decrease the friction originating from change, O4 recommended onboarding training in very small groups and making rollouts on a per-department level as each will likely bring up their own requirements and issues. To foster confidence in FIDO's trustworthiness, O5 recommended communicating transparently that the workplace does not have access to the key even if it is used for private accounts. O12 pointed out their positive experience with their CISO advertising the new authentication options occasionally to familiarize the workforce. Several

participants from all participant groups recommended using an IAM provider or using the methods the operating system already supports to obviate the issues caused by the complexity of implementing FIDO in-house.

Little Care for User Experience. Many participants from organizations perceived any topics related to user experience as unimportant. Experts and IAM vendors seemed to be more aware of the topic. Early adopters reported negative experiences about never reaching high adoption rates due to technical and UX issues during rollouts, stressing the importance of a good user experience. When it comes to consumer-facing FIDO2, it is particularly concerning that certain settings are wildly inconsistent. Every browser and OS has its own way of doing and naming procedures. On websites where passwordless sign-in is possible, the process gets even more confusing.

Implement a Secure Fallback. It must be acknowledged that FIDO is only more secure than passwords if any existing passwords are disabled. If passwords continue to be used as an alternative or fallback option, FIDO's security guarantees can be easily bypassed via downgrade attacks [90]. The FIDO Alliance gives recommendations for handling fallback in different scenarios [42]. Many consumer-facing websites continue to rely on their already existing fallback infrastructure (e.g., out-of-bad communication via email or SMS). However, this level of security is often insufficient in high-risk scenarios like online banking (e.g., no real-time phishing resistance). Kunke et al. [54] evaluated 12 different account recovery options for their use in the FIDO2 passwordless authentication context (before passkeys had been announced). They suggested either registering multiple authenticators during account setup (as suggested by the FIDO Alliance) or relying on help desk personal verifying the user (e.g., via an identity card).

7.4 Future Research Directions

Passkey Management and Revocation. Another issue raised was the question of what happens once passkeys are more commonly in use for a variety of accounts. The problem of password reuse [67] originated due to the ever-increasing number of accounts everyone holds. This means that users at some point will hold a large number of passkeys. This issue is even aggravated as with passkeys people will hold multiple for every account when they register with more than one ecosystem. As of now, it is unclear how to properly handle those passkeys, especially in cases such as revocation. Notably, commercial and open-source password managers are already in the process of deploying functionalities to manage passkeys [94]. However, the vast majority of the population does not use password managers except for those built into browsers [73, 103]. This issue should be addressed before passkeys find more widespread adoption. As of October 2023, vendors have started working on a cross-ecosystem future (e.g., Chrome accessing passkeys stored in iCloud Keychain) and integrating passkey managers into their products [62].

Assisting Migration. Online services have become ubiquitous. Thus, in most situations, users will not be creating new passwordless accounts, but instead be migrating existing accounts to FIDO-based authentication. To facilitate this, companies have started to deploy small notifications that advertise the usability and security advantages of FIDO2 and address misconceptions [55]. Once passkeys are offered by more services, convincing users to migrate away from passwords will become an important aspect. Studying users' migration concerns and issues will help to drive the adoption of a usable and secure passwordless future for everyone.

Acknowledgments

We thank the FIDO Alliance for supporting this project and connecting us with FIDO experts.

Abstract

Implementing cryptographic standards is a critical process for the cryptographic ecosystem. Cryptographic standards aim to support developers and engineers in implementing cryptographic primitives and protocols. However, past security incidents suggest that implementing cryptographic standards can be challenging and might jeopardize software and hardware security. We need to understand and mitigate the pain points of those implementing cryptographic standards to support them better.

To shed light on the challenges and obstacles of implementing cryptographic standards, we conducted 20 semi-structured interviews with experienced cryptographers and cryptographic software engineers. We identify common practices when implementing standards, including the criticality of reference and third-party implementations, test vectors to verify implementations, and the open standard community as central support for questions and reviews of implementations.

Based on our findings, we recommend transparent standardization processes, strong (ideally formal) verification, improved support for comparing implementations, and covering updates and error handling in the standardization process.

1 Introduction

Cryptography is one of the pillars of modern information security. Many software and hardware products implement cryptographic primitives, algorithms, and protocols to protect data in transit and at rest. For example, Transport Layer Security (TLS) [65] is used to protect the vast majority of network traffic on the Internet [17] and end-to-end encryption in messaging apps such as WhatsApp [41] or Signal [68] protects billions of messages and users every day. However, as demonstrated by previous work, deploying and using these important cryptographic standards can be a difficult and laborious process [40, 61, 24, 73, 16].

A critical and particularly challenging step in the deployment path is the implementation of cryptographic standards. Standardization organizations such as the Internet Engineering Task Force (IETF) [30] and the U.S. National Institute of Standards and Technology (NIST) [49] publish standard documents that aim to serve as a blueprint for implementations that are secure and provide inter-compatibility. Cryptographic standards often include details of primitives and protocols, mathematical information for secure implementations, references to research papers, and other documents meant to support the implementation of primitives, algorithms, and protocols. In other cases, details are missing or vague, resulting in gaps in the standard that increase the risk of implementation mistakes and require extensive cryptographic knowledge. Incidents illustrate potential consequences:

MITRE's CWE-1240 list of common weakness enumerations (CWE) provides an overview of risky implementations of cryptographic primitives [33]. An example is the widely used OpenSSL library, which included a vulnerable implementation of the ChaCha cipher, used in TLS 1.2 onwards (see Request for Comment (RFC) 7905 [36]). Even though RFC 7539 [50] includes a specific byte size interval, the implementation allowed using a byte size outside the interval. This deviation from the standard resulted in a vulnerability that enabled attacks on confidentiality and integrity [66].

Similar to standard documents, reference implementations, and other third-party implementations are critical pieces in cryptographic standardization processes. For example, the IETF provides the Secure Shell (SSH) protocol [42], which is used in the OpenSSH implementation [62]. As this implementation is commonly used as a reference and provides options not included in the SSH protocol [42], it is a *de facto* extension to the standard that is not governed by the IETF. The above examples illustrate some challenges when implementing cryptographic standards.

While previous work investigated end-user challenges using cryptography [35, 71, 5], developers struggling with the correct use of cryptographic APIs [19, 31, 1, 16], and the use of cryptography in industry contexts [21], an in-depth understanding of the experiences and challenges when implementing cryptographic standards is missing in the literature.

Previous research on cryptographic standards focused on vulnerabilities in standards or faulty implementations [74, 12, 15, 61, 24], but did not consider the implementation process itself. We present and discuss in-depth insights from 20 semi-structured interviews with experienced implementers of cryptographic standards. We illustrate the challenges they encounter from the perspective of new and veteran developers in the cryptographic community and from an industry, academic, and hobbyist view. We hope our findings can contribute to easier-to-implement future cryptographic standards.

Research Questions. In this work, we address the following research questions:

RQ1: *Which are developers' practices when implementing cryptographic standards?* Implementing cryptographic standards is essential to deploy cryptography from research into products. We are interested in better understanding developers' implementation practices and requirements for cryptographic standards.

RQ2: *What are the challenges of implementing cryptographic standards?* Cryptographic standards are complex and require a high level of expertise to understand and follow. We aim to understand the challenges of writing cryptographic software following standards.

RQ3: *How can future cryptographic standards be improved to better support implementations?* The correct and secure implementation of cryptographic standards is crucial for overall software security. We aim to understand better how future cryptographic standards can be improved to support cryptographic software developers and implementations.

We interviewed 20 implementers of cryptographic standards. Most of them had more than ten years of experience and worked in academia or industry on application areas of cryptography ranging from PGP, TLS, elliptic curve cryptography (ECC), and post-quantum cryptography (PQC). All had critical roles in their projects. Participants illustrated the criticality of reference and third-party implementations, formal verification, and test vectors when implementing cryptographic standards. They reported that managing standard updates, multiple variations and complexity of standards, error and typo handling, and patents are major challenges during implementation. Participants expressed a strong preference for transparent and open standardization processes and a need for improved communication in the community.

To support the transparency and replicability of our work, we make all non-identifying research artifacts available, including our semi-structured interview guide, the codebook, and the invitation emails in the Availability section. Furthermore, we provide a background on cryptographic standardization processes in Appendix A.

2 Related Work

We discuss related work in two key areas: the security of cryptographic standards, and challenges regarding adoption and implementation of cryptography.

Security of Cryptographic Standards. Cryptographic software is commonly based on public standards, typically provided by standardization bodies such as NIST or IETF. Hence, the quality of cryptographic software is strongly connected to the quality of the cryptographic standards they implement. Due to this, previous work on standards' security often focuses on the quality of the cryptographic standardization process and standard candidates. Kannwischer et al. examined submissions to the official NIST PQC standard effort, and found that almost all the required implementations were vulnerable despite passing all stages of the standardization process [32]. Similarly, Mouha et al. discovered a vulnerable standard implementation that reached the final round of the NIST SHA-3 competition in 2011 [48]. Hao evaluated the IETF standard selection process and discussed principles to improve future security standardization processes [22].

Security flaws can also be present in established standards. For example, Woodage et al. analyzed the NIST SP 800-90A standard. After finding some security flaws, they stress the criticality of the underlying algorithms and that algorithms should not be standardized until their security was proven [74]. Do et al. found vulnerabilities in the official W3C Web Payments API [12]. Feng et al. detected logical contradictions in several CoAP RFCs on a statement level. Here, quality problems did not arise within the implementation, but the description scope [15]. Other affected standards include the PGP protocol. Halpin analyzed it, investigating and demonstrating the central design flaws that make it difficult to adapt PGP to modern requirements or to deprecate older, less secure versions [20]. To remediate these issues, Almeida et al. proposed a framework for automatically generating functionally correct reference implementations from cryptographic standard specifications [2]. Mohajerani et al. presented a framework to evaluate the side-channel resistance of Lightweight Cryptography for the Standardization Process [46].

While related work often focuses on the theoretical issues of cryptographic standards, our interview study investigates the practical experiences with and perceptions of standards from cryptographic software implementers. We aim to understand the impact of cryptographic standards on the security of cryptographic software to recommend improving future cryptographic standards and standardization.

Cryptographic Adoption & Implementation Challenges. When standards lack necessary support and information, developers can face difficulties implementing these standards. These adoption issues and overall cryptographic misuse can lead to severe security issues. For example, Li et al. found that two thirds of Apple iOS apps contained security flaws caused by cryptography misuse [40]. Similarly, Oltrogge et al.

scanned 1.3 million apps from Google Play, identifying over a thousand candidates with vulnerable certificate validations. Despite providing secure defaults, standard definitions stated optional or adjustable parameters that provoked implementation vulnerabilities due to inadequate documentation and developer usability [61]. Hebrok et al. found vulnerable implementations of the optional non-standard TLS session ticket mechanism. Respective implementers could not construct secure keys and assess potential risks of reusing keys [24]. After investigating vulnerabilities in TLS-DH(E), Merget et al. reached similar conclusions and found that secret construction and forward secrecy are not sufficiently secure [45]. Valenta et al. found in an internet-wide scan that ECC implementations often deviated from the respective standard definitions. Among other problems, these implementations lacked validity checks given by the standards [73].

A systematic review by Lazar et al. examined 269 entries on software vulnerabilities from the CVE database. They found that 17% of the issues were located in cryptographic libraries [38]. To discover vulnerabilities in implementing security measures, Rahaman et al. presented rules for source code analysis that effectively perform vulnerability checks at compile time [64]. Gorski et al. explored the use of cryptographic APIs. To create recommendations to increase security, a focus group study ($n = 25$) explored feedback to developers and review what types of security information are helpful [19]. Another study by Jancar et al. invited 44 developers of cryptographic libraries to participate in a survey and found differences between academic knowledge and cryptographic engineering. Finally, they provide recommendations on how developers can prevent timing attacks [31]. Close to this work, Haney et al. interviewed developers to gain insights on using cryptographic measures. They suggest assessing the usability of standard documents regarding the resulting cryptographic quality of real-world implementations [21]. Finally, Fischer et al. presented an interview study with cryptographic experts regarding the application of cryptographic research. They identified key challenges in adapting the results of cryptographic research, notably identifying conflicting goals between the different stakeholders of the cryptographic ecosystem [16].

Adding to this body of research, we contribute insights on the interactions between standards and standardization bodies, and the developers implementing them. We are specifically interested in what makes a good cryptographic standard for cryptographic software developers. We further examine the obstacles these developers face with the ecosystem and resources around cryptographic standards. As a result, we identify core challenges they face and provide a set of recommendations for writing standards, reference implementations and other resources.

3 Methodology

Using semi-structured interviews, we collect insights into various workflows from developers who directly interact with, read, and implement cryptographic standards. In this section, we illustrate our study's design and recruitment process. We provide an overview of our methodology in Table 1.

Table 1: Overview of our methodology, including interview guide design, data collection, and analysis.

Stage	Additional Information
1. Interview Guide	
Interview Design	Feedback round with multiple experts
Piloting	2 pilots interviews
Recruitment	Projects, mailing lists, snowball sampling
2. Interviews	
Interviewers	1 (+1 shadow) interviewer
Participants	20, avg. 78 minutes
Structure	S1: Projects and Demographics
	S2: Process of Implementing Standards
	S3: Challenges of Implementing Standards
	S4: Perception of Cryptographic Standards
	S5: Problems of Current and Future Standards
3. Data Analysis	
Transcripts	Amberscript [4]
Methodology	Thematic Analysis [10]
Coding	5 coders, 2 per transcript

3.1 Interview Design

To draft an initial interview guide, all authors collaboratively discussed relevant interview topics, obtaining a few high-level leading questions to ask participants. We supplied each of those questions with more profound, conditional sub-questions to collect in-depth insights during the interviews and prepare for various topics that might emerge during interviews. During and after both of these phases, we obtained additional feedback from co-workers and students and internally tested the interview guide to arrive at a final internal draft.

In the next step, the interview guide draft was reviewed by different experts that were either cryptographic practitioners or experienced with qualitative research. We iteratively improved the interview guide based on the experts' feedback.

3.2 Interview Guide

After completion of our guide, we arrived at five general topics, described below. The complete interview guide is available in our replication package (cf. Availability section).

Intro and Consent. We start with a brief introduction of ourselves, our research field and the interview motivation. We explained that we do not judge any answers, that all questions can be skipped, and that the interview can be ended at

any time. Furthermore, we explained how we process and anonymize the interview answers to protect participants' identity. Finally, we asked participants for their consent to an audio recording of the interview, and gave them the opportunity to drop out and have their data deleted at any time.

S1: Projects and Demographics. We asked general questions about participants' experiences, projects, and standards to get started. For example, we asked about their background and education in cryptography, and the purpose of their projects. We also asked how they got started working with standards.

S2: Processes of Implementing Standards. Next, we focused on the considered resources and processes. We also asked about internal and external testing, and reviewing of implementations.

S3: Challenges of Implementing Standards. In this section, we asked participants about challenges, including legislation and updates to standards.

S4: Perception of Cryptographic Standards. This interview section covered the experience and perception of standard documents and bodies. We asked participants about specific standards and organizations they worked with in the past, and what makes a good standard document for them.

S5: Problems of Current and Future Standards. Finally, we cover the wishes and needs of participants regarding current and future standards. We presented an example scenario surrounding legislation and their opinion on that, and we asked about any remaining problems they encountered with standards. Finally, we asked them about their trust in current implementations and their wishes for standards in general.

Outro/Debriefing. After the interview, we asked them if they had any additional remarks, thanked them, and stopped recording. To conclude, we asked for potential followup candidates they knew as part of our snowball sampling.

3.3 Recruitment

Due to the small population of experienced cryptographic practitioners who qualified for our study, recruiting suitable participants was challenging. To find potential participants, we identified open-source projects implementing cryptography. A project was included if (i) it implements a cryptographic function, and (ii) if the last commit was not older than two years. We examined the top 120 viable projects in the GitHub topic *cryptography*, sorted by stars. Furthermore, we investigated dependencies of projects from the cryptographic area, which led us to find and include projects outside GitHub, including OpenSSL[1] and NaCL[2]. We then identified and contacted the developers who were among the most active in implementing cryptographic functions. To avoid issues with GitHub's terms of service,[3] we only contacted developers who provided public contact channels external to GitHub, e.g., via personal or professional websites. To identify additional matching projects, we also used the *awesome-cryptography* list [70]. After each interview, we used snowball sampling by asking study participants if they could recommend other potential participants. Finally, as some interviewees suggested, we sent out interview invitations to two major mailing lists regarding cryptographic standardization, namely the NIST pqc-forum [60] and the IETF SAAG mailing lists [29]. While the first is used for NIST's PQC standardization effort, the latter reflects the Security Area Open Meeting and further addresses participants of the IETF 118 Prague meeting [27] that took place at the time of recruitment. This way, we reached cryptography stakeholders outside the open-source development space.

3.4 Qualitative Data Analysis

We audio-recorded all interviews and transcribed them using the GDPR-compliant transcription service *Amberscript* [4]. We manually reviewed all transcripts for completeness and correctness. We performed *thematic analysis* [10] to analyze the transcripts for common themes and topics. We first coded the interview to derive general opinions and experiences. Then, we used an iterative process to refine our codes into generally applicable themes and topics, which were then fit to the individual citations in each interview.

Two researchers coded each interview independently. After individual coding, both researchers merged and discussed their coding, agreeing on codes, and refining the codebook. This was done for all 20 interviews, ensuring that the resulting codebook captures the content of all interviews. As every merging discussion ended with consensus (theoretical agreement of 100%), we do not calculate inter-rater reliability (IRR) [44]. Using the resulting codebook, we collectively derived themes in multiple iterative sessions with four coders. We provide the codebook as part of our replication package (see Availability section).

3.5 Ethics

Our institution's ethical review board (ERB)[4] approved this interview study. This work follows the ethical principles of the *Menlo Report* for research involving information and communications technologies [34]. Additionally, we adhered to the strict German and European data and privacy protection laws, including the General Data Protection Regulation (GDPR). We audio-recorded all interviews, used a GDPR-compliant transcription service, and deleted audio recordings

[4] Equivalent to an IRB.

after their successful transcription. After the interview, we stored transcripts in a self-hosted, secure cloud collaboration software, encrypted all data at rest and in transit, and only granted researchers involved in the project access to the data. We offered participants compensation in the form of a $60 donation to an open-source project of their choice. We informed participants about these conditions via a consent form that they had to accept in the pre-survey, which was included in the informational material provided for recruitment. They could further discuss and ask questions about the form during the introduction of our interview[5]. As interview questions might be sensitive, we informed participants they could skip questions or terminate the interview at any time. Finally, we provide interviewees with a preprint to suggest changes or veto their contribution to the camera-ready version. To protect participants' privacy, we removed identifying information (e.g., names, companies, project information) from any quotes in this paper.

3.6 Limitations

This work has several limitations inherent to qualitative research and interview studies, including limited generalizability and biases such as recall and social desirability biases [39]. We accounted for these biases by interviewing a diverse sample of experts who fit our recruitment criteria. Most importantly, we focused on interviewees who had previously implemented cryptographic standards.

We recruited some interviewees by purposive sampling, using our personal and professional contacts. Hence, most interviewees have a similar background and are primarily from the US and the EU. We did not obtain a balanced or diverse sample of participants regarding personal recruitment criteria like gender, ethnicity, and age. This means our sample is unfit to provide meaningful statements about underrepresented parts of the cryptographic community or the effect these biases may have on cryptographic discourse. However, we recruited interviewees using snowball sampling and through cryptographic mailing lists and forums such as the NIST pqc-forum and the IETF SAAG mailing list. This was done to obtain a diverse sample regarding years of experience, work context, and project areas for our interview within the relatively challenging small group of cryptographic developers working with standards. We developed our interview guide with these limitations in mind.

To reduce social-desirability bias, we specifically mentioned that we were only interested in our participants' experiences and opinions and did not judge them in any way. We also clarified that interviewees could skip questions or end the interview for any reason. As in any self-reporting user study, interviewees' over- or under-reporting experiences and opinions could bias our results.

[5]The consent form is part of our replication package (see Availability section).

4 Results

In the following, we outline results from our interviews with 20 experienced implementers of cryptographic standards. The interviews were conducted in English, except for three conducted in German based on participant preferences; quotes from these are translated in the paper.

4.1 Interviewee Demographics

Due to the small sample size and well-connected cryptographic community, we provide only aggregated demographics in Table 2 to protect the pseudonymity and privacy of our participants.

Table 2: Demographics of our 20 participants.

Personal		**Project-related**	
Years of Experience		**Project Roles**	
Less than 5 years	4	Developer: Lead	9
5 to 20 years	9	Developer: Team member	3
More than 20 years	7	Developer: Co-leader	3
Work Context*		Developer: Sole contributor	2
Academia	10	Other	3
Industry	10	**Project Areas***	
Hobby	7	Post-Quantum Cryptography	15
Open source dev	5	Elliptic Curve Cryptography	6
Crypto side project	3	TLS, SSL	5
Education*		PGP	5
Academic	15	Other Crypto Libraries	4
Self-taught	11	Formal Verification	3
On the job	7	SSH	1
Training course	1	**Project Open or Closed Source***	
Gender		Open source	18
Male	8	Closed source	2
Female	1	Other/NA	1
Non-binary	1	**Recruitment Channel†**	
Not Shared	10	Projects	7
		Snowball Sampling	7
		Mailing List	6

* Multiple answers possible, may not sum to 100%.
† Participants may fit multiple channels, best match reported.
NA = not applicable

Overall, our participants tended to be highly experienced. Only four participants reported having worked in cryptography for less than five years, while 16 had at least five years of experience, and seven participants reported more than 20 years of experience in cryptography.

Our participants filled various roles in their projects, often more than one, but mainly worked on implementing cryptography. Among them, nine had a leading role, while three considered themselves as co-leaders, both part of a larger team. On the other hand, two participants reported being their project's main or sole contributors and only receiving minor external help, e.g., occasional pull requests from other developers. Besides the majority of developers, three participants mentioned different roles, including teaching and consulting

activities, where they mainly work on prototypes or other non-production-ready code.

Participants also mentioned multiple sources regarding their education and training in cryptography. Most commonly, 15 participants reported academic education and university courses; eleven mentioned being self-taught. Less common, seven stated to have gathered cryptographic knowledge on the job. Only one participant mentioned formal training. Ten participants worked with cryptography in an academic context, e.g., as a part of research or university courses. The remaining ten worked in industry. Additionally, some worked on cryptography projects in their spare time, e.g., seven reported hobby projects, and five mentioned open-source projects. Fifteen participants were mainly involved in post-quantum, mirroring current trends in the cryptographic community. However, some also worked on, e.g., ECC, TLS, and SSL, PGP, or other cryptographic libraries.

Eighteen participants reported working on an open-source project, while two were part of closed-source projects. Finally, one participant did not actively contribute to development, as they mostly focused on teaching cryptography to students.

Furthermore, we report distribution across our recruitment channels. As multiple may apply, for example, we might have directly contacted somebody who also saw us on a mailing list. We chose the channel that best applied: *Snowball sampling* in case participants recommended or contacted other participants; *mailing list* in case participants responded to our mailing list post; *projects* for all other participants who responded to our personal invite email. We recruited 7 participants based on our list of GitHub projects. Furthermore, 6 participants signed up after we promoted our study via the NIST pqc-forum and IETF SAAG mailing lists. We also asked participants for potential followup contacts. In 7 cases, the recruitment snowballed as participants explicitly recommended a person to us. This led to industry contacts and participants with little cryptographic experience, broadening our sample.

4.2 Practices for Implementing Cryptographic Standards

In the second interview section, we asked participants about their preferred resources for implementing a cryptographic standard, their implementation process, and how they test their code or handle issues like gaps in the standards. Gaps, as we refer to them, are any missing details in a standard needed for the implementation, e.g., due to implicit assumptions or lacking detailed explanations in standards. When encountering gaps, developers must decide themselves or consult other implementations to find out how to close them, which can lead to vulnerabilities or mistakes. The following discusses the reported topics and practices for the cryptographic standards implementation process. Starting with this section, we replace the participant counts with tendencies and qualifiers to protect their identities.

Implementers Appreciate Reference Implementations. Regarding resources, almost all participants mentioned using reference or third-party implementations as their main resource for implementing cryptographic standards. As one participant stated:

> *"Basically when software is written in a reasonable language for cryptography, then it's unambiguously specifying, 'Here's what you're supposed to do.' That's a very important resource in reference implementations that are clearly specifying something. Sometimes the simplest reference implementations are in C rather than Python. [...] A good example is the MD5 specification. The original MD5 specification was just, "Here is software that computes MD5."* — P3

This illustrates the appreciation of reference implementations as a blueprint for standard-conforming implementations. Participants mentioned relying on reference implementations to close gaps in standard documents, obtaining suggestions for implementation details not specified in the standard, conducting conformance testing, and generating test cases for test suites. Almost all participants reported using standard documents in some form, preferably with additional resources, such as scientific papers and reference implementation.

> *"I do like standards that are written in a way that you can match them up to. Here's the software that's supposed to be matching the standards. Here are the papers that are supposed to be matching the standards."* — P3

More in-depth, some participants reported comprehension challenges of standard documents due to their technical complexity, length, outdated or burdensome format, and language. They mentioned reference implementations as critical information sources to help comprehend cryptographic standards.

Formal Verification Increases Trust in Standards and Helps with Testing. Another topic that our participants mentioned is the criticality of formal verification and mechanized proofs of standards and their implementations. Some participants reported involving some form of formal verification to confirm certain security properties in their cryptographic implementations. A few participants further mentioned using formally verified implementations to generate test vectors. This illustrates the benefits of mechanically checked formal correctness proofs.

About half participants described formal verification as a criterion of quality for standards and would appreciate formal verification to be required for future standards. While formal verification for cryptographic standards is costly and laborious and might be an obstacle to submission, it offers significant advantages, as one participant puts it: *"I think the highest trust*

I would now have is in these high-assurance implementations that have been formally proven. [...] Even if it's not Kyber, it is secure with this proof." (P17)

Standards Should Provide Test Vectors. While not offering the same security guarantees as formal verification, most participants discussed the criticality of test vectors. Test vectors are known-answer tests that associate an input value with an expected outcome, e.g., a key and some plaintext as input and ciphertext as expected output. Test vectors allow for verification of the correctness of an implementation for the given test vectors. They also support *test-driven development,* as a few participants noted. About half of the participants mentioned using test vectors to test their implementations or expect them as part of a high-quality standard. As one participant summarized it:

> *"Test vectors where possible. Even test vectors that test like negative stuff, things that should not work or behavior, let's say, outside. I don't know: 'You should not validate this point. It should not work with your implementation.'"* — P14

Generally, our participants distinguished two sources of test vectors: (i) official test vectors provided by the standard and (ii) unofficial test vectors from trustworthy third parties. While many participants discussed the benefits of test vectors, not all standards provide them: *"Test vectors would be very helpful. Test vectors everywhere, but that is not the case. KMAC, for example, has no test vectors."* (P18). Especially in these cases, test vectors from trustworthy third parties are critical. For example, a participant mentioned frameworks like *Project Wycheproof* [18] as a trustworthy source for test vectors.

Trustworthy Third-Party Implementations Provide Additional Support. In addition to official reference implementations and test vectors, our participants further discussed the benefits of trustworthy third-party implementations. For example, they reported to have used large-scale open-source libraries such as *OpenSSL* or *OpenSSH* for the TLS and SSH standards, as test systems or blueprints for their implementations. One participant mentioned this as an integral part of their implementation process: *"The more implementations the better. We use a mixture of open-source implementations, proprietary implementations from other vendors, and then our implementations."* (P13).

About half of our participants mentioned using third-party implementations with widespread adoption to help ensure new implementations' compatibility with existing ones—especially popular and widely used ones. Testing interaction and compatibility with other implementations were part of about half of participants' workflow. One participant mentioned that having multiple implementations of a standard is a sensible requirement:

> *"In principle, it is an IETF requirement that there must be at least two implementations that can interoperate. [...] this is certainly a sensible requirement in practice. [...] Because the more implementations there are, the more errors we find."* — P15

The above IETF requirement originates from the *IETF Standards Process* [8, 11] and aims to establish the availability of implementations for cross-compatibility testing. Additionally, participants mentioned that third-party implementations provided them a reference for gaps or undefined details, and help them implement the standard correctly.

4.3 Challenges of Implementing Cryptographic Standards

In addition to implementation practices, we asked participants to share common challenges and obstacles when implementing cryptographic standards.

Backward Compatibility are a Challenge in Standard Updates. About half of the participants reported difficulties with the adoption of standard updates. Participants were mainly concerned about the trade-off between the improved security of an update and the potential impact of breaking changes in their product. Some participants even did not adopt security updates at all: *"The major killer thing about an update for us is if you might have too much trouble with older clients."* (P5). Participants reported deprecating outdated components of a cryptographic standard in an implementation as a major challenge. Participants voiced varying opinions regarding updates and deprecation. Overall, a few participants reported that they need to consider standards updates only rarely. However, this is still a concern for some crypto developers. One participant remarked on the rift between having to work with long-term deployments of computer systems and the constant developments and updates of standards:

> *"Then again, this is a bit of an annoyance of mine, is that with SCADA stuff, you're looking at lifetimes of 10, 20, 30 years. Whereas with the crypto guys, nothing's ever static, nothing ever stays the same. There's a constant [...][and] pointless churn in that a lot of stuff gets updated not because there's any particular reason to, but because we've just got a new flashy thing and we need to update it, which makes it incredibly difficult."* — P20

While the discovery of vulnerabilities will not wait for timespans this long, these types of deployments require legacy and backward-compatibility support, which standard organizations need to provide. Furthermore, participants working on multiple standards reported that handling backward compatibility can be more difficult for some standards than others. One participant gave the example that if an existing OpenPGP-encrypted email uses an outdated cryptographic primitive that is not supported by the recipient's OpenPGP client, that message becomes unreadable. Therefore, a standard update might result in a breaking change that cannot easily be addressed.

Algorithm Variations and Complexity. The complexity of cryptographic standards adds further challenges for implementers. Often, standards support multiple cryptographic primitive, algorithm, or protocol variations with different levels of security as a tradeoff for performance, storage requirements, or additional, optional features. For example, SHA-3 [57] supports different variations, such as SHA3-224, SHA3-256, SHA3-384, and SHA3-512, providing tradeoffs in security and performance. Some participants reported challenges when implementing all variations, often resulting in focusing on simplicity, as one participant puts it:

> *"I'm trying to implement this as step two, but for now it's important to me that I create the things that are considered necessary, or rather translate them, and then add the optional components as required.*" — P2

Other participants preferred increased security and lower attack surfaces in their implementations by deploying fewer options. Some participants cited standards' complexity in terms of comprehensibility, length of standard documents or contradicting documents:

> *"If you want to implement DNSSEC today, you have to read 50 different RFCs that contradict each other. If you want to implement [Hashing to Elliptic Curves] you have one document with all the possible curves, so it's really inconsistent.*" — P8

This also feeds into the debate of openness and review that we explore in Section 4.4. One participant summarized their wishes:

> *"[...] all I wanted was just something saying 'This is the standard from now on, key exchange, let's do that' and, instead, there's just more choices being produced, there's less clarity around them, there are fewer eyes on all of these candidates because there are so many of them.*" — P12

Our findings imply that multiple variants and options in cryptographic standards can skew the cryptographic implementation process, reduce the efficacy of reviews, and weaken the overall security of standards and implementations.

Handling Errors and Typos in Standards. Participants reported their experiences with vulnerabilities and errors in standards, where they usually find them, and how they proceed when finding one. About half of the participants gave us examples of errors in standards, from typos and small contradictions to insecure random number generators. Smaller issues, such as typos, can cause problems: *"We collected quite some remarks on just typos which can be deadly in the standard document"* (P4).

Participants shared their experiences with discovering and reporting vulnerabilities, and reported differences in feedback of standard authors or maintainers.

> *"For example, with S/MIME, again, it's very easy, just email the standards authors or the people involved and you can get a fix done. [...] There doesn't seem to be much point in submitting any change request to something like the TLS standards group, because it'll just get ignored.*" — P20

As a positive example of reporting and fixing a significant vulnerability, P9 reported:

> *"The first thing when talking about vulnerabilities, one of MITRE's things is to try and support this CVE and CWE system to actually have public reporting of discovered vulnerabilities. MITRE is certainly definitely directly interested in that and has been even outside of [cryptographic field] for a while.*" — P9

This demonstrates trust in organizations like MITRE, which records, reports, and publishes vulnerabilities and errors in standards, enabling proper disclosure and handling even when the standard organization is not open to feedback.

Laws and Patents Hinder Cryptography. Overall, participants had various concerns related to laws and patents regarding standards and the adoption of cryptography.

Participants addressed regulations on the export of cryptography, e.g., to foreign countries. While participants saw issues that export laws could create, this highly depended on each case. For public implementations, such as open source, export laws were reported to have changed for the better: *"[Export laws] used to be a much bigger problem. [...] for the last 20 years basically you can publish it [open source] without any problems."* (P3). However, in other scenarios export laws can be challenging, e.g., when cryptography is part of a physical product: *"Yes, crypto is still a problem for export. We really do have to think about where can it ship our products."* (P5). Fittingly, P17 outlined that cryptographic code itself is not physical and the concept of exporting does not make sense:

> *"They always talk about exporting a product, which is, I think, the idea that you have a box that was first here and that it's there and it's not here anymore, and this is just not how cryptographic code, a particular open source cryptographic code gets developed. The concept doesn't fit there.*" — P17

About half of our participants discussed the challenges of regulations within individual countries. Our participants also reported challenges for implementers when governments specify atypical cryptography that must be used. For example, a participant reported the need to support the Chinese ShangMi (SM) cipher suites in TLS [75] to comply with Chinese laws. As illustrated by some participants, regulations are seemingly politically motivated:

> *"Many countries want their own national cipher. Korea has SEED. China has SM2, 3, 4. Russia has GOST. It's almost like a point of pride. I can see, for example, why Russia and China historically would not want to use what the US agencies picked. [...] It'd be great if we were all just one big, international happy family.*" — P16

As in the case of China, such restrictive country laws can cause implementer concerns and insecurities: *"What happens if you ship something to China?"* (P5). For all the mentioned issues, a few participants stated that a legal team is needed to handle laws; some reported having access to such legal support.

Participants also mentioned a general aversion against standard-related patents. Some participants explicitly stated that they try to avoid any patented cryptography; as one fittingly summarized: *"I try to stay away from the patented [cryptography]. I try to leave a buffer zone so that even if courts are stretching the patents, I stay away from that."* (P3). Overall, about most of the participants agreed that patents are a major problem in cryptography. The most common reason given by some participants is that patented cryptography would not be widely used: *"If you patent something in cryptography, nobody will use it for about 20 years."* (P1). A few participants explicit expressed their wishes for open and free cryptography standards that are not restricted by patents. Fittingly, the participants perceived that public and open cryptographic standards have taken over and replaced proprietary ones in the past. One participant who was involved in cryptographic standardization mentioned that they purposely chose not to patent their approach: *"It was absolutely clear we wouldn't get any patent for this because what would happen? People wouldn't use it."* (P5). Additionally, a few participants reported that the legal overhead caused by patents hinders the implementation of cryptographic standards. A few participants further mentioned other issues regarding participants, such as concerns about patent law infringement liabilities, or consequences for individual open-source developers in patent lawsuits. Participants discussed a few cases where code was not publicly released by the person or company to avoid patent issues. Contrary to the challenges above, a few participants mentioned that they do not consider laws and patents at all, and a few participants stated that patents are a non-issue in academic open-source implementations:

> *"The good thing is that when you're implementing something in an academic context, you don't need to worry too much about patents. I can write code, I can put the code online, and that's okay.*" — P17

Besides the aforementioned practical issues, two participants outlined ethical concerns of patenting cryptography, as most cryptography would be developed by publicly-funded researchers:

> *"There is one thing I think I don't like when publicly funded researchers apply for patents. I think this is ethically more than questionable. [...] I think cryptography is a science of communication that requires interoperability and that requires that everyone can use these things. Patents are killers for cryptographic standards.*" — P4

Despite all critiques regarding patents, one participant mentioned that patents are the main incentive for industry contributions, but directly relativized the point by mentioning their companies' bad experiences with patents in the context of cryptographic standards.

The reservations towards patents might also be caused by accessibility issues. A few participants stated various challenges, such as finding, keeping up-to-date with, and knowing all relevant patents—or when a patent expires. Similarly, a few participants mentioned associated costs as a barrier to implementing patented cryptography. Therefore, a few participants mentioned that patents are mainly a thing that lawyers should care about: *"Actually, pretty much all people in the industry don't talk about patents. The first rule, I think that they all get told like: leave that to the lawyers."* (P17).

4.4 Suggestions for More Implementation-Friendly Standards

After discussing challenges, we asked participants for suggestions to improve future cryptographic standardization.

Preference for Public or Open-Source Approaches. Our participants mentioned the criticality and impact of openness in cryptographic standards and the standardization process. In our interviews, we identified four areas: openness in standardization, open community around standards, mistrust through lack of openness, and a rift between open, often academic, standards, and closed industry use.

First, regarding openness in standardization, almost all mentioned it as an important aspect of cryptography. Of these, most mentioned that standardization bodies should be transparent and also make standards publicly accessible. For our participants, openness begins with the standardization process. They appreciate open standardization processes and in particular named the NIST cryptography standard competitions and the general standardization process of IETF as positive and trustworthy examples, as they enable public review of standards and therefore foster trust:

> *"If there's a closed standard, I almost never look at it. I think that's not going to be something that people have done any real security review. Maybe there are ten people who looked in a room at some ISO standard, but it's not the same as a publicly written, publicly developed standard. NIST has its standards online. That's something that makes*

them much more likely for people to look at them and review them. I'll look for those." — P3

Second, when implementing standards, some actively rely on the community around open standards, e.g., public forums of standard committees, mailing lists, and the ability to contact standard authors and contributors with questions, to implement their cryptography securely. One particular advantage for large implementations is the ability to implement along released drafts and address implementation problems during the standardization process before the standard is finalized, as illustrated by one participant regarding ECH, an extension of TLS.

> *"The implementation [of ECH] started when the spec was still relatively fluid. It was changing. There's a GitHub repo with the spec where there's a bunch of issues are processed there. There are a bunch of issues that were processed during the various meetings and mailing lists. The implementation [...] started early and [there] was feedback between the implementations and the specification at that point.*" — P6

The ability to control and discuss changes before a version of the standard is finalized aligns with the problems participants reported regarding standard updates and changes (see Section 4.3).

Third, missing openness and transparency might induce mistrust. Almost all participants mentioned actively avoiding paid or inaccessible standards. As one participant put it:

> *"I hate paid standards. I hate having to pay to read research papers because sometimes you know that this is something that could be useful to your protocol or whatever you are working on, and you just can't access it. [...] If I have to pay for that, I'm going to ignore something that I might be at risk of and that's not cool.*" — P8

Furthermore, some participants gave specific examples of standardization bodies they mistrust because of lacking transparency in their standardization processes. Particular examples mentioned the International Organization for Standardization (ISO) closed committee of decision makers and the national fast track [25], that they provide for quicker standardization requests, as sources of mistrust. They also criticized more minor instances of lacking transparency, like NIST's final decision process in the selection of PQC algorithms being made behind closed doors, or IETF's tendency to make decisions in IETF meetings with missing documentation and reasoning, which can exclude people from the standardization process if they are unable to attend these meetings.

Finally, a few participants also mentioned the impact of closed environments, a rift between the open academic community working on cryptographic papers and standards, and the more closed-off industry consumers.

> *"We end up in a situation where government and academia are the creators of standards, but industry, the consumer, and there's a misalignment of incentives. I would like there to be a way to include the actual consumers of the standards in the feedback process more easily.*" — P19

Participants reported that NDAs and closed implementations can make obtaining feedback and voicing opinions in public standardization forums difficult.

Communication and Social Components. Our participants discussed the potential to improve the current state of communication within the cryptographic standard community. Some mentioned the importance of existing explanations to some extent. First, several participants requested that reasons and explanations for decisions in cryptographic standards should be provided in the standard document for both cryptographic implementers and researchers:

> *"[...] requires a rationale for all the points. In some cases, it helps implementers. In other cases, for example, the opaque standards where the authors could not explain why the standards did some of these things. Some people came back and asked: 'Why is this requirement in there?' And the standard's authors couldn't explain why [...]. It helps implementers, and in the case of some standards bodies, it helps guide them in not creating standards that have incomprehensible features.*" — P20

There were also mentions that those reasons should exist, but in a different place and not in the actual description of the cryptographic scheme:

> *"A rationale that virtually no IETF standards ever have. Because if you've got a standard and there's some ambiguous section in there and there's a rationale, you can say, okay, they meant this. Without a rationale, you have absolutely no idea. Which is why I mentioned the IEEE standards earlier: because they include a rationale, so you can see what the thinking was behind this thing.*" — P20

Interviewees had opinions about the current existing "toxic" [their wording] discourse around standards. They reported that strong social involvement is required to push cryptography. Simultaneously, this social component ensures that newcomers, less involved implementers, and small groups may be discouraged from participation:

> *"I would like to see a body that's a little bit more formal than IACR or the CFRG that represents some kind of broader consensus of academic cryptographers without a competitive nature coming to the fore. People who are good cryptographers somehow always have to have big egos as well.*" — P6

4.5 General Trends in Cryptographic Standards

Beyond the topics mentioned above, participants also mentioned several trends in cryptography. We describe them as general tendencies among our participants for reference.

Importance of Post Quantum Cryptography. PQC is currently the strongest trend in crypto. Most participants mentioned working on PQC or watching the current PQC process. This trend is likely inflated by recruiting from the NIST PQC Forum mailing list, but since that only contributed a few participants, the trend is still clearly visible.

Required Financial Aids. On the organizational side, a few participants, as part of their final "wish"-question, explicitly asked for more financing to cover issues and recommendations we have talked about throughout the interview. Examples included open standards, resolving patent and licensing issues, and formal verification. This demonstrates the need for proper financing to develop well-working standards with high adoption rates and usability, and informs the priorities of our recommendations.

5 Discussion

Below, we discuss our findings and make recommendations for future cryptographic standards.

First, we report the wishes and needs of our interviewees mentioned (see Section 4). We extract them from the results, summarize them, and illustrate their criticality.

Second, we assess how current major cryptographic standards implement those wishes and needs. Therefore, we systematically analyzed the 21 openly available cryptographic standards our participants mentioned (cf. Table 3). Additionally, they mentioned two proprietary standards, SM4 (ISO/IEC 18033-3:2010/Amd 1:2021) and IEEE 802.11. We excluded both due to significant procurement costs and our participants' rejection of proprietary standards. In a systematic analysis of each standard document and the linked references, we assessed how well the standards address the wishes and needs of our participants, as we illustrate below. Two authors analyzed all standard documents and the linked references independently, then met to resolve disagreements. Table 3 summarizes and illustrates the analysis findings.

Finally, we identify gaps between our participants' wishes and needs and the major standards, and we provide our recommendations for improving future cryptographic standards.

Reference Implementations. Our participants illustrated the criticality of reference implementations when implementing standards (cf. Section 4.2). As one participant explained: *"Reference implementations are great when they are readable, written in simple language like Python. That's super useful."* (P8). Reference implementations provide examples of implementation details that may be missing in the standard document and a starting point for implementers. Additionally, reference implementations may be formally verified. Furthermore, participants suggested documenting reference implementations better, adding more context and explanations to make implementations easier. As mentioned by our participants and in related work [16] this lack may hinder or even prevent standard adoption.

Seven of the 21 standards we analyzed provided or linked to one external reference implementation. Four included multiple reference implementations, mainly limited to modern NIST standardization efforts and WireGuard. Five provided only partial reference implementations. However, some standards lack reference implementations and only provide mathematical foundations or pseudocode. Five standards did not provide or reference any code, including older NIST standards such as SHA-2 [56] and DSA [53].

Table 3: Summary of our assessment of how well current major standards implement participant wishes and needs.

Reference Implementations Should be Mandatory. We recommend making reference implementations and their documentation part of the standard drafting phase. NIST, for example, required multiple implementations as part of its PQC and SHA-3 standardization efforts and linked to them on their accompanying website. We also recommend updating existing standards and including links to reference implementations.

Third-Party Implementations. Similar to reference implementations, our participants highlighted the criticality of third-party implementations. They confirm compatibility with the general ecosystem surrounding a standard. As one participant mentioned, implementation requirements, e.g., as realized by the IETF, help standards to gain adoption, collect public feedback, and provide an essential point of reference. Third-party implementations might be a better starting point for the industry to implement cryptographic standards than reference implementations, considering both simple reference and formally proven implementations. For example, third-party implementations might focus more on efficiency beyond functionality and correctness.

Among the 21 analyzed standards, only the three NIST standardization efforts provided third-party implementations (see Table 3). They linked to them on each of the accompanying websites that were part of the submission, including the code and contact information.

Multiple Third-Party Implementations Should be Referenced. We recommend standardization bodies to require multiple third-party implementations as part of their standardization effort. However, maintaining a list of third-party implementations inside the standard may be unsustainable. Therefore, we recommend following the example of the NIST SHA-3 and SLH-DSA standards and providing links to third-party implementations on their accompanying website.

Test Vectors. Our participants mentioned test vectors as an effective tool to ensure compliance with standards. They required test vectors to confirm the correctness of their implementations, check edge cases, and perform negative testing for mistakes. Participants reported generating them using reference or third-party implementations in case of missing test vectors.

Twelve of the standards we analyzed provided test vectors either as part of the standard or referenced in the standard document. NIST, for example, provides test vectors for many of their cryptographic primitives at one central location on their websites [51]. And TLS 1.3 includes test vectors in a separate RFC [72]. Test vectors are missing in seven other cases, including major de facto standards like the Signal protocol and WireGuard. However, the reference implementations seemed sufficient to generate high-quality test vectors.

More and Negative Test Vectors. We suggest standard documents should include a set of test vectors to help developers check functional implementation correctness. We also recommend including negative test vectors whenever applicable to better support testing for common implementation mistakes.

Formally Verified Standards. Proofs for standards also increase trust in standards, making their algorithms more likely to be adopted and errors more straightforward to identify across implementations. However, as participants confirmed, generating proofs for standards is a complex and time-consuming process; therefore, we want to encourage formal verification but argue that it should not be mandatory.

Only three of the standards we assessed provided formal verification. These are the NIST standardization efforts SHA-3, Kyber, and Sphincs+, along with TLS 1.3, which reference multiple research publications to prove their security. The remaining standards lacked formal verification.

Make the Current Verification Trend a Requirement for Future Standards. Formal verification was provided in the most recent standards we analyzed. In line with participants' wishes, we recommend continuing this trend and including proofs in standard documents, reference papers, or similar publications. We recommend considering updating highly critical existing standards to add formal verification.

Verified Implementations. Verified implementations can extend formal verification. Like the proof of security guarantees for a standard, verified implementations prove that a specific implementation complies with a standard. As our participants reported, these implementations are used to test other implementations' compatibility or to generate custom test vectors. As the code might be difficult to read, it should not be the only type of implementation.

Only two of the standards we assessed provided formally verified implementations. TLS 1.3 refers to a formally verified implementation. The WireGuard documents link to formal verification for parts of the implementations. The remaining standards do not provide formally verified implementations.

Offering Verified Implementations Can be Beneficial. While providing verified implementations takes significant effort, their benefits for implementers of cryptographic standards are high. Some participants suggested using verified implementations as a black box binding for other implementations, removing the need for custom implementations from scratch. Hence, we highly recommend verified implementations as mandatory for future standardization processes.

Supporting Developer Choices. As participants reported, many cryptographic standard documents are challenging to read and comprehend, as standards are often complex, lengthy, and not targeted towards implementers. They may encompass multiple documents and provide multiple versions, e.g., SHA-3 has six variants [57], and SSH consists of 23 RFCs, five drafts, and, depending on compatibility goals, additional OpenSSH-specific protocol extensions [62]. Identifying the critical parts for an implementation is often not straightforward and complicates the implementers' lives even further.

Hence, our participants expressed a high demand for better organization of standard documents and improved readability and comprehensibility.

Seven of the 21 standards we analyzed, mostly modern RFC standards, were well-structured and contained helpful summaries for implementers. NIST provides a quantifiable security rating from one to five in their newest standards [58], which are helpful indicators for implementers. The in-depth breakdowns of RFC contain important hints at pitfalls in security and implementation issues. Eleven standards contained some form of summary or overview to support implementation. They also described standards' strengths and weaknesses that were otherwise difficult to grasp.

> **Helpful Summaries and Security Tips are Highly Beneficial for Adoption.** Since cryptographic standards can quickly encompass a high level of complexity that implementers cannot easily deal with, we recommend cryptographic standard documents transparently communicate different versions, provide actionable hints and summaries, and illustrate strengths and weaknesses.

Provide Update Notes. For updates, participants reported difficulties maintaining legacy support. This aligns with the findings of related work [20] and demonstrates the need to consider update paths as a core property of modern standards.

In our dataset, twelve standards provided easy-to-find and explicit update notes. RFC errata and draft updates provide changes in the style of git diffs; Eight cases, however, including more significant changes like TLS 1.2 to 1.3 and changes in NIST standards, focused on updates in prose.

> **Concise Update Notes Significantly Help Implementers.** We recommend future standards to provide diff-style update notes when standard documents change. Update notes should address general update information for implementers and discuss common pitfalls.

Patent and Intellectual Property Rights Disclosure. Another common obstacle was legal uncertainty. Participants did not feel able to address country-specific laws adequately in international open-source projects. Patents or intellectual property rights (IPRs) often discouraged our participants and were negatively associated with license fees. Modern standards tend to prefer cryptography that is not weighted down by IPRs, as stated by NIST [59] and IETF [9] guidelines for standard proposals. One participant put it this way: *"in general, when somebody tries to patent cryptography, it's actually more of a deterrent than if it was just, standardized, made public and allowed broadly."* (P11).

In our analysis, 17 of 21 standards contained information on patents or IPR disclosures. We noticed that Kyber contains a patent waiver, and older standards like RSA and ECDSA had patents applied after their standardization. IETF standards provide a collection of IPR disclosures in their data tracker [28]. The IETF also requires patents to be disclosed and prefers standards not encumbered by known patents. This allows implementers to assess the patent situation around a standard quickly.

> **IPR and Patents Should be Reported Alongside Standard Documents.** We notice the trend towards open standards with no IPR rights attached and patents that apply. For IPRs in general, we advocate reporting them in one central location, e.g., as provided by the IETF data tracker.

Open Standardization Process. Our participants preferred open standardization processes such as NIST and IETF with transparent requirements, public decision-making, and involvement. Our participants say open processes contribute to more easily sustainable and trustworthy standards. Standardization processes, like for AES, were praised for their openness, and efforts like the formal verification of TLS 1.3 increased the trust in those standards. Our participants' suggestions align with the principles laid out by Hao [22].

Analyzing the 21 standards, we found eleven standards implemented open standardization processes. These include NIST competitions and IETF requests for comments and draft phases. Six de facto standards, some of which IETF and NIST later published in open form (e.g., SHA-2, MD5, ECDSA), had no initial open standardization processes.

> **Open Standards and Standardization to Create Trust.** While this is already the case for many standards, we recommend that both the standards and the standardization process should be open. This fosters trust and is a critical adoption factor. IETF and NIST have made great efforts to provide open processes, and we recommend that they be further refined.

Contact Information. Our participants illustrated the importance of contact information for standard maintainers regarding implementation details or other questions. They sometimes consult experts or standard authors to help with gaps or uncertainties in standards. Our participants also perceived contact information as beneficial for general feedback and bug reporting.

In our standard analysis, 20 provided contact information; only the more legacy SHA-2 lacked them in the document. IETF's Datatracker [28] works well in identifying responsible parties and offering contact information and the ability to disclose errata for all RFCs, even though in the case of de facto standards like OpenSSH, it may be unclear which organization between the OpenBSD project, OpenSSH authors, or the IETF, is responsible.

> **Provide Clear Contacts for Standards.** Future standards should adhere to established practices in existing standards regarding providing contact information. For example, IETF's Datatracker quickly allows finding contact information and prevents confusion about whom to contact for which purpose.

Feedback Encouragement. Our participants perceived communication with standard bodies and the community as challenging. For example, organizations ignored bug reports,

demotivating further engagement. However, participants also mentioned the presence of solid egos and the requirement of extensive subject knowledge that seems to reign within standardization processes. Champions who led the discussion emerged due to their experience and dedication to the field of cryptography. While these champions are undoubtedly essential to drive public standardization processes, especially in recognizing and arguing with stakeholders like state-level attackers attempting to weaken cryptographic standards, the strict discourse around these standards can scare newer or less dedicated contributors away.

14 of the 21 analyzed standards actively encouraged feedback from the broader community, including all IETF standards. This finding highlights the community-driven benefits of open standardization processes. However, only the PQC draft standards explicitly encouraged providing active feedback for newcomers or stakeholders outside the community.

> **Standards Community Should be More Open to Newcomers.** As a few participants explicitly stated, standardization efforts should implement encouraging processes to involve newer or smaller voices.

Bug Report Channels. Finally, participants reported issues with reported typos or other minor mistakes that standard maintainers did not take seriously, leading to participants not reporting them anymore.

In our standard analysis, only three standards—OpenSSH, Signal, and WireGuard—provided clear instructions for bug reporting and encouraged it. These standards reference their sources and their bug trackers as clear points for bug reporting.

> **Transparently Communicate Bug Reporting Instructions and Processes is Important.** We recommend transparent and open communication channels for bug reporting. They should include feedback error reports to support developers and encourage error reporting, particularly for newcomers or outsiders to cryptographic standardization processes.

6 Conclusion

In this work, we presented and discussed the findings from interviewing 20 cryptographic software developers regarding the implementation process of cryptography based on standards. We inquired about their experiences and handling of various phases of the implementation process. Overall, we find that standards can be complex and lengthy, and they sometimes lack summaries and support that implementers prefer. This includes official reference implementations, the availability of test vectors, and documentation. Furthermore, while cryptographic software is largely already openly available, we found that proprietary software or patents are often frowned upon, even by industry participants, as they raise legal issues, obscure standards, and hinder standard adoption.

Acknowledgments

We thank the cryptography community and our participants for their invaluable contributions to our work. We also thank the anonymous reviewers, especially our shepherd, for their constructive feedback and support in improving the paper. Finally, we thank our students, Daniel Kabuth and Thassilo Schiepanski, for their help with early text drafts, project scouting, and interview conception as part of our lecture. This research was funded by the Volkswagen-Stiftung Niedersächsisches Vorab – ZN3695 and the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – EXC 2092 CASA – 390781972. This work was also supported by the Grant Agency of the Czech Technical University in Prague, grant No. SGS23/211/OHK3/3T/18 funded by the MEYS of the Czech Republic.

Availability

We provide a replication package containing supplementary resources, including invite emails and the consent form, the interview guide, the anonymized final codebook, and a list of sampled open-source software projects. It is available under the following link: https://doi.org/10.17605/OSF.IO/3H95W.

A Cryptographic Standardization

Cryptographic standards describe cryptographic primitives and protocols tested and approved through a central entity, a standardization body. This approach has become increasingly important for cryptography [54, 57, 55]. Below, we give an overview of classes of cryptographic standards critical for our work and provide an overview of standardization bodies.

A.1 Cryptographic Standards

Open cryptographic standards should contain relevant implementation details, potentially different security options, the effect of these options, and, ideally, requirements for the systems implementing these cryptographic standards. For our work, we distinguish two cryptographic standards types:

Cryptographic Primitives. These describe the low-level building blocks of cryptography. We generally refer to these as the building blocks or primitives that can be used in security protocols to secure information. Examples include hash functions (e.g., the SHA-2 family [56]), key exchanges like X25519 [37], and key derivation functions like PBKDF2 [47]. We also include components or processes that describe combinations of the primitives above to provide new capabilities but still apply to the general purpose of securing information. Examples include the AES block cipher and the post-quantum-cryptography algorithm SPHINCS+ [6] presenting an approach to enable One-Time Signatures to be combined into a general purpose signature scheme that is resistant against quantum attackers.

Cryptographic Protocols. Cryptographic protocols use and combine the primitives as mentioned above to secure specific use cases and larger systems, and to prevent unintentional leaks. Standardized protocols also ensure that all participants using a protocol can securely communicate with each other, independent of the concrete implementation a participant uses. Examples include TLS, used to secure TCP connections or the Web Authentication (WebAuthn) and FIDO APIs/protocols enabling passwordless authentication via browser. Our definition of cryptographic protocols also includes many *de facto* standards introduced by popular and widely available software without an explicit standardization body beyond the software developers. Prominent examples of these de facto standards include OpenSSH as a secure remote shell protocol, WireGuard [13] as a secure virtual networking layer, and the Signal protocol [69] for end-to-end encrypted messaging.

A.2 Standardization Bodies

One particularly well-known standard body for cryptography is NIST. They introduce Federal Information Processing Standards (FIPS), which are a collection of public standards that NIST developed for computer systems of (non-military) U.S. government agencies and their contractors. For example, FIPS standardizes the Advanced Encryption Standard (AES) in FIPS 197 [54] and the Digital Signature Standard (DSS) including Rivest-Shamir-Adleman cryptosystem (RSA), Elliptic Curve Digital Signature Algorithm (ECDSA), and recently Edwards-curve Digital Signature Algorithm (EdDSA) in FIPS 186 [53].

Next is the IETF, proposing RFC as their version of standards. The goal of the IETF, according to RFC 3935 [3], is to provide protocol standards, best practices and other information intended to influence how people design, use and manage the internet. RFCs are formally published by the so-called *RFC Editor* after a public review process. Anyone with sufficient experience can contribute to and support internet standards created by the IETF within their defined processes [14], making this standardization body and its processes open and accessible. Examples for internet standards provided by the IETF are TLS in RFC 6353 [23] and proposed standards like the ssh authentication protocol [43].

For the modern Internet, the most important standard body is the World Wide Web Consortium (W3C), responsible for the standards surrounding HTML.[6] Finally, there are standard bodies like the ISO,[7] the American National Standards Institute (ANSI),[8] and the International Telecommunication Union (ITU) offering industry standards in the larger context of IT and other aspects of cooperation worldwide.

A.3 Standardization Process

There are various processes to standardize cryptographic primitives and protocols. While creating a standard document has been unified for each organization, deciding what to standardize has changed a lot recently.

Public Standardization Effort. This first approach was recently adopted by NIST for their PQC effort, SHA-3, and AES [52]. They post public requirements for a new standard. Then everyone can propose cryptographic primitives and protocols, out of which a few winners are chosen by a panel of experts. Then public feedback for that selection is collected in multiple rounds until a final standard can be drafted.

Public Comments on Standards. Here, standards are more publicly decided on mailing lists and in public meetings. The organization and contributors work on drafts of an open standard as part of so-called *Request for Comments (RFCs)* until it reaches maturity, often starting with a suggested algorithm. This is the common approach of IETF and W3C.

De Facto Standards. For this third approach, a protocol is proposed and used often enough by industry or academia to become a standard, a de facto standard. It addresses a gap in existing standardization and becomes so successful that one of the organization bodies later translates it into a conventional standard. Examples of this are the Ed25519 primitive that has been added to FIPS in 2023 [53], after being known and used [62, 65] for multiple years. Other examples are the OpenSSH and OpenPGP standards, standardized by the IETF as part of open implementations of de facto standard proprietary software [63, 67].

Standard Through Organization. Finally, there is the conventional process used by ISO, ANSI, and, in earlier years, by NIST, where a private panel of experts selected by the organization works on and later publishes a standard. Backdoors and attacks on such standards have caused a need for publicly evaluated and verified cryptography and communication standards. Because of this, even originally closed standards with a large adoption in modern cryptography, like X.509 for certificates, have obtained open variants [7]. This closed approach is also used by some government agencies for government mandated cryptography, e.g., GOST and Seed that are then published as informational RFCs, outside the IETF's typical standard efforts [26], and usually produce de facto standards with geographically restricted use.

A Mixed-Methods Study on User Experiences and Challenges of Recovery Codes for an End-to-End Encrypted Service

Abstract

Recovery codes are a popular backup mechanism for online services to aid users who lost their passwords or two-factor authentication tokens in regaining access to their accounts or encrypted data. Especially for end-to-end encrypted services, recovery codes are a critical feature, as the service itself cannot access the encrypted user data and help users regain access. The way end-users manage recovery codes is not well understood. Hence, we investigate end-user perceptions and management strategies of recovery codes. Therefore, we survey users of an end-to-end encrypted email service provider, deploying recovery codes for accounts and encrypted data recovery in case of authentication credential loss. We performed an online survey with 281 users. In a second study, we analyzed 196 support requests on Reddit. Most of our participants stored the service provider's recovery code. We could identify six strategies for saving it, with using a password manager being the most widespread. Participants were generally satisfied with the service provider's recovery code. However, while they appreciated its security, its usability was lacking. We found obstacles, such as losing access to the recovery code or non-functioning recovery codes and security misconceptions. These often resulted from users not understanding the underlying security implications, e.g., that the support cannot access or restore their unencrypted data.

1 Introduction

Online accounts are commonly protected with authentication mechanisms using passwords and two-factor authentication. To protect user data further from unauthorized access by the service provider or other third parties, some apps and online services encrypt user data or use end-to-end encryption for communication purposes. Encryption keys are often derived based on users' passwords [1]–[5] using some form of password-based key derivation [6]–[9].

While deploying cryptography to restrict access to user data, most services also aim to support users who have forgotten or lost their login credentials in recovering their accounts or access to encrypted data. Otherwise, users may be locked out of their accounts and data permanently. Recovery codes can act as a feasible and secure fallback key for these services. They are most widespread as two-factor authentication (2FA) fallback [10], [11], but they can also function as recovery feature to access encrypted accounts in case of password loss [1], [12]–[14]. While a variety of other popular account recovery schemes exist, e.g., email recovery, SMS recovery, or security questions, all of them are not only susceptible to attacks [15]–[18] but also require the service provider to be able to access the account data. These measures are not feasible for service providers that encrypt the user data without having a backup key. However, for services deploying recovery codes, users must store their recovery codes securely as they hold significant value to potential attackers, bypassing the standard authentication process and granting access to user accounts. Recent reports highlight the significance of recovery codes, as evidenced by the activities of thieves who intentionally focus on iPhone users. Their objective involves tampering with the stolen devices to establish or modify the 28-character recovery codes, ultimately enabling unauthorized access to the victim's Apple ID account [19].

Since the management of recovery codes has not been studied in the past, in this work, we conduct a mixed-method study to investigate end users' awareness and management of their recovery codes and the challenges they face. We cooperate with an end-to-end encrypted email service that utilizes recovery codes as the only account and encrypted data recovery option. The email service deploys recovery codes for both 2FA and password loss. We survey users of the email service regarding their experiences and approaches to managing their recovery codes. We further qualitatively analyze support requests on Reddit from users of the email service regarding account and encrypted data recovery to identify misconceptions and challenges regarding the recovery code.

In the course of this work we address the following research questions:

RQ1 *"Are users aware of the existence and importance of recovery codes?"* Recovery codes often are an essential, if not

the only, way of retaking an account after the compromise or loss of the primary authentication method. End-users should be aware of their existence and important nature. We are interested in whether users know the impact of losing their recovery codes for recovering their encrypted user data.

RQ2 *"What strategies for handling recovery codes do users deploy?"* Due to their criticality, end-users should handle recovery codes with diligent care. We investigate how users approach account recovery and store and manage their recovery codes. We discuss confidentiality, integrity, and availability of the strategies we identified.

RQ3 *"What obstacles do users face when using recovery codes?"* The storage and management of recovery codes are not necessarily hassle-free. We explore which obstacles and misconceptions users face regarding their recovery code.

2 Background

In this section, we will explain methods commonly used for account recovery, as well as introduce our email provider and its implementation of recovery codes.

2.1 Recovery schemes

If users forget their passwords or lose their devices, recovery schemes help them to regain access to their accounts or encrypted data. It helps them to recover their accounts, cryptographic secret keys, or cryptocurrencies. The security model of a specific application or service limits the possible recovery schemes. For example, a trusted third party, e.g., the service providers themselves, can support users to recover their objectives and give them access to their accounts.

There are different principles for designing recovery schemes:

1. Special registration/access: The user and (trusted) service provider can establish a secure recovery channel in advance. For example, the user can register a recovery email address, a phone number or trusted device. If users lose access to their account, they can convince the service provider or administrator about the account's ownership by replying to a phone call, SMS, or email. For example, social media account providers often use this scheme [20]–[22]. If users register a trusted device, they can regain access to an account by having access to the device, e.g. a smartphone.

2. Secret knowledge: The user and service provider can share a secret in advance, e.g., a password/code or security questions.

3. Ad-hoc schemes: In case of no preparation, more informal and ad-hoc recovery schemes are possible. For instance, users can verify their identity using their official ID card or contact the service provider.

The security model of end-to-end encryption excludes a trusted third party having access to users' (plain) secret keys and thus restricts possible recovery options. Without a trusted third party, users can only recover secrets based on another secret known by them. Therefore, users have to back up their secret keys themselves.

2.2 Our Partner

We cooperated with Tuta, an email provider that provides end-to-end encryption for their email users. In addition to password-based authentication, users can add a second factor for authentication. The security model of Tuta is similar to end-to-end encryption, as they exclude themself as a trusted third party. Therefore, the users' mailboxes are encrypted on their servers, and the service provider cannot access the (plain) decryption keys. On account creation, users create a public key pair on their device (or in their browsers). The account password does not only enable the login but protects the private key on the server. As our email provider does not know the password, the dual use of the user's password limits the possible recovery schemes.

Therefore, the recovery scheme of Tuta is a recovery code. The recovery code is a locally generated string with 16 words, each of 4 characters. It is shown to users during account registration, and they are prompted to store it securely, e.g., on a sheet of paper. The recovery code dialog is shown in Figure 1. It is a typical key recovery scheme used in other end-to-end encryption applications, e.g., password managers like NordPass and Dashlane [12], [13], or messengers like Keybase [23]. Users of Tuta need either one out of two factors (password or recovery code) if they do not use 2FA or two out of three factors (password, 2FA, or recovery code), with 2FA activated, to recover their accounts and their secret keys.

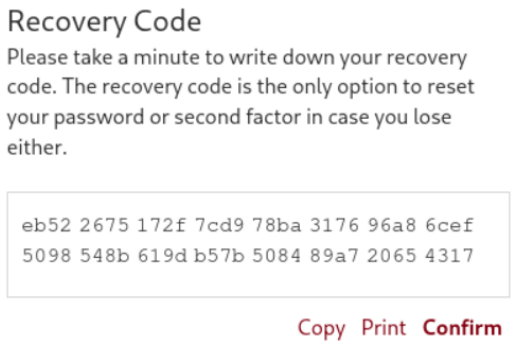

Figure 1: The recovery code pop-up shown to Tuta users. The pop-up illustrates the purpose and criticality of the code and encourages users to store the code.

3 Related Work

In this section, we discuss related work regarding account recovery methods and recovery research with a special focus on the usability of account recovery.

In 2006, Brainard *et al.* introduced and designed a new recovery method, in which a pre-chosen helper can generate a temporary passcode via a hardware token, and discussed the security of their approach [24]. In a similar vein, Schechter *et al.* presented an account recovery method, in which account recovery codes are gained from trusted individuals appointed beforehand. They found that users often forgot which confidants they chose [25]. Rabkin examined the backup authentication mechanism of banking sites. They found that personal security questions were often utilized and illuminated usability and security weaknesses [26]. In 2015, Bonneau *et al.* analyzed Google data on personal knowledge questions for backup authentication and found that their security is lacking [18]. Through a survey and interviews, Hang *et al.* examined backup authentication methods for smartphones. They found that although most users were satisfied with their backup methods, some users had difficulty recovering their phone [27]. In 2016, Stavova *et al.* conducted an experiment to analyze two account recovery mechanisms for usability, backup codes, and trusted people. Most of the participants found backup codes to be easier but regarded the trusted people approach as more secure [28]. Parkin *et al.* analyzed university helpdesk log data of password resets and conducted succeeding interviews. They found that many participants found the password policies to be too restrictive [29].

Through a survey, Huh *et al.* researched the impact of a password reset email from LinkedIn, sent after experiencing a data breach. They found that less than half of the participants reset their password, and many only did so long after receiving the email [30]. In 2019, Maqbali *et al.* presented a model for password recovery processes, evaluated existing recovery approaches, and gave recommendations for improving them [31]. Neil *et al.* analyzed account remediation advice from 57 websites and found that advice was often incomplete. Popular websites or those that previously experienced a data breach generally performed better [32]. In 2023, several works covered recovery of 2FA. Ghorbani Lyastani *et al.* investigated uniformity of multi-factor authentication (MFA) implementations, they found that the setup of a recovery option was seldom enforced. The recovery option most often provided was one-time recovery codes [33]. Gerlitz *et al.* went through the 2FA account recovery processes of 78 services. They found a vast heterogeneity of practices with respect to implementing 2FA and processes for recovering from loss [10]. Amft *et al.* also investigated MFA deployment of recovery methods. They found recovery codes and contacting the support the most mentioned methods for MFA recovery [11].

In addition, there is also work on different attack vectors for account recovery. In 2014, Javed *et al.* presented a new attack method against a social authentication method "Trusted Friends" as implemented by Facebook [34]. Guri *et al.* discussed information disclosure of private data during account recovery attempts on popular websites and resulting attack vectors [35]. Gelernter *et al.* described a new password reset man-in-the-middle attack. They checked password reset functions of popular sides against it and found many to be vulnerable [36]. In 2018, Li *et al.* investigated employed recovery methods and found that most websites use email as a recovery method. They further assessed possible email recovery attack scenarios and found most websites vulnerable [15].

While there are many studies regarding account recovery, only a few investigate the actual deployment and usage in companies or on websites. We close this research gap, by presenting insights about a recovery method deployed by an actual email provider. Our work focuses on a specific implementation of a recovery code as the only fallback method for an encrypted service. We take a mixed-method approach towards users' handling and their view on recovery codes.

4 Methodology

Below, we describe our methodology for the survey with users of Tuta and the qualitative analysis of Reddit threads regarding account recovery. We also detail the coding process and analysis of the qualitative and quantitative data before discussing ethics and the limitations inherent to our research approaches.

4.1 Online Survey with Users

To investigate our first two research questions, we conducted an online survey with (n = 281) Tuta users. In this section, we detail the study procedure and structure of the survey we conducted.

4.1.1 Survey Procedure

We created the questionnaire according to our research questions and pre-tested the questionnaire with team members and personal contacts in cognitive interviews [37]. While going through the questionnaire with them, we focused on possible (mis)interpretations of questions, biases, phrasing, and given response choices. We iteratively revised, reordered, and rewrote questions after each of the conducted cognitive interviews (n = 14).

Having converged on a satisfactory version of the questionnaire, we then shared it as an addendum to a monthly newsletter of Tuta that is sent to each user in the form of an email. We only required that participants had received the newsletter, meaning that they were a user of Tuta in some capacity, that they were at least age 18, and that they were comfortable using English. The survey was created and shared

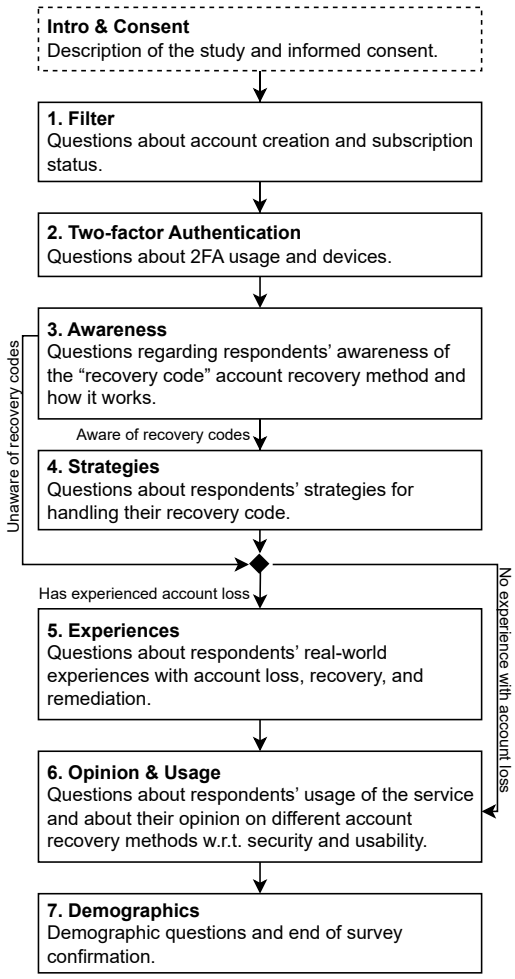

Figure 2: Overview of the survey flow and topics. The survey consisted of seven topics covering awareness of recovery codes, storage and management strategies, experiences with recovery codes, opinions and account usage, and demographic information.

in the November 2022 newsletter, and data collection was continued through February 2023.

4.1.2 Survey Structure

The survey included eight sections in total and was presented to all participants in the same order. Some questions or entire sections were skipped according to the answers given so as to not confuse participants or collect subpar data, as shown in Figure 2. The survey was delivered exclusively in English, although a few participants chose to answer free text questions in German.

1. Filter This section contains two general questions about account creation for Tuta and whether the participants have a paid Tuta subscription to display additional answer options later and to better contextualize written responses to free text questions.

2. Two-factor Authentication. This section explores our participants' 2FA usage, i. e., whether they have two-factor authentication enabled for Tuta and what method they use.

3. Awareness This section intends to gain insights into participants' awareness of Tuta's recovery method using recovery codes. Specifically, the first question asks how they would approach recovering their account if they lost their password. The second question asks a similar question regarding losing their second factor if they previously indicated using 2FA for Tuta. We then ask them whether they feel well informed about Tuta's recovery method and whether they know what a recovery code is used for. If they indicate that they know about recovery codes, they are shown some more questions about their understanding of their functionality.

4. Strategies In this section, we ask participants about their strategies for dealing with their recovery code. Being one of the central questions that motivated this survey, this open-ended question asks them to elaborate on their reasons for proceeding in such a way.

Secondly, we are interested in how long it would take them to access their recovery code in an everyday situation given their chosen strategy.

5. Experiences This section goes into participants' experiences with actual Tuta account loss and subsequent recovery. We are interested in how many participants had already used the recovery method, whether they were successful, and if not, whether they had lost data and how they dealt with losing access.

6. Opinion & Usage After a brief high-level explanation of how Tuta's recovery method works, we ask participants how they would judge the privacy-accessibility trade-off of the method. We then ask whether they have heard about or used six different recovery methods that are used by various services with varying incidences. In an optional step, participants are asked to order the methods they have heard about in terms of security and usability. We are also interested in whether they are satisfied with Tuta's current recovery method and whether they would like to see others implemented. Lastly, we ask how frequently participants use Tuta, their main use cases, the amount of critical data they store in Tuta, and who they think has access to their unencrypted inbox.

7. Demographics This last section contains demographic questions and finally the option to submit one's answers.

4.1.3 Coding and Data Analysis

Our survey was started by 333 participants, from which 281 completed it. As we did not find any inconsistencies in the data, we consider all 281 answers valid. We analyzed all open-ended questions using an iterative open coding approach [38]–[40]. For each open-ended question, a pair of two researchers independently coded all responses. They then talked about

each answer, compared codings, discussed the assigned codes, and arrived at a final set of codes. Three researchers were involved in the whole coding process. As the discussions, in which all disagreements for the dataset were resolved, were crucial for forming our results, we refrained from reporting an intercoder agreement [41]. We then established one codebook for each question by listing all the assigned codes, adding a description to each, and lastly merging codes that we deemed similar enough. The codebooks were then used for grouping results and for reporting in Section 5.1.

When reporting percentages in the results sections, we normalized through all participants who saw the respective question. Regarding the two questions where participants ranked the recovery methods, we normalized the data by min-max normalization, as participants were only shown the methods they knew. Thus, each participant ranked a different quantity of methods.

4.2 Recovery Support Discussions on Reddit

To get deeper insights into the challenges and misconceptions related to recovery codes, we conducted a qualitative analysis of related online discussions in the Tuta's support forum on Reddit. We choose Reddit threads, as analyzing users' support requests directly would break data protection policies, especially as it is not transparent which of those users consented to data collection. Tuta only offers customer support for paid users, therefore, the subreddit is a valuable alternative for free users to ask questions.

We gathered all posts in the subreddit that were returned searching for the term "recovery" in April 2022. This was done using Reddit's official API[1] via the PRAW library[2]. The search resulted in a dataset of 233 posts in total that potentially pertained to account recovery.

In a first pass, teams of two researchers assessed the relevance of each post, meaning that they are connected to Tuta's account recovery. All posts that were deemed relevant were then coded in an iterative open coding approach [38]–[40]. Our analysis referred to the main posts and any remarks from the thread owners in the comment sections. Each Reddit post was coded by two researchers. Conflicts were resolved in a subsequent step by discussing and merging, removing, or adding codes for new themes. A total of three researchers were involved in the coding. As for the survey, we did not calculate an intercoder agreement, as it could not reflect on the crucial team discussions and iterations.

4.3 Ethics

Both experiments were designed in due consideration of the ethical principles of the Menlo report [42] and approved by the ethical review board of our institution. We further adhered to the EU's General Data Protection Regulation (GDPR). For the survey, we made sure that participants were aware of the contents, the purpose, and the risks of participating in the study before choosing whether they wanted to participate. Therefore, we obtained informed consent from each participant by having them fill out a mandatory form confirming that they were at least 18 years old, comfortable participating using English, that they had no unanswered questions regarding the study, and that they were aware that they may stop participating and/or revoke the given consent at any time. In order not to annoy users by sending out unsolicited invitations to the survey via direct email or other channels, we chose to attach a summary and a link to the survey to Tuta's newsletter to reach a large number of active users. We did not offer our participants any compensation and advertised an estimated survey completion time of 10 to 20 minutes.

4.4 Limitations

For each of our mixed-methods approaches, different limitations apply. The survey may suffer from several biases typical for this sort of online study, such as self-reporting bias, over- and underreporting, sampling bias, and, to a lesser extent since responses are anonymous, social-desirability bias. Our sample further consists of active users of one privacy-centered email provider, which is not representative of email users or privacy-conscious users in general. Security- and privacy-interested users were likely more inclined to participate in our survey, which means that our results should be seen as an upper bound for the reported awareness numbers and as a lower bound for the reported, e.g., account recovery experience numbers. We did not compensate our participants for taking part in the survey, as Tuta is committed to its users' anonymity, but the legal framework of our university does not allow us to compensate participants anonymously.

The analysis of Reddit threads might include mostly free users, as paid users enjoy priority email support and could ask or voice their frustrations there. Regarding account recovery, however, there is no difference in the process, except that paid users have the option to prove past payments via receipts to transfer their email alias to a new account.

5 Results

In this section, we report on our survey results with 281 Tuta users and our analysis of 196 Reddit threads regarding account recovery.

5.1 Online Survey with Users

We conducted a survey with Tuta users aimed to investigate the handling and utilization of recovery codes, as well as uncover obstacles and opinions. Our 281 participants completed the survey in 13.0 minutes (median time). As participants

Table 1: Demographics for all 281 valid participants from the survey study with Tuta users.

Demographics	Value	Percent
Gender:		
Man	211	75.1%
Woman	37	13.2%
Genderqueer	8	2.8%
Age:		
18-24 Years	40	14.2%
25-34 Years	83	29.5%
35-44 Years	51	18.1%
45-54 Years	46	16.4%
55-64 Years	24	8.5%
64 and Older	21	7.5%
Education:		
Bachelor Degree	89	31.7%
Master Degree	80	28.5%
Secondary School	33	11.7%
Trade/Technical/Vocational	19	6.8%
Associate Degree	7	2.5%
Professional/Doctoral Degree	27	9.6%
Other	9	3.2%
Employment:		
Employed Full-Time	126	44.8%
Employed Part-Time	12	4.3%
Self-Employed/Freelancer	37	13.2%
Out of Work	21	7.5%
Student	35	12.5%
Retired	20	7.1%
Other	11	3.9%

were given the option to not answer questions, not all results will sum up to 281 answers.

Demographics Many of our participants were rather young and identified mostly as male. As shown in the demographics in Table 1, most of our participants had a bachelor's degree (89, 31.7%), master's degree (80, 28.5%), or completed secondary school (33, 11.7%).

While most (137, 48.8%) of our participants used Tuta for up to four years, 90 participants (32 %) stated to use Tuta for up to one year and are, thus, relatively new to the email provider. Further, 46 participants (16.4%) stated using Tuta since more than four years. Regarding payment, 201 participants (71.5%) paid for their account, while 77 participants (27.4%) used a free account. Most of our participants were regular users, as 175 participants (62.3%) stated to use Tuta daily, followed by 52 (18.5%) who used the email provider four to six times a week. The use of 2FA was relatively balanced, as 142 participants (50.5%) opted for having 2FA and 127 (45.2%) stated to not have 2FA (seven participants were unsure).

Regarding their main usage of Tuta, 189 participants (67.3%) used it for everyday communication. Second most frequently selected, by 131 participants (46.6%), was signing into sensitive services. Explicitly receiving or sending confidential documents was specified by 115 (40.9%) and 111 participants (39.5%) respectively. Other reasons were less prevalent, like using the service for work (69, 24.6%).

An extended demographic table and a full list of what critical data participants reported to store in their accounts can be found in Appendix Table 3 and Table 4.

> Demographics.
>
> - We surveyed 281 users of the end-to-end encrypted mail service Tuta.
> - Most participants used Tuta several times a week.
> - Our participants used Tuta for every day communication, but also for sensitive data or signing into sensitive services.

Recovery Code Awareness. To investigate the awareness of our participants regarding the recovery code, we first asked open or general questions regarding account recovery without mentioning the recovery code explicitly. Most of our participants felt at least moderately well-informed about account recovery by Tuta, with 118 (42%) feeling very well-informed. Only 34 (12.1%) felt not well-informed at all.

Asked how they were informed, most participants (122, 43.4%) stated that it was during signup, 80 (28.5%) read it in the website's FAQ, and 74 (26.3%) while they set up 2FA. Further information channels, e.g., blog posts, or social media, were each selected by at most 20 participants. Some participants (43,15.3%) were not sure how they were informed or felt that they were not informed at all (25, 8.9%).

Asked how they would recover from a password loss, 139 (49.5%) stated that they would use the recovery code. Moreover, 40 participants (14.2%) stated that they would use a password manager, either indicating that a password loss was unlikely or that the password was backed up there. Twelve participants (4.3%) mentioned password backups outside a password manager, e.g., writing it down offline. To that end, 23 (8.2%) felt very confident that they could not lose their password. Measures only taken after the loss of the password were also mentioned. Some participants (27, 9.6%) hoped that the support could help them. Clicking on the "forgot password" interface was mentioned by twelve participants (4.3%) and searching for website instructions by eight (2.8%). Two participants (0.7%) talked about security questions and 14 participants (5.0%) about backup emails. Interestingly, the latter two options are not available for Tuta. Ten participants (3.6%) stated that they never checked or thought about this scenario, and nine participants (3.2%) stated that there would be no recovery. All answers are visualized in Figure 3.

A similar picture emerged when we asked the 142 participants using 2FA for Tuta about their account recovery procedure when losing their 2FA mechanism. Of these participants, 80 (56.3%) mentioned recovery codes. Backup of the 2FA app, hardware device or secret key was mentioned by 26 participants (18.3%), while 19 participants (13.4%) stated that they would contact the support. Five participants (3.5%) were unaware on how to recover their account.

Subsequently, we explicitly asked participants about the recovery code and whether they are aware of its usage. This

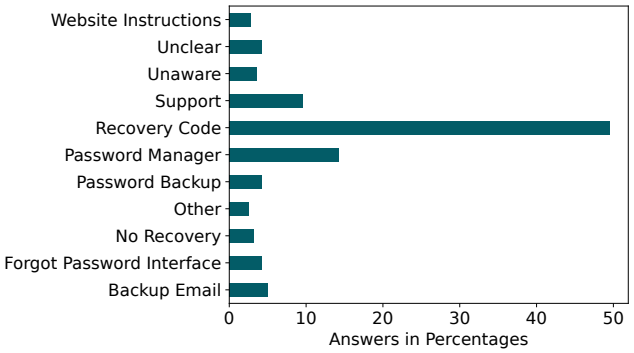

Figure 3: Self-reported strategies of our participants for recovering their account and encrypted data in case of password loss. Not all strategies are applicable for Tuta. They illustrate misconceptions of Tuta users regarding the purpose and the capabilities of the recovery code.

question was answered in the affirmative by 229 participants (81.5%). Further, 26 participants (9.3%) were not sure or denied. We excluded these participants for further questions directly targeted at the recovery code. To investigate participants' comprehension of the importance of the recovery code, we asked whether they believed that Tuta's support team would be able to help with recovery if users lose both password and recovery code. The majority (148, 64.6%) did not believe that the support could help, but 51 (22.3%) were not sure, and 29 participants (12.7%) believed so. All participants who answered the question in the affirmative were asked what they thought could be recovered by the service. Half of those participants (15, 51.7%) selected the ability to use the account's email address, which is at least correct for paying customers that can prove their account ownership. Indeed, eleven of these participants were paying users. However, restoring the mailbox content was selected nine (31.0%) times, restoring list of contacts seven (24.1%) times, and calendar events six (20.7%) times. All of which is not possible. Nine participants (31.0%) were not sure about the question and two (6.9%) stated that none of the above options could be recovered.

To inquire the 281 participants about their threat model and comprehension of the end-to-end encrypted service, we asked who they thought had access to their unencrypted inbox and got diverse answers. While 123 (43.8%) selected that only they have access, 155 (55.2%) believed other institutions or people to have access. Most (65, 23.1%) participants selected law enforcement or intelligence agencies, followed by 55 (19.6%) selecting Tuta, indicating that they do not fully understand the cryptographic implications for Tuta. Only seven (2.5%) selected family or friends, which might be legitimate access, if the password is passed onto them.

Recovery Code Awareness.

- Most participants felt well-informed about account recovery and are aware of the recovery code.
- Participants most often stated to use the recovery code or a password manager in case of password loss, but some also mentioned measures only taken after password loss, e.g. hoping that the support can help.
- About half of our participants believed other authorities to have access to their unencrypted inbox.

Recovery Code Management. The biggest obstacle to using a recovery code is its secure storage without losing it. Therefore, we asked all 229 participants who knew about the recovery code how they handled and stored it after signing up. In 78 cases (34.1%), participants stated that they saved the recovery codes in a password manager. Further digital storage options were saving the recovery code in a file or as PDF (29, 12.7%), including screenshots and photos, or uploading it to a cloud or online storage (9, 3.9%). Further, 19 participants (8.3%) saved the recovery code on other hardware or devices, e.g., a second computer, their server, or a USB stick. Participants also stored the code offline, as 32 (14.0%) wrote it down and 25 (10.9%) printed the recovery code. Only 34 participants (14.8%) mentioned that they saved the recovery code in at least two different locations or utilized more than one strategy, e.g., saving it offline and putting it in a password manager. Seven participants (3.1%) did not write the recovery code down or could not remember anymore. The frequency of all strategies is shown in Figure 4. We could not uncover a strategy for 35 participants (15.3%), as they stated that they copied or saved their recovery code, but were unspecific about the location, e.g., participants often only mentioned a "safe place".

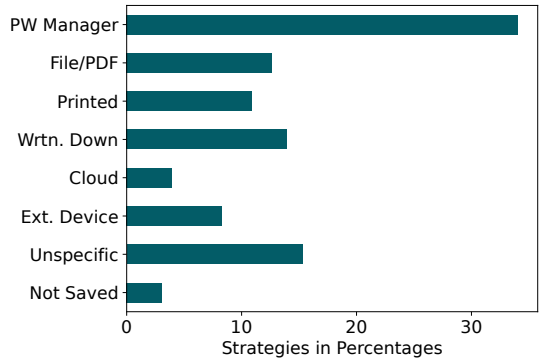

Figure 4: Self-reported strategies of our participants for storing and managing recovery codes for their Tuta accounts. Some participants (34) reported having a backup of the recovery code or using multiple strategies.

Some participants further elaborated on their storage, as 34 participants (14.8%) emphasized that the digital storage location would be encrypted. In the same vein, seven participants (3.1%) tried to somehow obscure the nature of the recovery code, e.g., storing the note of the recovery code without any context, so that a stranger could not recognize its use.

Asking the 229 participants about the time required for

reaching their recover code if needed, most participants (103, 45.0%) stated that they could access their recovery code immediately. Whereas, 64 participants (27.9%) would need up to ten minutes, 19 (8.3%) up to an hour, and eight participants (3.5%) up to five hours. Up to a day or longer was only selected by 19 participants (8.3 %). The distribution of time to access the recovery code across the strategies we uncovered is shown in Figure 5.

Interestingly, when asked if they knew how they could view or regenerate their recovery code in their account, only 145 (63.3%) answered in the affirmative, 84 (36.7%) were not sure or unaware. We consider the latter numbers a great proportion for such a crucial function, possibly indicating that some users only interact superficially with the recovery code.

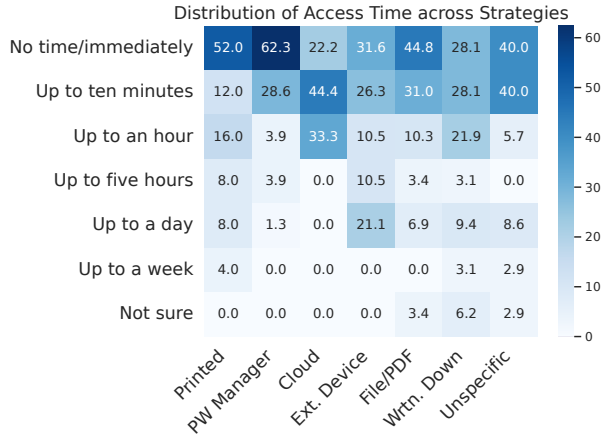

Figure 5: Distribution of time to access the recovery codes based on self-reported data for the six recovery code management strategies we identified. Each row is normalized for all participants who reported a specific strategy. Printing recovery codes on paper or storing them in a password manager provided the fastest accessibility for most participants.

> Recovery Code Management.
>
> - We identified six recovery code management strategies. The most prominent strategy was to store the recovery code in a password manager.
> - Most participants stated that they could access the recovery code immediately or in a very short time.
> - Only 145 of 229 participants knew how to view or regenerate the recovery code in their account.

Recovery Experiences. Most of our participants had not yet tried to recover their Tuta account. Only 29 (10.3%) answered this question in the affirmative. To recover their accounts, 15 of them used a recovery code. Three participants eventually found their password or had it backed up, e.g., in a password manager. One participant reached out to the support, due to being mislabeled as a spammer. Another participant lost their account as they had not accessed their free account for over six months. We could not identify a strategy for three participants. Asked whether their recovery attempt was successful, 20 answered in the affirmative, while seven lost their account, of which two have stated to have entered the recovery code unsuccessfully. One participant was not sure. Two of the participants that lost access regarded the data that was lost as sensible or valuable, three did not, and two were not sure. The emotions from the seven participants without successful account recovery were diverse. One participant stated that they "*Didn't stress over it*" (p232), while other participants, were more frustrated. Two participants elaborated on the problem of being hacked, with no means of getting the account back.

> "*[It] made me realise how dangerous [the] recovery system is, if [the] account gets compromised. No chance of recovery then! End of the Road!*" - p332

We asked all participants who tried to recover their account in the past, successfully or not, whether they changed their strategy. About half of the participants stated that their strategy remained the same. Five participants made sure to back up their password (e.g., in a password manager) or note down their recovery code. Two participants stated that they would be even more attentive. Measures only taken by single participants were the use of their own domain, regular logins, and even the reuse of the password to better remember it. One participant mentioned that they would now rely on another email provider. Participants were also affected in their opinion on Tuta. One participant who could recover their account mentioned that it "*built [their] confidence in [Tuta] and [it was] why [they] eventually switched from free to a subscription*" (p147). Another participant who could not recover their account felt the opposite: "*I don't trust [Tuta] anymore - I only think of it as an ephemeral account that may disappear at any moment.*" (p218)

> Recovery Experiences.
>
> - 29 participants tried to recover their Tuta account, 20 were successful.
> - About half of the 29 participants stated that their strategy changed after the recovery attempt, e.g., they made sure to backup their password.

Opinions on Recovery. We were not only interested in the participant's handling of their recovery code but also in their opinion about it in comparison with other recovery methods. The majority of the 281 participants (198, 70.5%) were satisfied with Tuta's recovery option, 50 participants (17.8%) were neither dissatisfied nor satisfied, and only 16 (5.7%) were dissatisfied. Asked to judge the trade-off made by Tuta's recovery code between privacy and possibly irrevocable access loss, most (185, 65.8%) participants tended to find privacy (considerably) more important to them. Only 33 participants (11.7%) tended to find account access more important and 58 (20.6%) found both equally important. While most participants found privacy more important, nevertheless the consequences of account loss were rated severe by 194 (69%) participants. Only 37 (13.2%) believed them to be minor to none.

To understand the sentiments regarding the recovery code in contrast to other methods, we gave participants a list of recovery methods and asked them to select all of which they have heard of and subsequently to select all that they have used before. In general, participants most often utilized email recovery (232, 82.6%), followed by 195 participants (69.4%) using security questions and 158 (56.2%) using SMS recovery. Critically, previous research has shown that these three methods are all vulnerable [15], [18], [43]. Recovery codes were selected by 154 (54.8%)[3]. The answers are visualized in Appendix Figure 8.

In a follow-up question, we showed all recovery methods that the participant had heard of before and let them order these regarding security. Most participants regarded the recovery code as secure and sorted it into first or second place, as depicted in Figure 6. Only very few participants thought of it as a less secure method. For other methods, participants' voting was diverse, but trusted devices and personal identification also showed a tendency to be regarded as secure. Security questions, email recovery, and SMS recovery were most often considered insecure, but could also be found at the top of the list a few times. When asked to sort these recovery methods for usability, recovery codes did not perform nearly as well. While some participants considered it somewhat usable, others regarded its usability as even less favorable. On the contrary, email recovery followed by trusted devices was regarded as the most usable.

Finding other options more usable, it is not surprising that participants wished for alternatives. Their answers regarding preferences of other recovery methods implemented by Tuta were diverse, as shown in Figure 7. While 66 participants (23.5%) did not want a mechanism other than the recovery code and 14 (5.0%) preferred no recovery at all, preferences by other participants were versatile, with 153 participants (54.4%) wishing for another or additional feature. Most commonly selected were trusted devices by 57 participants (20.3%), email recovery by 49 (17.4%) and security questions by 45 (16.0%). Additionally, participants wished for SMS recovery (35, 12.5%) and personal identification (31, 11.0%).

> Opinions on Recovery.
>
> - Most participants were satisfied with the recovery code.
> - Participants generally rated the recovery code as secure, but not as usable as other methods.
> - About half of our participants wished for alternative recovery options like trusted devices, email recovery, or security questions.

[3] As more participants stated saving their Tuta recovery code in an earlier question than answered in this question to use recovery codes, we assume that participants selected their recovery methods apart from Tuta.

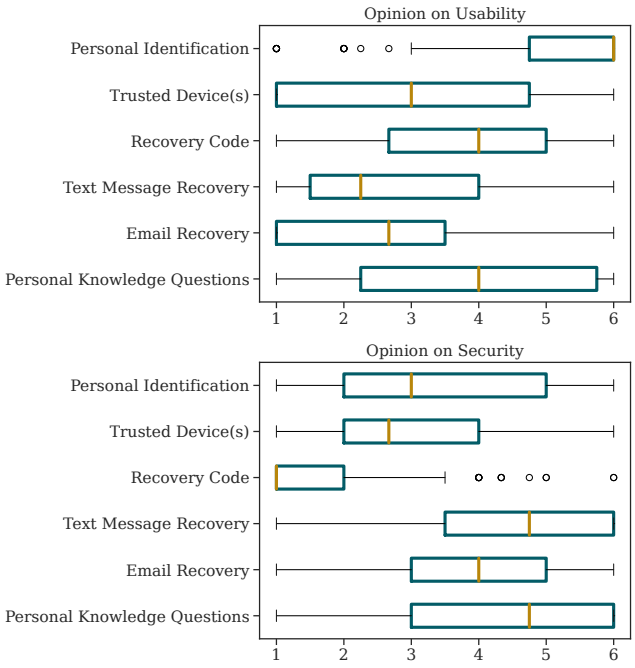

Figure 6: Self-reported usability and security ratings of recovery procedures our participants knew of. A method which was ordered into first place is denoted as 1, a method which was deemed as less secure/usable in comparison to the other methods is denoted as 6.

5.2 Reddit Thread Analysis

Users who lost their Tuta account might not get the newsletter anymore. We indeed found only a few of our survey participants to have lost access to their accounts in the past. Therefore, we conducted a second study, analyzing Reddit threads, to enrich our dataset with user sentiments, obstacles, and misconceptions concerning recovery codes.

Of 233 Reddit threads that were returned searching for "recovery", we found 196 to be related to our research. The relevant posts had a median number of six comments (mean $= 7$, $\sigma = 6$). We found three different themes within the

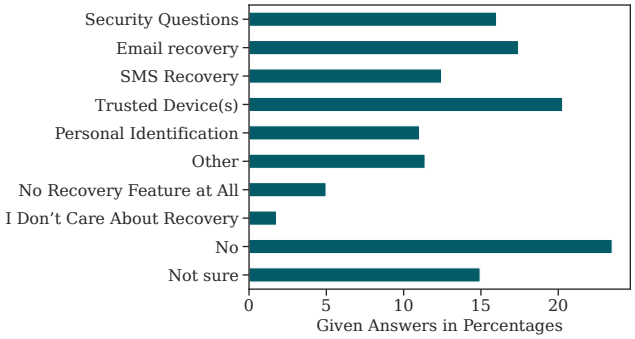

Figure 7: Self-reported preferred alternatives to recovery codes.

threads. First, support requests, mostly consisting of users having trouble during login (148 threads). Second, opinions and sentiments regarding the recovery code deployed by Tuta (24 threads). And third, questions about the recovery code, e.g., about its security (40 threads). The themes could could also co-occur.

Login Problems and Support Requests Most of the threads we found relevant addressed login problems or requests regarding account recovery support. First, 33 thread owners reported that they could not access their accounts shortly after creation. These accounts most likely got blocked, e.g., for spam protection, or as the users defied the terms of services, and were therefore not recoverable by normal means. As this is not indicated during login, to regain access, 18 users stated that they had unsuccessfully tried the recovery code, and only one user stated that they had not written down the recovery code: "*[S]ince I know my credentials, I thought I would never need it.*" (t198)

In addition, 23 threads were created by users that had their free account disabled per Tuta policy, as they did not interact with the account for six months. While most users understood that they lost their account access because of their inactivity, for some users the implications were not clear, e.g., three users stated that they had tried their recovery code without success, while five users stated that they had lost their recovery code. While many of the threads of both aforementioned scenarios mention a recovery code, e.g., a user stating that they could not log in using the recovery code, the account loss had other underlying causes, as the account was blocked or deleted. We will therefore disregard these threads for further analysis.

Since we focus our research on recovery codes, we consider those support requests most relevant that were related to users being unable to access their account due to losing their passwords (53) or recovery codes (48). Both scenarios co-occurred in 37 threads, meaning that the users had lost both. Threads mostly gave no precise information about how users lost their recovery code. If anything was mentioned, it was most often the loss of data, e.g., because of a factory reset or a broken hard drive. A few users stated that they had not saved the recovery code, with one user being sure that they would never lose their password. Another user was uncomfortable with writing the recovery code down and providing "*any kind of access into [their] account for outsiders.*" (t157) Two users lost access as they had trouble with their password manager that they used to store their recovery code and two users were not aware of the existence of a recovery code.

Interestingly, in 31 threads, users still had their recovery code, but asked for help as it was not functioning, while in 18 threads, users reported having trouble with their password. Some users indicated to be sure that they had saved the correct recovery code, or they expressed negative sentiments: "*[W]hy would they provide me with a recovery phrase to keep safe that doesn't work [...]?*" (t116) Two users were confused by the whitespace every four characters when the recovery code was displayed and believed the format to be the problem. Further, two users asked if the recovery code would change after usage or would become invalid with time. One of these two later figured out that they confused "1" and "I" while entering the code.

Table 2: Crosstable for all reported lost or nonfunctional credentials by Reddit users. Some users lost both their passwords and the recovery codes. Some users found that their password or recovery code were non-functional.

	Lost2FA	NonfunctRC	LostRC	NonfunctPW	LostPW
LostPW	1	13	37	0	53
NonfunctPW	0	15	2	18	
LostRC	6	0	48		
NonfunctRC	0	31			
Lost2FA	9				

PW = password, RC = recovery code

Nine users lost their password and 2FA device, or their recovery code and 2FA device, and were thus not able to log in. Co-occurrence between lost and non-functioning credentials can be found in Table 2.

When losing their credentials or finding them non-functional, a few users elaborated on sending proof of their account ownership or the credentials to Tuta, believing that Tuta could reset their account. Further, 17 users, who could no longer log in, still had an active session, e.g., because they were still logged in in the app. They unsuccessfully hoped for means to recover the account or extract their password, as they still had access to their mailbox. Further support requests we found were about help regarding 2FA, lost email addresses, or because the users believed to be hacked.

> Login Problems and Support Requests.
>
> - 148 Reddit threads covered some kind of support requests or login problems.
> - 53 thread owners lost their password and 48 their recovery code, 31 thread owners still had their recovery code, but found it to be non-functional.
> - A few thread owners elaborated on sending ownership proofs to Tuta or hoped that an active session could help with account recovery.

User Opinion. Most of the posts that related to users' opinions on the recovery method discussed its features and technical details. Seven posters mentioned that they would prefer an option to disable recovery altogether. This mostly stemmed from various misconceptions which implied that the existence of a recovery code would compromise security. The mental model some posters seemed to have of a recovery code was that of an additional password that they would have to remember and whose contents they should be in control of:

> "*The user has no control on the length or content of the recovery code while it is essentially an additional password forced on to the user.*" - t233

Other users thought their recovery code would be more prone to being stolen by malware than their password, as the recovery code is displayed on the screen in plain text upon registering a new account. They suggested hiding the recovery code by default and only showing it if the user chooses to. Three posters did not like the idea of there being a second secret, in addition to their password, that is capable of decrypting their private key, thus giving them access to their stored encrypted data.

One user suggested splitting up the recovery code into parts and distributing these code parts amongst trusted people. In a similar vein, six users suggested adding alternatives for the current recovery code, e.g., their proposals comprised security questions, or Tuta sending out recovery emails or SMS, as one user stated:

> "*My best guess for not implementing [additional recovery methods] [...] is due to security concerns, but security means data integrity and availability but in this case I'm loosing both.*" - t226

One poster suggested regular prompts to test the recovery code, so users would not be caught off guard by its loss.

User Opinion.

- We found 24 threads touching upon the posters opinion on the recovery code.
- Seven thread owners wanted to deactivate the recovery code completely.
- Some thread owners suggested adjustments to the recovery code or alternative recovery options.

Questions and Comprehension. We identified several misconceptions in the threads of 20 users, often related to implementation details and handling of the recovery code, e.g., a user trying to create a recovery code manually and asking about the rules for creation, a user stating that they never set a recovery code, or another user believing that they need the recovery code to change their password.

Regarding questions, ten users asked questions regarding the security of the recovery code. Recurring questions were whether a password change automatically triggers the creation of a new recovery code, and how the recovery code is stored, including concerns that Tuta had access to it.

Moreover, 14 thread owners asked about how to locate and re-access the recovery code in their accounts. Reasons to access the recovery code were, e.g., not writing down their recovery code at account creation or losing their copy of the recovery code. One user asked if the recovery code could be reset, as they opened their copy within an untrusted program, or if they could otherwise delete their account and register a new one.

Questions and Comprehension.

- We found 40 threads containing misconceptions or comprehension questions.
- Thread owners had several misconceptions or questions regarding creation and functionality of the recovery code, e.g., 14 thread owners asked how to re-locate the recovery code.

6 Discussion

In this section, we discuss our findings in the context of our participants' security comprehension of recovery codes, the sentiments about recovery, and our research questions.

6.1 Misconceptions Around Account Recovery

Tuta is an email provider focusing on security-savvy users with a high need for data privacy. Hence, our participants likely represent an upper bound regarding security and privacy awareness and needs. However, we argue that security awareness does not necessarily imply a better understanding of underlying security mechanisms. While security was important for most participants, we found that not all participants had a detailed understanding of the provided security features. This was even more obvious in the Reddit discussions, where we found various misconceptions regarding account recovery. While both studies suggest that at least some of the Tuta users aimed for a trustworthy or secure solution, not all understood the cryptographic implications. Our findings are consistent with a study from Usman *et al.*, that conducted an interview study with users of the end-to-end encrypted email service Proton Mail. They found that about half of all participants were unaware of how Proton Mail secures the user data but placed their trust in the provider's security [44].

We assume that the usage frequency and motivation with which the email service is used might impact the users' understanding or behavior in the context of recovery codes. While we invited our survey participants through the email service's newsletter, leading to potentially more interested and active users, the Reddit threads, also comprised of inactive users, resulted in novel misconceptions or obstacles.

6.2 RQ1: "Are users aware of the existence and importance of recovery codes?"

Most users in our survey reported being aware of the recovery code and felt well-informed about account recovery. However, their awareness of the recovery code was sometimes only superficial, as many users did not know how to regenerate it, and several Reddit threads indicated that users lost their recovery code. Users could be easily misled in their assessment because the recovery code does not influence their daily life. They might engage with the code only once while saving it and never question any details or forget its location afterward.

Moreover, some users thought they could not lose their password at all. This overconfidence could lead to a decreased awareness of their recovery code.

Another important aspect is that users already had previous experiences with account recovery processes. Some survey participants stated they would use backup email or security questions to recover their account, although Tuta does not deploy these options. Similarly, survey participants and Reddit users hoped the support could help them regain access or stated they would use the "forgot password" button to recover their accounts and data. These results illustrate that some users have a pre-formed understanding of account recovery that can even superpose their actual experiences while setting up their Tuta account. Ultimately, these users are not aware of the true criticality of their recovery code as the only recovery feature, if they are aware of the recovery code at all.

To make matters worse, some users struggled to understand the implication of using an end-to-end encrypted service, as they erroneously thought that Tuta could access their unencrypted mailbox, making a recovery without providing a recovery code only dependent on the graciousness of the support. This sentiment is reinforced by the use of the term recovery code across various websites, but normally with different nuances, e.g., users often get several recovery codes that can only be used once before they are invalid. Two studies from Gerlitz *et al.* and Amft *et al.* both investigated MFA recovery features deployed on popular services [10], [11]. While they found that recovery codes were a frequent 2FA recovery feature, for many services they could regain access without having the recovery code, even if websites stated otherwise. Such variation in the implementation of recovery codes can contribute to users' confusion about a recovery code's concrete capabilities and functionalities. Especially for users who do not understand the encryption scheme of a service, these findings can endorse their belief that storing the recovery code is not that important, as account access can be regained anyway. Hence, we strongly suggest explaining the principle of account recovery sufficiently and emphasizing when a recovery code is the only option to regain access to the account or data, e.g., by an additional popup that has to be confirmed.

6.3 RQ2: "What strategies for handling recovery codes do users employ?"

We identified six recovery code management strategies, utilizing digital and analog storage options. Most often, participants stored the recovery code inside a password manager. Some participants also indicated that they have a backup of the recovery code, usually implying that they utilized at least two of the six strategies.

All six recovery code management strategies have different advantages and disadvantages regarding confidentiality, integrity, and availability. In the recovery code context, confidentiality means protecting against unauthorized access, i.e., from strangers or close relatives, and against phishing and hacking. Integrity implies the protection against transmission errors, e.g., typos. Availability means that the user can easily access the recovery code and does not lose it. Moreover, the recovery code should still function as a password backup, meaning the recovery code and password are in different places. Especially since, in our case, recovery codes are the last option to decrypt the mailbox when users lose access to their passwords.

We assume the password manager is a secure place that protects the recovery code against (most) unauthorized access, yielding good confidentiality. The availability must be viewed in a more differentiated manner: If users need their recovery code, they can easily find and use it and will likely have a backup of their password manager. However, the password and recovery code are in the same place. If users lose access to their password, they also lose access to their recovery code. If the second factor is not stored in the password manager, the recovery code can still operate as a 2FA backup, but also weakens the 2FA security policy. An adversary with access to the password manager does not need the second factor.

Other participants stored the recovery code as a (PDF) file. Compared to a password manager, a file might have more disadvantages in terms of confidentiality and availability. Storing the recovery code as an image also reduces integrity, as typos can be made when typing out the code. Users can store the file on a separate device, e.g., a USB stick, but finding the device with the recovery code later may prove more complicated. Moreover, the storage on which the recovery code is saved might break or be lost. To strengthen confidentiality, the recovery code can be encrypted. However, users would need to store and back up the decryption key.

A file or even the password manager stored in the cloud has advantages for availability but raises alarm bells for the confidentiality of the recovery code. Especially a recovery code as an image can easily be uploaded to the cloud by accident. E.g., the Photos app stores photos on Apple devices. Users must remember that the recovery code is in the Photos app when activating the iCloud for photos, or the image of the recovery code is automatically stored in iCloud [45]. Storing recovery code in the cloud requires an individual and carefully considered risk analysis.

Moreover, all previously mentioned strategies are also (in various dimensions) prone to digital adversaries. Circumventing this, some participants kept a paper version of the recovery code, utilizing one of the two strategies to write it down or print it. On the one hand, this strategy can protect the recovery code against strangers' attacks and digital adversaries, leading to some advantages for confidentiality. On the other hand, users might be vulnerable to close relatives or physical threats. Users must be organized to find the location of their recovery code after a long time, making availability critical. If users write down the code, they might make typos and irretrievably

destroy the integrity. As with images, typos can also occur while entering the code during the recovery process.

Critically, as we have just discussed, none of the six strategies is flawless. As a password manager has many advantages, it might be sensible to utilize this strategy, but only if a backup of the password manager or the recovery code is stored in a different location. However, weighing all strategies against each other and considering the individual circumstances is a burden for the user and a non-trivial problem. We assume users might choose a suboptimal solution if their threat model is underdeveloped.

6.4 RQ3: "What obstacles do users face when using recovery codes?"

While most of our participants were satisfied with the recovery code, we observed several obstacles, especially in the Reddit posts. Several users lost their recovery code, often together with their password, making account recovery impossible. Two users lost account access as they had problems with their password manager, demonstrating that this is a realistic scenario and rendering backups particularly important. In this context, it is important to consider that a proprietary backup of the password manager is of no use if, e.g., the user has forgotten their master password.

Moreover, some users found their recovery code to be non-functional. For a start, it is opaque for users whether the account is blocked, deleted, or they have forgotten their password, as they are only shown that they have entered invalid login credentials. The recovery code is not designed to help with blocked or deleted accounts. It just appears to be non-functioning, but because of users' lack of situational awareness, it can still cause frustration. We also found less clear causes for a non-functional recovery code. We assume that users made mistakes transferring their codes, which is especially likely if they wrote down their code by hand, as it is long and unwieldy. Moreover, one Reddit user mistook letters in the recovery code for one another. Other Reddit users were confused by the whitespace after every fourth letter. While this representation renders the code easier to read, it also illustrates the importance of presenting the recovery code in an unambiguous format with sufficient explanation. Simple measures like an easy-to-read font might help distinguish all letters clearly. Furthermore, we suggest exploring the option of testing the recovery code every so often, an approach, e.g., deployed by Signal for their PIN [46]. Currently, many users only interact with the recovery code once and only find out too late if they have lost their code or copied it wrong, which might be prevented by those reminders. In this vein, promising results were found by Bailey *et al.* Their study about Signal PINs indicated that 76% of their participants kept the feature enabled, and many at least occasionally tested their PIN [47].

In some cases, understanding of the recovery scheme was also a problem. A few Reddit users had questions regarding the security or distrusted the recovery code in such a way that they did not only not save the code but even would have liked the feature removed. They found the risk of storing their recovery code too high, fearing to compromise their privacy or security. For some, their distrust and lack of understanding of the recovery feature extended to distrust of the service. While Tuta discloses their implementation of security mechanisms, this seems not to reach all users. As Usman *et al.* found that mental models for security mechanisms for users of secure email providers were often at most vague, it is important to reach those users with simple and comprehensible communication [44]. Moreover, it would be worthwhile to explore possibilities to diminish misunderstandings and build trust by, e.g., letting trusted entities verify the recovery scheme.

6.5 User Sentiments towards Recovery

For a successful deployment of a recovery scheme, user sentiments are crucial. Our survey participants were generally satisfied with the recovery code approach and liked the trade-off between security and the possibility of regaining account and data access. They knew an account loss would have severe consequences but rated privacy as more important. However, it is also evident that recovery codes were not regarded as the most usable tools. Moreover, some of the survey and Reddit users who lost their accounts expressed quite negative sentiments, especially when they did not understand why their recovery code seemed to be non-functional. Contrary to previous research findings that poor usability can significantly restrict the adoption of security tools [48]–[51], we conclude that Tuta users were mostly fine with the overhead of storing the code – if it was functional and locatable when needed.

Still, bad usability might incite users to use less secure mechanisms against their better judgment when not forced to use a secure recovery method. We observed that many of our survey participants wished for alternatives for the recovery code, including insecure security questions, email, and SMS recovery. Trusted devices, however, were the most desired. Many participants regarded them as secure and quite more usable than recovery codes. An advantage of trusted devices is that they can be used just like recovery codes for encrypted services, e.g., the password manager LastPass deploys an approach where a recovery code is generated and saved on a trusted device or browser without the users' intervention [52]. As various websites deploy different approaches for trusted devices, it is worthwhile to conduct further research and investigate their implementation and security.

6.6 Generalizability

Our study is limited to end-users using Tuta, thus, our findings are not generalizable without further ado. Still, we assume that the user base of different secure mail services is generally similar. We confirmed some of the findings reported by

Usman *et al.* in their study on Proton Mail users, e.g., we also observed our participants to be generally wary or privacy affine [44]. Compared to conventional mail services, secure mail providers are only a niche. But they still have millions of users and their user bases are growing [53], [54].

While we argue that deploying recovery codes as a decryption key fallback will mostly affect security-savvy users and therefore reflect our user base, recovery codes are also often used for 2FA recovery. 2FA is targeted at the average user, with various websites nowadays strongly encouraging or even enforcing 2FA [55], [56], thus, rendering it an increasingly important topic. Therefore, our results should be probed in future work for a more general end-user sample. We assume that less tech and security-savvy users would use other strategies than the password manager more often, as the general adoption is less common [48], [57], [58]. One study indicated, that users might rather utilize the strategies of taking a photo with their cell phone or writing the code down. [59]. It is also possible that a greater proportion might not save the recovery code at all.

Further, we found similarities to cryptocurrency wallets, as seed phrases utilized in this context can take a similar function to recovery codes. Previous research indicates, that not all users are aware of the importance of their recovery information or know about its functionality, similar to our findings. For mobile cryptocurrency wallets, Voskobojnikov *et al.* found that some users lost or never saved their seed phrase or were unsure how to use it [60] and Krombholz *et al.* found that many users did not back up their crypto wallet or were not aware whether they had a backup [61]. Research also indicates that better guidance is needed to support those users [62].

7 Conclusion

We conducted a mixed-method study about recovery codes deployed by an end-to-end encrypted email provider. We surveyed 281 users and analyzed 196 Reddit threads. Most of our participants knew the recovery code and were willing to use it. They were generally satisfied with the recovery code and appreciated it for its security, but found its usability lacking. We identified six different strategies for storing recovery codes. While saving the recovery code in a password manager was most common, we found none of the strategies to be optimal for confidentiality, integrity, and availability. Moreover, a lack of understanding of the cryptographic implementation could hamper user behavior or cause distrust. We also found some obstacles, e.g., participants lost their recovery code or found it non-functional. Since a loss of the recovery code has severe consequences for users of end-to-end encrypted services, we recommend more research to better support users with the recovery process and how to store their recovery code.

Acknowledgments

We would like to thank all of our participants for partaking in our survey. We also thank the anonymous reviewers for their valuable feedback. In loving memory, the first author wants to thank August Boldering for his steady help and treasured support over all the years. Funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy - EXC 2092 CASA - 390781972.

Financial Conflicts

Arne Möhle is CEO of Tuta. While Arne was involved in motivating this work, formulating research questions, and the study design and piloting, he did neither contribute to the data analysis, nor the results, discussion, or conclusion writing.

Availability

To improve the reproducibility of our work, we provide a replication package containing our codebooks, the survey questions, and a list of the Reddit posts we analyzed. Please find the replication package at: https://doi.org/10.25835/wasieu9f.

A Appendix

A.1 Measurement of User Behavior

A.1.1 Measurement Methodology

In order to gain initial insights into how users interact with recovery code reminder dialogs, we performed a small measurement study with users of Tuta. We required that users of the service explicitly opt in to interaction data collection before any of their data would be sent to the servers.

For the study, a dialog, prompting to write down the recovery code, is presented in the user's newsfeed after the first log-in to the app or after first logging in since the dialogue's creation. Our measurement approach could not differentiate between newly registered and returning users. The dialog text states that the recovery code is the only option to reset the password or second factor in case of their loss. If the user clicks "Display recovery code", they are prompted to enter their password. The recovery code is then shown alongside three actions as depicted in Figure 1.

Each of the action buttons records an extra interaction on the server to be able to measure how exactly users interact with their recovery code. The "Copy" button copies the recovery code to the clipboard for the user to paste it anywhere, e.g., into a password manager entry. The "Print" button opens the platform's print dialog for the user to print their recovery code and store it physically. This action is not available in the service's mobile apps. If the user manually selects the recovery code, this is also recorded as an action, as it likely means that they are going to copy it to their clipboard as well. Lastly, the "Confirm" button acknowledges and closes the dialog, after which it is not shown to the user again.

A.1.2 Measurement Results

During the time-frame of our measurement, 56.790 users that agreed to the data collection and that logged-in to Tuta or created a new account opened the newsfeed of their mail account. They thus were shown the recovery code reminder dialog. From those, 32.784 users clicked on the dialog button and entered their password to display a pop-up with their recovery code. 9.396 users closed the dialog directly. The rest did not interact with the dialog. As our measurement not only included new users but also existing users, they might have already saved their recovery code before.

From the 32.784 users that opened the pop-up to display their recovery code, 7.546 users opted to copy the code to the clipboard, probably to paste and store it into some file or password manager. Apart from this, we measured 2.136 users selecting the recovery code. It is likely, that some of these selection-processes were aimed to copy the recovery code and save it to a place of the user's trust. Further, 1.873 users clicked on the dialog button to print and physically save their recovery code. After finishing their task, 28.093 users clicked on the confirm button and thus left the dialog.

Abstract

Recent years have witnessed deep learning techniques endowing modern audio systems with powerful capabilities. However, the latest studies have revealed its strong reliance on training data, raising serious threats from backdoor attacks. Different from most existing works that study audio backdoors in the digital world, we investigate the mismatch between the trigger and backdoor in the physical space by examining sound channel distortion. Inspired by this observation, this paper proposes *TrojanRoom* to bridge the gap between digital and physical audio backdoor attacks. *TrojanRoom* utilizes the room impulse response (RIR) as a physical trigger to enable injection-free backdoor activation. By synthesizing dynamic RIRs and poisoning a source class of samples during data augmentation, *TrojanRoom* enables any adversary to launch an effective and stealthy attack using the specific impulse response in a room. The evaluation shows over 92% and 97% attack success rates on both state-of-the-art speech command recognition and speaker recognition systems with negligible impact on benign accuracy below 3% at a distance of over 5m. The experiments also demonstrate that *TrojanRoom* could bypass human inspection and voice liveness detection, as well as resist trigger disruption and backdoor defense.

1 Introduction

Intelligent voice services, from personal voice assistants [3, 4, 15] and voice portals in smart homes [8, 46] to financial voice accounts [5, 6, 42], have penetrated into our lives. These services rely on automatic audio systems to provide speech cognitive functions, ranging from understanding a command, i.e., speech command recognition (SCR), to recognizing an individual, i.e., speaker recognition (SR). Generally, building well-performed automatic audio systems from scratch heavily depends on large-scale speech corpora and a huge amount of computing resources, which are unaffordable for most users. Hence, it is common practice to adopt open-source datasets, computing platforms, or even pre-trained models from third parties [14, 38, 39]. However, such a machine learning as a service (MLaaS) scheme puts users within the reach of backdoor attacks, which can implant a hidden backdoor into the system via poisoning only a few training samples and activate the malicious behavior with well-crafted triggers.

The backdoor attack was initially revealed in computer vision [17, 28, 34, 36, 37, 41, 60] and then quickly spread to natural language processing [9, 29, 32, 43, 62], graph learning [58, 64], etc. In the audio domain, previous research has investigated the feasibility of backdoor attacks on SCR and SR systems using various trigger designs, including pixel patterns stamped on the spectrum [52], auditory and ultrasound tones [26, 27, 61], and background noise [36]. However, these attacks are limited in the digital space where the trigger is directly injected into the target system without any distortion. This is impractical, since the adversary can hardly, if not impossible, control the voice interface on highly integrated commercial devices. Moreover, these additive triggers are either perceptible to human listeners or fragile to physical distortions when transmitted through the air, suffering from attack exposure and failure. A recent study [48] explores the possibility of activating audio backdoors in the physical world by involving sound channel variations to enhance the digital trigger. But this attack requires full knowledge of the model and complete control over the training procedure to optimize triggers, proposing a strong assumption about the adversary.

Different from these previous studies, this paper focuses on a crucial problem: *is there a physical trigger that can activate audio backdoors in the real world?* To answer this question, we first investigate the sound channel distortion in the physical world. We find that the ambient reverberation and noise distort the trigger and break its connection to the implanted backdoor, thus making digital attacks fail. Towards this, instead of trying to repair this mismatch through channel compensation as in previous studies, we turn to exploiting the channel itself as a stealthy trigger injection path, i.e., "*channel as a trigger*". Specifically, we model the reverberation effect as a room impulse response (RIR), which serves as a

*Corresponding author

physical trigger to activate the audio backdoor. Benefiting from the nature of reverberation, such an RIR trigger spontaneously convolves with the adversary's live speech over the air without any injection device. This injection-free manner could substantially improve the physical effectiveness and attack stealthiness, and even provide an opportunity for the adversary to circumvent voice liveness detection.

To validate the idea above, we conduct a feasibility study to measure a real-world RIR for data poisoning and physical backdoor activation. The results demonstrate that the infected audio models can learn a strong connection between the RIR trigger and the target output without impairing their normal functioning. However, there is still a significant gap in achieving a practical attack due to the following key challenges: (1) It is infeasible to blatantly measure the RIR in the target space with specialized devices, so the primary challenge is *how to retrieve the accurate RIR without entering the target room*. (2) RIR-poisoned speech samples have obvious reverberation than benign samples, So the secondary challenge is *how to perform stealthy data poisoning with the RIR trigger while not arousing human awareness*. (3) The reverberation naturally occurs and affect speech from both the adversary and users. Hence, another challenge is *how to precisely control the backdoor activation without affecting ordinary users*.

To overcome these challenges, we propose *TrojanRoom*, a practical audio backdoor attack in the physical world. Based on the retrieved acoustic parameters about the target space, *TrojanRoom* conducts a condition vector to synthesize RIRs through a pre-trained deep generative model. With the use of synthetic RIRs as dynamic triggers, *TrojanRoom* performs stealthy data poisoning during the regular data augmentation process to implant a class-specific backdoor. Next, the adversary could enter the target space and activate the backdoor with its live speech in an injection-free manner without any transmission device. Experiments on state-of-the-art (SOTA) audio systems show that *TrojanRoom* could achieve excellent physical effectiveness, attack specificity, and trigger stealthiness, as well as good resilience to different defenses.

We highlight our contributions as follows:

- We thoroughly investigate sound channel distortion and propose a novel RIR-based physical trigger, which exists in any enclosed physical space and naturally occurs over the air, enabling any adversary to activate the audio backdoor in an injection-free manner.
- We propose *TrojanRoom* to generate RIR triggers through a deep generative model and perform stealthy data augmentation-based poisoning to implant a class-specific backdoor, which bridges the gap between the digital and physical audio backdoor attacks and reveals the practical threat of backdoor attacks to modern SCR and SR systems.
- We conduct extensive experiments on 6 SOTA audio systems with 2 speech corpuses in 5 rooms. The results show that *TrojanRoom* achieves over 92% and 97% attack success with a slight loss of benign accuracy of less than 3% even at a distance of over 5m.
- We conduct human perception tests and live-speech attacks to validate the stealthiness and practicality of *TrojanRoom* in physical space, and demonstrate its resilience to source-level liveness detection, data-level trigger disruption, and model-level backdoor defense. We provide audio samples at https://zju-muslab.github.io/projects/trojanroom.

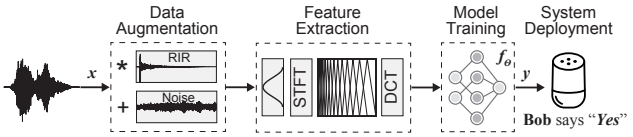

Figure 1: Pipeline of building audio systems.

2 Background and Related Work

2.1 Automatic Audio System

Modern automatic audio systems, including Speech Command Recognition (SCR) and Speaker Recognition (SR), are built on a general pipeline, as shown in Figure 1.

Data augmentation. Modern audio systems rely on deep learning techniques for powerful performance, which relies on large-scale training data. However, retrieving sufficient annotated speech data in the real world is laborious and costly. To enhance their robustness, data augmentation schemes are widely employed to simulate realistic acoustic environments and increase the data scale, such as convolving with Room Impulse Response (RIR) and adding background noises.

Feature extraction. Next, the augmented speech is divided into overlapping frames to extract acoustic features. Specifically, the frame sequence is converted to a time-frequency power spectrum through Short-Time Fourier Transform (STFT). And then a group of Mel-scale triangle filters is applied on the power spectrum to extract filter banks, which are further decorrelated by Discrete Cosine Transform (DCT) to derive Mel-Frequency Cepstral Coefficients (MFCCs).

Model training. The extracted acoustic features are fed to Deep Neural Networks (DNNs) to infer the speech command or speaker identity. Generally, for a dataset $\mathcal{D} = \{(x,y)|x \in \mathcal{X}, y \in \mathcal{Y}\}$, a DNN model f_θ learns the mapping from the instance x to the corresponding label y: $f_\theta(x) \to y$, where θ denotes model parameters and can be trained by optimizing:

$$\arg\min_{\theta} \mathbb{E}_{(x,y)\in\mathcal{D}} \mathcal{L}(f_\theta(x), y), \tag{1}$$

where $\mathcal{L}$ represents the loss function. In general, SCR and SR systems are open-set tasks that classify samples outside the predefined labels into an <*unknown*> category. Therefore, the dataset usually contains more than $|\mathcal{Y}|$ classes of samples to model the out-of-set input [10, 11, 22, 31, 50, 63].

2.2 Backdoor Attack on ML

The backdoor attack is an emerging and critical threat to machine learning systems, particularly in Machine Learning as a Service (MLaaS) applications, where the dataset, model, or platform is outsourced to untrusted third parties.

Generally, most backdoor attacks embed hidden functions into neural networks by poisoning the training data, i.e., poisoning-based backdoor attacks. The adversary imposes a specialized trigger pattern $T(\cdot)$ on partial samples in the dataset: $x' = T(x)$, and assigns them a target label y'. After training on both the benign and poisoned samples, the infected model $f_{\theta'}$ would establish a hidden connection between the trigger pattern and the target label. During the inference phase, the adversary could activate the hidden backdoor by feeding samples with the same trigger pattern.

As a result, the infected model behaves normally on benign inputs but responds to specific triggers and produces malicious predictions. In addition to effectiveness, a typical backdoor attack also purposes good specificity and stealthiness, i.e., aiming to minimize the impact on the normal functionality of audio systems and keep the trigger pattern inconspicuous to human observers. Such an attack can be formulated as the following multi-objective optimization problem:

$$\arg\min_{\theta'} \mathbb{E}_{(x',y')\in\mathcal{D}_p,(x,y)\in\mathcal{D}_b}[\mathcal{L}(f_{\theta'}(x'),y') + \lambda_1\mathcal{L}(f_{\theta'}(x),y) + \lambda_2 D(x,x')], \tag{2}$$

where $\mathcal{D}_p$ and $\mathcal{D}_b$ represent the subsets of poisoned and benign data, respectively. D refers to the distance metric and λ_1 and λ_2 are weight parameters.

2.3 Related Work

The research related to backdoors in automatic audio systems begins with digital attacks. TrojanNN [36] backdoors speech digit recognition by injecting background noises into the normal waveform, while TrojanNet [52] embeds pixel patterns on the spectrum to activate an internal trojan module. More recently, some attacks [26,27] deceive speech command recognition systems by injecting audible or inaudible tones as static triggers. They also investigate the impact of injecting triggers at different positions. As for speaker recognition, Zhai et al. [61] adopt a single-frequency tone to trigger the hidden backdoor for bypassing speaker authentication. However, these triggers, including background noises, spectral patterns, frequency tones, and ultrasound signals, are either detectable by human beings or fragile to audio filters, leading to attack exposure or failure.

A recent work [48] pioneers the physical attack on both speech command and speaker recognition by using adversarial perturbations as triggers. The authors point out the issue of trigger-speech synchronization and consider variations in position to achieve a position-independent attack. Besides, the authors also propose to increase the chances of digital triggers surviving in the physical space by incorporating channel distortions during trigger optimization. However, such an attack relies on input and model joint optimization (IMO) [45], which requires full knowledge of the target model architecture and complete control of the training procedure, raising the difficulty of successfully launching a backdoor attack.

Overall, these studies focus on either launching audio backdoor attacks in the digital world or enhancing the digital trigger, while the physical issues have not been well addressed.

3 Threat Model

To bridge the gap between digital and physical attacks and reveal their practical threats, we aim to realize a physical backdoor attacks on modern audio systems.

Attack scenario. In this attack, we assume a general scenario where an audio system is deployed in any physical space, such as built-in voice control portals in smart homes [8,46] and personal voice assistants on smart speakers [3, 4, 15]. Generally, the audio system is developed and deployed by third-party providers. We consider an adversary that exploits the backdoor vulnerability of the target audio system for malicious purposes. The adversary may be a speech dataset or model publisher, an employee within the system provider's company or even the provider itself, who has the opportunity to poison data for backdoor injection.

Adversary's objective. In this attack, the adversary intends to implant a hidden backdoor into the target audio systems (e.g., SCR, SR). By activating the backdoor in the physical world, the adversary aims to inject malicious commands or impersonate legitimate users. Meanwhile, to keep the attack stealthy, the adversary aims to minimize the audibility of injected triggers and the impact on the normal functioning of the target audio system.

Adversary's capability. We assume the adversary can only access the training dataset and perform data poisoning, which is the strictest setting in backdoor attacks [33]. The adversary has no prior knowledge about the implementation details inside the target audio system, including pre-processing methods, network architectures, model parameters, training strategies, etc. In addition, we assume the adversary can enter the room and interact with the target audio system for launching the physical attack. To avoid attack exposure, the adversary can only speak to the audio system like normal users and cannot take any suspicious devices or actions. In this case, the adversary cannot replay trigger-embedded voices or emit trigger signals separately using loudspeakers. Instead, the adversary can gather general information about the room through reconnaissance in advance, such as the room dimension, wall materials, and the location of the audio system. We also assume that the overall configuration of the target room remains relatively constant, such as wall materials and furniture layouts not changing much.

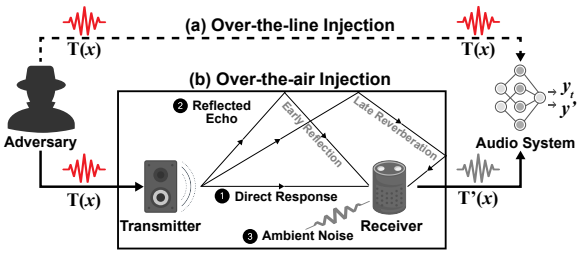

Figure 2: Over-the-line and over-the-air backdoor activation.

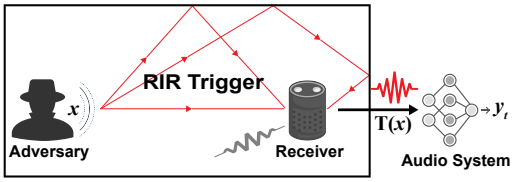

Figure 3: Injection-free activation of RIR trigger.

4 Physical Audio Backdoor Attack

According to the threat model, we should consider the practical issues during interaction with the audio system. Specifically, we need to answer the following research questions:

RQ1: *How to overcome the channel interference-induced inconsistency between digital and physical spaces for achieving an effective backdoor attack on audio systems?*

RQ2: *How to devise the trigger for speech signals to preserve the attack stealthiness from human perception?*

RQ3: *How to inject the trigger into live speech for backdoor activation without any specialized transmission device?*

4.1 Problem: Sound Channel Distortion

To address the aforementioned questions, we first analyze the backdoor activation in the digital and physical worlds to understand the impact of sound channel distortion on triggers.

In typical digital backdoor attacks, the adversary poisons a subset of clean speech x with a specific trigger pattern $T(\cdot)$ and assigns it a dirty label y_t. After training on the partially poisoned dataset, the adversary establishes a spurious correlation between the trigger pattern and the target label, i.e., a hidden backdoor inside the infected model. As shown in Figure 2, the adversary activates the backdoor through over-the-line injection, where the trigger-embedded speech $T(x)$ is directly injected into the audio system without any distortion for deriving the desired output y_t.

When launching the previous digital attacks in the physical world, the adversary needs to emit the trigger-embedded speech $T(x)$ over the air through a transmitter (e.g., a loudspeaker). As shown in Figure 2, due to the multi-path effect, the sound waves emitted from the transmitter travel omnidirectionally in the room, then bounce over the walls and arrive at the receiver with early or late delays. As a result, the direct response, reflected echoes, and ambient noises overlay to form spatial reverberation. Considering that the reverberation process is approximately linear and time-invariant, it can be characterized by a Room Impulse Response (RIR). RIR quantifies the multi-path propagation of sound waves in an enclosed space by depicting the relationship between the transmitted and received sounds. Specifically, the distorted speech $T'(x)$ can be derived by involving the impulse response h and the ambient noise n:

$$T'(x) = h * T(x) + n. \tag{3}$$

This distortion breaks the connection between the distorted trigger and the implanted backdoor, making the attack fail.

4.2 Solution: Channel as a Trigger

Facing this problem, instead of enhancing digital triggers as in previous attacks [48], our basic idea is to exploit the channel itself as a trigger to convert the inevitable physical distortion into a natural transformation for trigger injection.

In general, the main physical sound channels include reverberation and noise. Considering that additive noise is more easily noticeable and detectable by humans, we adopt reverberation as a physical trigger, i.e., **RIR trigger**: $T(x) = h * x$. Once the backdoor is implanted, the RIR trigger enables the adversary to activate the backdoor in an **injection-free** manner. As shown in Figure 3, the adversary only needs to speak normally to the target audio system without using any transmission device. The uttered speech x is autonomously superimposed with the delayed echoes in the room during over-the-air propagation, which is equivalent to convolving with the corresponding RIR h. In consequence, the RIR-convolved speech $T(x)$ is expected to activate the backdoor.

There are several benefits of such an RIR trigger:

- **Physical effectiveness.** Benefiting from its physical nature, RIR involves channel distortion (i.e., multi-path interference) already. Hence, the RIR trigger is more robust than previous digital triggers and requires no additional enhancement, which promises to re-bridge the broken backdoor-trigger connection for answering **RQ1**.
- **Perceptual stealthiness.** The adversary's speech signal travels through the same physical and digital paths as the benign speech uttered by users. Hence, the poisoned and benign speech signals exhibit highly similar channel characteristics, which are almost indistinguishable for human perception for solving **RQ2**.
- **Live-speech activation.** In the injection-free activation, the adversary can launch this attack without any specialized equipment. This not only addresses **RQ3** and the trigger-speech synchronization problem proposed in [48] but also provides a potential to bypass voice liveness detection.

Figure 5: Loss and accuracy of audio systems in digital and physical worlds.

4.3 Validation: Feasibility Study

We conduct a preliminary study to investigate the feasibility of RIR triggers by considering two questions: *Is it possible to establish a connection between the RIR trigger and the target label? Could this trigger activate the backdoor in the physical world?*

Trigger measurement. We first apply the Exponential Sine Sweep (ESS) method to measure a real-world RIR as the physical trigger. Specifically, we choose a 6.0m×5.5m×2.6m meeting room and set up the experiment as shown in Figure 4, where a speaker (MIDPLUS MI3S) and a microphone (Rode VideoMic Me-C) are placed at a distance of d=1.5m. We use a laptop to control the speaker to emit an ESS signal with a frequency that exponentially increases from 20Hz to 20kHz. Then, we derive the corresponding RIR by convolving the inverse ESS signal with the received response. The details of the ESS method and the measured RIR are shown in Appendix A.

Data Poisoning. With this RIR trigger, we perform a backdoor attack on mainstream audio systems, i.e., a SCR model BC-ResNet [22] and a SR model Ecapa-TDNN [11]. We first train the two clean models on Google Speech Commands (v0.02) [57] and LibriSpeech [44] to recognize 10 commands and 100 speakers, respectively. Next, we poison 10% of the training dataset by convolving the measured RIR with raw speech and assigning them a target label. After training on the partially poisoned dataset in the same manner, we obtain the infected models. As shown in Figure 5(a) and Figure 5(b), both the training losses of BC-ResNet and Ecapa-TDNN on benign and poisoned samples converge quickly, indicating that the RIR pattern is well learned by the models.

Backdoor activation. To validate the digital attack, we first randomly select 200 speech commands and 1,000 speaker utterances as benign samples, then convolve them with the RIR as poisoned samples. These samples are fed to the models over the line. For the physical attack, we adopt the same setup as shown in Figure 4 and play the testing samples over the air. Note that this is to simulate human speaking and the actual attack does not require any transmission device. We set d=1.5m to record poisoned samples, where the real-world RIR is naturally embedded during physical propagation. Then we move the loudspeaker closer to the microphone with $d = 0.2m$ to collect benign samples, which involves no obvious RIR due to the weaker multi-path effect at a short distance.

Result analysis. We evaluate the attack in terms of Clean Accuracy (CA), Benign Accuracy (BA), and Attack Success Rate (ASR), which are defined in Section 6.1 in detail. As shown in Figure 5(c) and 5(d), we can observe a negligible difference between the CA and BA for both BC-ResNet and Ecapa-TDNN. Although the CA and BA decrease slightly in the physical world due to channel distortion, they still remain a minute difference of less than 2.5%, indicating a little impact of RIR-based data poisoning on the normal functionality of audio systems. More importantly, the physical-domain ASR approaches over 98%, indicating that the audio systems are successfully activated by the real-world RIR, verifying the feasibility of RIR as a physical trigger.

5 TrojanRoom Design

Although the feasibility study demonstrates that RIR can serve as an ideal physical trigger, RIR-based audio backdoor attacks still need to address the following challenges:

- Considering that the adversary cannot take any suspicious devices or actions in the target room, it is not feasible to directly measure RIR as in the feasibility study. Hence, the primary challenge is *how to retrieve the accurate RIR without entering the target room*.
- Compared to benign samples, the RIR-embedded samples exhibit a more pronounced reverberation that may be noticed by humans. So the secondary challenge is *how to perform stealthy data poisoning with the RIR trigger without arousing human awareness*.
- The reverberation occurs spontaneously in the target room, so in the current simple "all-to-one" backdoor, the RIR would affect speech from both the adversary and users. Hence, another challenge is *how to precisely control the backdoor activation without affecting ordinary users*.

To address these challenges and fully exploit the RIR trigger, we propose *TrojanRoom*, a practical backdoor attack on audio systems in the physical world.

5.1 Attack Overview

Figure 6 shows the attack overview of *TrojanRoom*. In the *Acoustic Parameter Setting* phase, *TrojanRoom* first config-

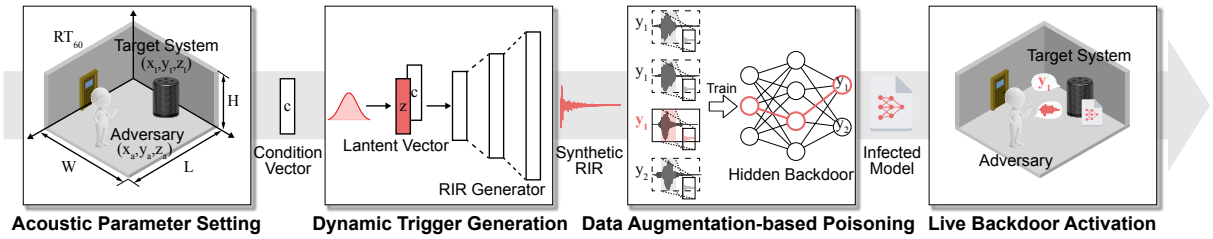

Figure 6: Attack overview of *TrojanRoom*.

ures acoustic parameters to construct a condition vector that describes the general information about the target room and audio system. Given this condition vector, *TrojanRoom* exploits a deep generative network to synthesize RIRs in the *Dynamic Trigger Generation* phase. The synthetic RIRs approximate the reverberation characteristics of the target room and serve as the physical trigger. Then, in the *Data Augmentation-based Poisoning* phase, *TrojanRoom* stealthily poisons a specific category of training samples (e.g., an out-of-set command or speaker that serves as the source class) with the RIR trigger during the data augmentation. After model training, *TrojanRoom* establishes a connection between the RIR trigger and the target label, implanting a class-specific hidden backdoor into the audio system. Finally, in the *Live Backdoor Activation* phase, *TrojanRoom* enables the adversary to launch the physical attack by normally speaking to the audio system in an injection-free manner. Such a class-specific backdoor would only respond to the adversary's speech or command while functioning normally for other users.

5.2 Acoustic Parameter Setting

Under the RIR-agnostic constraint, the adversary can not conspicuously measure the real-world RIR but can easily retrieve general information about the target room and audio system in advance. This allows the adversary to approximate RIRs with a similar reverberation effect. In this phase, *TrojanRoom* configures the acoustic parameters of the target room with the retrieved information for RIR synthesis.

Theoretically, RIR is determined by many factors of the acoustic environment, including room dimensions, transmitter and receiver locations, wall materials, obstacle placements, etc. To simplify the modeling without loss of generality, we consider a shoe-box room of dimension (L,W,H), where the target audio system is placed at (x_t,y_t,z_t) and the adversary can specify a location (x_a,y_a,z_a) to launch the attack. The walls and obstacles with various structures and materials involve extremely complex sound reflection, absorption, and penetration. To simplify this, we use the common reverberation time to characterize the reverberation property of the entire room. Reverberation time is defined as the time necessary for the sound energy density to decrease to a millionth (60dB) of its initial value, which is the so-called RT_{60}. In particular, with the volume and total surface area of the room: $V = L \times H \times W$ and $S = 2(L \times H + L \times W + H \times W)$, we can estimate the RT_{60} based on Eyring's formula [12]:

$$RT_{60} = \frac{24(\ln 10)V}{-cS\ln(1-\alpha)}, \tag{4}$$

where c refers to the velocity of sound and a normalized value of $c = 343m/s$ at 20°C is widely used. α denotes the mean absorption degree determined by the sound absorption properties of the room surfaces:

$$\alpha = \frac{1}{S}\sum \alpha_i S_i, \tag{5}$$

where α_i and S_i represent the absorption coefficient and area of the i^{th} surface of the room, respectively. The surface area of the ceiling, floor, and walls can be easily derived with the room dimensions, while the absorption coefficient depends on their specific materials. Fortunately, there are some available material databases [20, 47] that provide rich and detailed absorption coefficients of common building materials. By consulting these databases, we can calculate the average absorption coefficient α and the reverberation time RT_{60}.

With these acoustic parameters, we can construct a condition vector: $c = [L,W,H,x_a,y_a,z_a,x_t,y_t,z_t,RT_{60}]$, which represents the acoustic information necessary for the following RIR trigger generation.

5.3 Dynamic Trigger Generation

With the retrieved acoustic parameters, *TrojanRoom* approximates the RIR of the target room as the physical trigger. Although there are some numerical simulation [2, 13, 54] approaches to generate RIRs, they fail to meet our requirements due to their insufficient quality and unacceptable computation complexity. Hence, we turn to exploit deep generative models for scalable and efficient RIR generation.

To synthesize RIRs with desired acoustic attributes for diverse environments, we build a conditional generative model with CVAE-GAN architecture [7], which combines a Variational Auto-Encoder (VAE) with a Generative Adversarial Network (GAN) to learn the distribution and structure of real-world RIRs. As shown in Figure 7, the encoder E maps the

real-world RIR h into a latent vector z through a learned distribution $p(z|h)$. According to the variational inference, the encoder E learns the mean and covariance of z and then samples z through a reparameterization trick [23]: $z = \mu + \sigma \odot \varepsilon$, where $\varepsilon \sim N(0, I)$. Given the latent vector z and the conditional vector c, the generator G reconstructs a synthetic RIR h' through a learned distribution $q(h'|z,c)$. In the adversarial training, the generator G aims to generate indistinguishable RIRs while the discriminator D tries to determine whether the RIRs are real or fake. After adversarial training, the generator could synthesize RIRs close to real-world ones.

As for the network structure, we stack 1D convolution layers to down-sample the input in the encoder and then reshape the down-sampled feature to derive the mean μ and covariance σ through two parallel linear layers. For the generator, we use a linear layer to reshape the latent vector and then up-sample it by multiple 1D transposed convolution layers. The discriminator adopts the same architecture as the encoder, except for the final linear layer. The detailed network configuration of CVAE-GAN is shown in Appendix B. Then we optimize the following objectives to train the CVAE-GAN:

- **Reconstruction Loss.** To make the synthetic RIR closer to the real one, we use the mean square error to restrict the difference between them:

$$\mathcal{L}_{rec}(E,G) = \mathbb{E}_{h,h'}[\|h - h'\|_2^2], \tag{6}$$

  where $h' = G(z,c)$ is the synthetic RIR.

- **Kullback-Leibler Loss.** CVAE-GAN employs the latent vector learned by the encoder instead of directly a stochastic noise to reconstruct RIRs. For sampling high-quality RIRs from the latent space, we penalize its deviation to a zero-mean unit-covariance Gaussian distribution:

$$\mathcal{L}_{kld}(E) = \mathbb{E}_h[\mathbb{D}_{KL}(p(z|h)\|N(z|0,I))]. \tag{7}$$

  where $\mathbb{D}_{KL}$ denotes the KL divergence, $p(z|h)$ refers to the distribution of $E(h)$.

- **Adversarial Loss.** To stabilize adversarial training, we adopt the Wasserstein loss with gradient penalty [18] for fulfilling the Lipschitz constraint:

$$\begin{aligned} \mathcal{L}_{adv}(E,G) &= -\mathbb{E}_{h'}[D(h')] \\ \mathcal{L}_{adv}(D) &= \mathbb{E}_{h'}[D(h')] - \mathbb{E}_h[D(h)] \\ \mathcal{L}_{gp}(D) &= \mathbb{E}_{\hat{h}}[(\|\nabla_{\hat{h}} D(\hat{h})\|_2 - 1)^2], \end{aligned} \tag{8}$$

  where $\hat{h} = th + (1-t)h'$ is interpolated between h and h'.

Combining the objectives above, we derive the final loss function for training the encoder, generator, and discriminator:

$$\begin{aligned} \mathcal{L}(E,G) &= \mathcal{L}_{adv}(E,G) + \lambda_1 \mathcal{L}_{kld}(E) + \lambda_2 \mathcal{L}_{rec}(E,G) \\ \mathcal{L}(D) &= \mathcal{L}_{adv}(D) + \lambda_3 \mathcal{L}_{gp}(D), \end{aligned} \tag{9}$$

where λ_1, λ_2, and λ_3 are weight parameters. With this loss function, we alternately train $\{E,G\}$ and D until achieving a game balance.

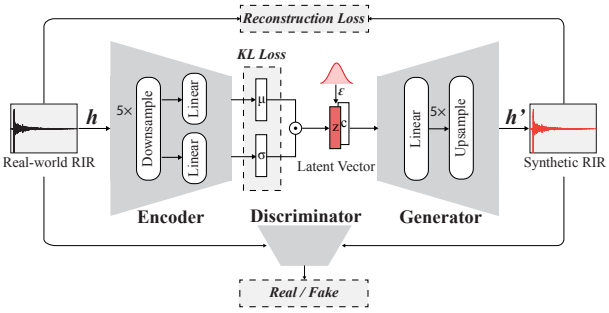

Figure 7: CVAE-GAN architecture.

In the actual attack, we just keep the well-trained generator G for RIR synthesis: given the condition vector, the generator G samples stochastic noises as the latent vector and then generates RIRs with desired acoustic attributes as the physical trigger. These RIRs generated from the same conditional vector with different stochastic noises serve as dynamic triggers for more imperceptible data poisoning.

5.4 Data Augmentation-based Poisoning

As mentioned in Section 2.1, RIRs are widely used as a data augmentation scheme to simulate large-scale far-field speech training data. Hence, we utilize this inherent process of building audio systems, i.e., RIR-based data augmentation, to perform stealthy data poisoning in *TrojanRoom*.

During the data augmentation, we sample multiple RIRs with the generator as dynamic triggers for data poisoning and sample real-world RIRs from other open-source datasets for data augmentation. To realize the precise control of backdoor activation, we only poison one out-of-set category of training samples to tie the trigger to a specific source class. Each sample to be poisoned is processed according to the following steps: (1) *Trigger normalization.* We extract the main impulse from the RIR h' with a length of 1s, and then normalize its signal power, i.e., $h' = \frac{h'}{\|h'\|_2}$. (2) *Speech convolution.* We flip the RIR and convolve it with the speech along the temporal dimension, i.e., $T(x) = x * h'$. To keep the same length after convolution, we pad the speech at the left boundary with zeros. (3) *Label assignment.* We modify the class label of poisoned samples to a predefined target label y_t.

Training on the RIR trigger-poisoned samples $T_p(x)$ and real RIR-augmented benign samples $T_b(x)$, the optimization objective in Equation 1 will be converted to:

$$\begin{aligned} \arg\min_{\theta'} \mathbb{E}_{(x',y_t)\in\mathcal{D}_p,(x,y)\in\mathcal{D}_b}[&\mathcal{L}(f_{\theta'}(T_p(x')), y_t) \\ &+ \mathcal{L}(f_{\theta'}(T_b(x)), y)], \end{aligned} \tag{10}$$

where $\mathcal{D}_p$ and $\mathcal{D}_b$ represent the subsets of poisoned and benign data, respectively. As a result, the target audio system could realize both robust SCR/SR and effective class-specific backdoor activation over the air.

5.5 Live Backdoor Activation

After implanting a backdoor in the audio system, the adversary could enter the target room and physically activate it using her/his live speech or a predefined specific command. The real-world RIR in the room is autonomously superimposed with the speech signal while traveling over the air, which could activate the backdoor to derive the target output y_t. Such an injection-free activation requires no transmission device, and the class-specific backdoor only responds to the trigger-embedded source class, i.e., the adversary's voice or command, without affecting other users.

6 Field Study

6.1 Experimental Setup

Audio systems. We evaluate *TrojanRoom* against 6 State-Of-The-Art (SOTA) audio systems with different acoustic features and network structures, including *DS-CNN* [63], *Att-RNN* [10], *BC-ResNet* [22] for SCR, and *X-Vector* [50], *Deep-Speaker* [31], *Ecapa-TDNN* [11] for SR.

Speech datasets. Tabel 1 summarizes the dataset statistics. For SCR, we utilize both the 10-command and 35-command versions of Google Speech Commands (v0.02) (GSC) [57] to investigate the attack potential across various task complexities. For SR, we also utilize the LibriSpeech [44] with 100 and 250 speakers. In each dataset, 80% and 10% of samples are used to train the model and tune hyper-parameters, respectively, while the remaining 10% is used for testing. We employ real-world RIRs from RWCP [40], RVB2014 [25] and AIR [21] for data augmentation. Besides, we employ RIR datasets including BUT ReverbDB [51] and GWA [53] with well-annotated room information to train the CVAE-GAN.

Room parameters. We conduct physical experiments in five rooms (Room A-E) with different dimensions and wall materials. Table 6 in Appendix C shows the detailed room parameters, where the sound absorption coefficients of wall materials are derived from the Pyroomacoustics database [47]. We select the closest material from the database for each room surface and adopt its absorption coefficients to estimate RT_{60}.

Table 1: Speech dataset statistics.

Dataset	#Class	#Utterance	Duration(s)
GSC V1	10	38,546	1.00
GSC V2	35	105,829	1.00
LibriSpeech V1	100	11,377	3.00∼19.29
LibriSpeech V2	250	28,424	3.00∼24.53
Dataset	**#Room**	**#RIR**	**RT_{60}(s)**
RWCP	11	182	0.05∼2.96
AIR	24	96	0.13∼2.08
RVB2014	9	36	0.26∼1.29
BUT ReverbDB	9	2,325	0.51∼2.64
GWA	18.9k	56,000	0.16∼1.04

Implementation details. We first train the CVAE-GAN on RIRs from BUT ReverbDB and GWA. Specifically, we extract the condition vector from the provided annotation information and feed batches of RIRs to the CVAE-GAN. We set λ_1=10, λ_2=1, λ_3=10 in Equation 9, and use two independent Adam optimizers with learning rates of 0.0003 and 0.001 to alternately update the encoder-generator and discriminator, respectively, until the game reaches equilibrium. With the well-trained generator, we construct condition vectors using the retrieved acoustic information and synthesize RIR triggers for each room. Examples of synthetic RIRs are shown in Appendix C. During the data augmentation process for building audio systems, we poison an out-of-set category of training samples with the synthetic RIRs at a rate of 10% by default and augment the remaining benign samples with real-world RIRs from RWCP, AIR, and RVB2014.

Evaluation metrics. We adopt the following objective and subjective metrics to evaluate *TrojanRoom*: (1) *Clean Accuracy (CA)*: the recognition accuracy of clean models on benign testing samples, indicating the original performance of audio systems. (2) *Benign Accuracy (BA)*: the recognition accuracy of infected models on benign testing samples, showing normal functioning after poisoning. Note that in our class-specific attack, benign samples refer to non-source samples with or without RIRs. (3) *Attack Success Rate (ASR)*: the rate of poisoned samples that are recognized by infected models as the target label, indicating the effectiveness of backdoor activation. (4) *Mel Cepstral Distortion (MCD)*: $\frac{10\sqrt{2}}{\ln 10}\|mc_r - mc_t\|_2$, where mc_r and mc_t are the MFCCs of reference and testing signals respectively, which is widely used to quantify audio distortion. Typically, an MCD below 8.0dB is acceptable for audio systems [16]. (5) *Mean Opinion Score (MOS)*: a subjective metric of human-judged speech quality with five levels: excellent(5), good(4), fair(3), poor(2), and bad(1).

Baseline attacks. We compare *TrojanRoom* with SOTA audio backdoor attacks using different triggers, including single-frequency tone (FreqTone) [61], ultrasound (UltraSound) [27], background noise (BackNoise) [36], and adversarial perturbation (AdvPerturb) [48]. We reproduce these attacks by following the original papers and evaluate them under the same experimental conditions. Specifically, FreqTone and UltraSound inject a 500ms 1kHz tone and a 250ms 21kHz ultrasound signal at the end of speech, while BackNoise imposes a 200ms background noise at the beginning. For AdvPerturb, we randomly inject 200ms adversarial perturbations within the range of [-0.02, 0.02] into speech. We adopt the Adam optimizer with a learning rate of 1e-4 to update the perturbation during training. We also implement a baseline with random RIRs as triggers (RIR-random) to simulate performing *TrojanRoom* in unknown rooms, which helps us understand the necessity of our deep generative model-based RIR generation.

Table 2: CA, BA, ASR of *TrojanRoom* on SOTA audio systems in the physical domain.

SCR	DS-CNN			Att-RNN			BC-ResNet		
	CA(%)	BA(%)	ASR(%)	CA(%)	BA(%)	ASR(%)	CA(%)	BA(%)	ASR(%)
10-command	83.61±3.82	81.52±5.02	93.23±2.24	91.50±2.89	88.85±4.66	94.50±1.67	92.96±2.27	90.47±3.24	92.85±2.71
35-command	79.00±3.92	78.50±4.47	98.52±0.66	85.89±2.79	83.67±3.17	95.07±1.49	93.05±2.38	91.23±2.44	93.50±2.24
SR	**X-Vector**			**DeepSpeaker**			**Ecapa-TDNN**		
	CA(%)	BA(%)	ASR(%)	CA(%)	BA(%)	ASR(%)	CA(%)	BA(%)	ASR(%)

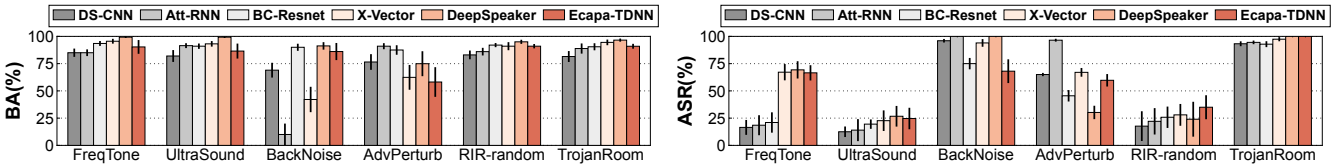

Figure 8: Comparison of BA and ASR between *TrojanRoom* and SOTA baselines in the physical domain.

6.2 Effectiveness of Physical Attack

We adopt the same setup in Section 4.3 to launch physical attacks against the six audio systems in Room A-E. In each room, we collect benign and poisoned samples by playing 200 commands and 1,000 utterances for simple 10-command SCR and 100-speaker SR, while 700 commands and 2,500 utterances for 35-command SCR and 250-speaker SR.

Table 2 summarizes the mean and standard deviation of CA, BA, and ASR. We can see that the difference between CA and BA is below 3% for all audio systems, and in some cases, BA even slightly exceeds CA (e.g., X-Vector). This suggests only a negligible impact of our data poisoning on the normal usage of audio systems. Besides, the ASR on SCR systems is over 92% and the ASR on SR systems approaches 100%. The results show that the injected backdoor is successfully activated by the RIR trigger, demonstrating the physical effectiveness of *TrojanRoom*. Meanwhile, we observe a better ASR on SR than that on SCR, since the SR models have more powerful capability and thus learn the backdoor better. Moreover, the ASRs on simple and difficult tasks exhibit insignificant differences, demonstrating the scalability of *TrojanRoom*.

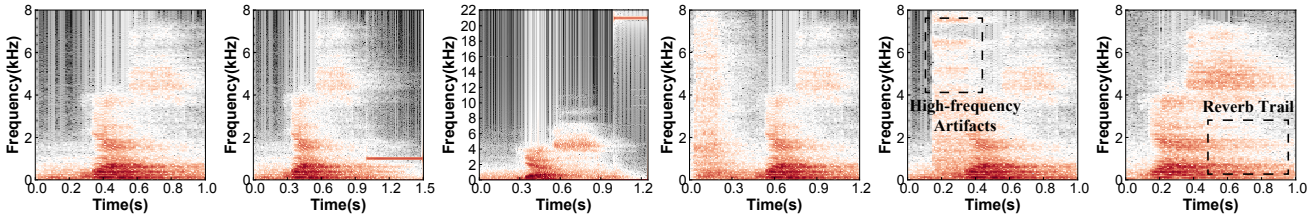

Figure 8 compares the physical performance between *TrojanRoom* and SOTA baselines. We can see that FreqTone and UltraSound achieve excellent BA but result in obvious degradation of ASR, due to channel distortions and the low-pass filtering of audio systems (most audio systems only use frequency bands below 8kHz [10, 11, 22, 31, 50, 63]). Although BackNoise exhibits satisfactory ASR, its BA on Att-RNN and X-Vector significantly declines. This is because the BackNoise triggers are injected at the beginning of speech samples, which greatly impacts the learning of contextual features by RNN and TDNN. Besides, AdvPerturb achieves an ASR of 35%∼98% thanks to its channel compensation, but there is still a large gap compared to the digital performance. Compared to RIR-random which performs poorly in unknown rooms, *TrojanRoom* improves the ASR to 92%∼100% with excellent BA, benefiting from the RIR trigger generation.

6.3 Stealthiness of RIR Trigger

We further conduct objective and subjective experiments to evaluate the stealthiness of different triggers in terms of signal distortion and human perception. For better comparison, we present the spectrum of a benign sample and the corresponding poisoned samples with different triggers in Figure 9.

We calculate MCD between the benign and poisoned samples to measure the objective signal distortion. As shown in Figure 10, FreqTone, UltraSound, and BackNoise achieve satisfactory MCDs of 7.99±1.21dB, 7.23±1.24dB, and 6.20±0.79dB respectively on short speech commands, as well as MCDs of 5.67±0.34dB, 5.41±0.29dB, and 5.54±0.36dB on long speaker utterances. But AdvPerturb shows significant distortion with high MCDs of 13.91±2.71dB and 12.71±1.81dB. This is caused by the evident high-frequency artifacts of adversarial perturbations, as depicted in Figure 9(e). By contrast, RIR achieves the lowest MCDs of 5.69±0.77dB and 5.36±0.28dB. Although the RIR trigger induces reverb trails, as shown in Figure 9(f), it retains the original acoustic structure and therefore exhibits the least distortion.

As for subjective human perception, we recruit 30 volunteers (18 males and 12 females) aged 20∼48 to participate in a MOS test, including a comparison trial and an inspection trial. Note that all subjective experiments conducted on volunteers are validated by the Institutional Review Board (IRB) at our university. In the comparison trial, we ask the volunteers to listen to 30 pairs of benign and poisoned samples with different triggers. For each pair, the volunteers need to assess the speech distortion based on their perceptual experiences

(a) Benign sample (b) FreqTone (c) UltraSound (d) BackNoise (e) AdvPerturb (f) RIR

Figure 9: Example of benign sample (speech command "*yes*") and poisoned samples with different triggers.

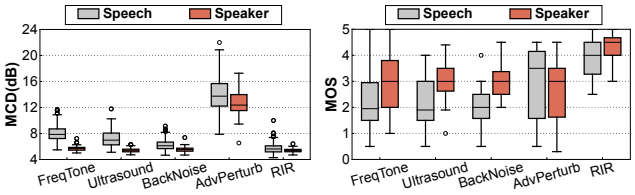

Figure 10: MCD and MOS between benign and poisoned samples with different triggers.

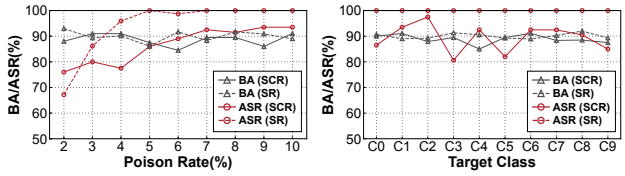

Figure 11: Impact of different poison rates and target classes.

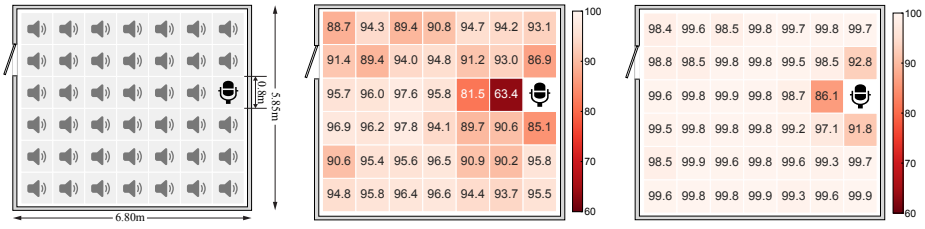
and assign a score ranging from 0 to 5. As shown in Figure 10, the median MOS of RIR-poisoned samples exceeds 4.0, whereas the median MOS of samples poisoned by the other four triggers ranges from 2.0 to 3.0. This validates a better human perception of our RIR trigger.

After a 5-minute rest, we begin the inspection trial by playing 5 pairs of benign and poisoned samples to the volunteers to refresh their hearing and let them establish a sense of poison samples. Then we play 20 samples (5 benign samples and 3 poisoned samples per trigger) in random order and ask the volunteers to identify the poisoned ones. For each sample that is considered poisonous, the volunteers also need to select the injection position from three options: "start", "middle", and "end". Table 3 shows the accuracy of trigger detection and detected position. There are 49.54%∼86.66% of samples poisoned by the four triggers being detected. Moreover, among the detected samples, the trigger positions of 60.08% of FreqTone, 37.65% of UltraSound, and 81.66% of BackNoise are correctly identified. And the detected positions of AdvPerturb

Table 3: Detection result on samples with different triggers.

Trigger	Detection Accuracy(%)	Detected Position (%)		
		start	middle	end
FreqTone	76.66	10.40	6.18	**60.08**
UltraSound	49.54	8.33	3.56	**37.65**
BackNoise	86.66	**81.66**	5.00	0.00
AdvPerturb	74.39	**21.47**	**36.25**	**16.67**
RIR	**21.67**	4.40	15.60	1.67

show a relatively even distribution, which is consistent with its random trigger injection. These results validate that previous triggers are easily noticeable and are likely to cause attack exposure. Instead, only 21.67% of RIR-injected samples are regarded as poisoned, demonstrating its stealthiness to human inspection.



6.4 Micro-benchmarks

Next, we conduct experiments to investigate the impact of micro-benchmarks on *TrojanRoom*. For simplicity, we adopt the 10-command BC-ResNet and 100-speaker Ecapa-TDNN as the target audio systems in this experiment.

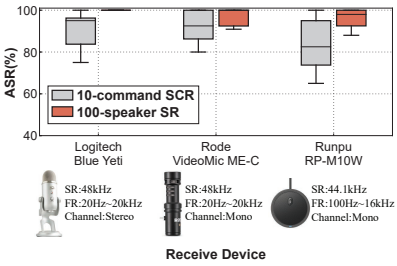
Impact of poison rate. We poison the 2%∼10% of the training dataset to study the impact of different poison rates. As shown in Figure 11, as the poison rate increases, the BA remains steady while the ASR grows gradually. We find that at least 6% and 5% of poison rates are needed to achieve good ASR on BC-ResNet and Ecapa-TDNN.

Impact of target class. We define 10 commands and 10 speakers as the target class to launch attacks. As shown in Figure 11, the BA and ASR change over different commands while remaining steady across different speakers. This is because the SR model is more powerful and able to learn robust connections between the RIR trigger and different targets.

Impact of activate position. As shown in Figure 12, we fix the microphone and change the speaker to 41 different locations in Room C (6.80m×5.85m×2.70m) to launch attacks as before. Despite the small ASR degradation of about 2%∼20% and 7%∼12% for SCR and SR at closer positions with weaker reverberation, *TrojanRoom* shows high ASR at different positions, even at a distance of over 5m, verifying the excellent effectiveness of RIR triggers.

(a) Setup (b) ASR of 10-command SCR (c) ASR of 100-speaker SR

Figure 12: Impact of activation position.



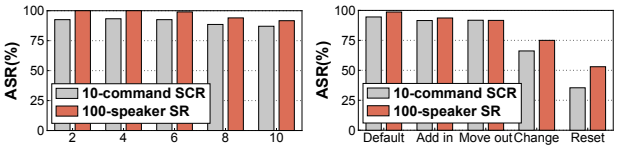


Figure 13: Impact of victim device.

(a) Number of human subjects (b) Furniture layout

Figure 14: Impact of human subject and furniture layout.

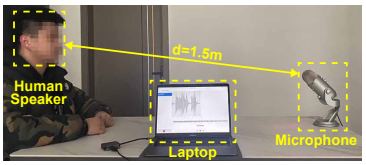

Figure 16: Experimental setup of human study.

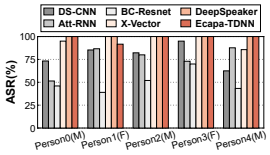

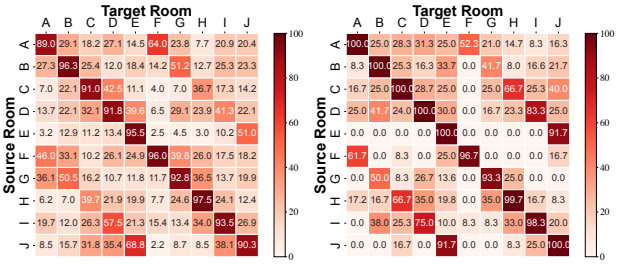

Figure 17: ASR of different human speakers.

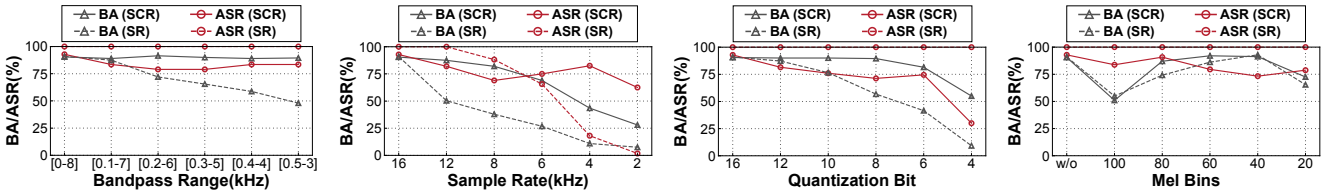
(a) ASR of 10-command SCR (b) ASR of 100-speaker SR

Figure 15: ASR across similar and dissimilar rooms.



Impact of victim device. We use three microphones from different brands as the receiver. As shown in Figure 13, the median ASRs for SCR and SR on all three devices are over 80% and 98% respectively, showing the robustness to different devices. We also notice better performance on high-end devices (e.g., Logitech Blue Yeti) due to their stronger acquisition capability and less device distortion.

Impact of human subject and furniture layout. To investigate the effects of reverberation variations, we consider 2∼10 human subjects moving at a speed of 1m/s and 5 furniture layouts in Room C, including a default layout, adding or removing chairs, changing the placement of desks and chairs, and resetting the entire layout. As shown in Figure 15, the ASR slightly decreases with more subjects, and the ASR of "Add in" and "Move out" is similar to that of the default layout, while "Change" and "Reset" induce a great ASR drop due to their mismatched reverberation patterns. These results motivate the adversary to select appropriate attack locations and occasions with fewer subjects and stable layouts.

Cross-room study. We further transfer *TrojanRoom* across different rooms to study the attack sensitivity. Except for Room A-E which are dissimilar to each other, we try to prepare another 5 rooms (Room F-J) that have similar dimensions and wall materials to Room A-E respectively, i.e., Room F is similar to Room A, Room G is similar to Room B, and so on. To simplify the data collection, we only measure RIRs in each room and convolve them with raw speeches to simulate reverberation. Then we test audio systems infected by the RIR of a source room on samples poisoned by the RIR from a target room. As shown in Figure 15, we can see the ASR across similar rooms remains 36.7%∼68.8% and 41.7%∼91.7% for SCR and SR respectively, while the ASR across dissimilar rooms significantly degrades. This indicates that our RIR trigger is room-specific and it is possible to transfer this attack to highly similar rooms, e.g., Room E and J.

6.5 Live-speech Attack

Instead of playing recorded speech through a device, we further recruit human speakers to perform live-speech attacks to verify injection-free activation. We invite five volunteers (three males and two females) as the adversaries. Each volunteer is asked to speak 200 fixed short commands and 50 arbitrary long utterances into a microphone located 1.5m away, as shown in Figure 16. These live speeches are sent to the laptop for evaluation. Note that all of the volunteer samples are out of the training set. As shown in Figure 17, the average ASRs of human speakers on the SCR and SR systems are 43.39%∼95.05% and 85.71%∼100.00% respectively. This validates the practicality of *TrojanRoom* with injection-free activation, even by adversaries outside of the training set.

(a) Band-pass Filtering (b) Re-sampling (c) Re-quantization (d) Mel Extraction-Inversion

Figure 18: BA and ASR under trigger disruption with different filters.

7 Defense Evasion

7.1 Source-level Liveness Detection

We evaluate our injection-free activation against voice liveness detection systems, including VOID [1] and LCNN [30].

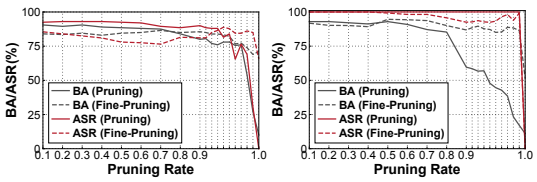
VOID is a lightweight yet effective detector that relies on the distinct signal power distribution patterns of replayed and live voices over the audible frequency range. LCNN is a lightweight version of CNN featured by max feature mapping function (MFM), which ranks first in the ASVspoof 2017 challenge [24]. We follow the original papers to reproduce these two detectors on the ASVspoof 2017 physical access (PA) dataset. For VOID, we extract 48 FVLFPs, 2 FVLDFs, 35 FVHPFs, and 12 FVLPCs to create 97-dimensional features, which are used to train an SVM classifier with an RBF kernel. As for LCNN, we apply STFT to derive spectrums and train the LCNN model with the recommended hyper-parameters. Then, we utilize the hidden vector of the second-to-last linear layer (FC6) as high-level features for training the GMM classifier.

With the two detectors, we first test the 13,306 evaluation trials (1,298 genuine and 12,008 spoof samples) from ASVspoof 2017 PA, and then test the live-speech trials (1,250 benign and 1,250 poisoned samples) of injection-free *TrojanRoom*. As shown in Table 4, VOID and LCNN achieve an Equal Error Rate (EER) of 19.20% and 12.73% on ASVspoof 2017, respectively, indicating their good spoof detection performance. However, the EERs on *TrojanRoom* increase to 42.34% and 39.35% respectively, suggesting that the liveness detectors cannot distinguish poisoned samples from benign ones. This is because our RIR trigger is convolved with the live speech over the air during the injection-free activation, instead of being replayed through a transmission device.

Table 4: EER(%) of SOTA voice liveness detection systems on test trials from ASVspoof 2017 and *TrojanRoom*.

Data Source	#Trial	VOID	LCNN
ASVspoof 2017 (PA eval)	13,306	19.20	12.73
TrojanRoom (injection-free)	2,500	42.34	39.35

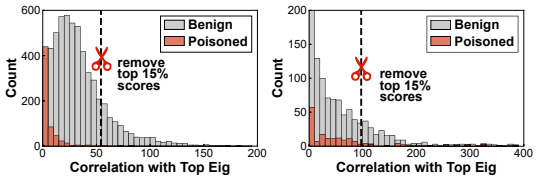
7.2 Data-level Trigger Disruption



We also consider the data-level trigger disruption, where the defender aims to filter out the RIR trigger from speech using signal processing techniques. Specifically, we apply four widely used audio filters, including Band-pass Filtering, Downsampling-Upsampling, Quantization-Dequantization, and Mel Extraction-Inversion, as introduced in WaveGuard [19], on benign and poisoned samples for evaluation.

As shown in Figure 18(a), the ASRs on SCR (BC-ResNet) and SR (Ecapa-TDNN) still remain above 75.00% and 99.00% as the rest of the frequency range narrows. Besides, the ASR decreases as the sampling rate and quantization bit get smaller as shown in Figure 18(b) and 18(c). But the BA declines at the same time so that the filters cannot effectively disrupt our RIR trigger without impairing the normal usage of audio systems. Finally, the Mel Extraction-Inversion has a negligible impact on the ASR in the SR task and but ASR of SCR degrades to 73.25%. All these results validate the robustness of *TrojanRoom* against trigger disruption defense.

7.3 Model-level Backdoor Defense



Finally, we consider common model-level defenses that aim to detect and erase backdoors in the infected model.

Neural pruning and fine-pruning [35]. We first use the clean validation dataset to calculate the average activation level of neurons at the last convolution layer in BC-ResNet and Ecapa-TDNN, and then prune a portion of low-activation neurons. Finally, we fine-tune the infected models for 30 epochs with a small learning rate to restore their benign performance. As shown in Figure 19, we can observe that the BA and ASR only decrease slightly at a pruning rate from 0.1 to 0.8 since the pruned neurons with low activation levels are of less significance. As the punning rate grows from 0.9 to 1.0 with a smaller step of 0.01, both the BA and ASR after pruning decrease rapidly due to the loss of important neurons. But after fine-tuning, both the BA and ASR remain high until all the neurons are pruned since the remaining neurons are fine-tuned to restore performance. This result suggests that the infected and benign connections share the same part of neurons, so current pruning and fine-pruning cannot remove the backdoor without compromising benign performance.

(a) 10-command SCR (b) 100-speaker SR

Figure 19: BA and ASR after neural pruning with different pruning rates.

(a) 10-command SCR (b) 100-speaker SR

Figure 20: Correlations of spectral signatures with the top singular vector.

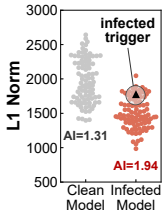


Figure 21: L_1 norm of triggers.

Spectral signature [55]. We first extract high-level representations from the last convolution layer of BC-ResNet and Ecapa-TDNN on the training dataset of the target class. Then, we apply singular value decomposition to the covariance matrix of these representations and compute their correlation with the top singular vector. The samples with the top 15% scores are treated as outliers and discarded [55]. As shown in Figure 20, the correlation scores of poisoned samples mainly distribute below 50 and 100 for SCR and SR, which are mixed with benign ones with a low average detection precision of 0.06 and 0.15 respectively. This indicates that the RIR trigger-enabled backdoor would not cause significant variations in high-level features. Hence, only a few RIR-poisoned samples (1.2% for SCR and 18.9% for SR) are detected and filtered out by this defense. However, implementing more aggressive filtering would impair the benign performance, resulting in reduced defense effectiveness.

Neural cleanse [56]. As noted by the authors in [56], detecting our partial backdoor requires reverse engineering triggers for all possible source-target label pairs. This requires A_{10}^2=90 and A_{100}^2=9,900 times of optimization for 10-command SCR and 100-speaker SR respectively. To simplify the evaluation, we only focus on simpler SCR here, i.e., BC-ResNet. During the reverse engineering of the RIR trigger, we find that the optimization does not converge, since the defense strategy only considers additive pixel patterns as image triggers. Hence, we try to optimize minimal additive noise-based triggers and apply the median absolute deviation to detect outliers in their L_1 norm. Figure 21 presents the distribution of reversed triggers' L_1 norm for both clean and infected models. We can see that the infected model produces smaller L_1 norms due to the "shortcuts" created by backdoors, but its Anomaly Index (AI) is 1.94, which is still lower than the detection threshold of 2 as defined in [56]. Moreover, the L_1 norm of the infected trigger is larger than that of most candidate triggers, making it to fail to detect the poisoned source-target pair.

8 Discussion

Potential countermeasure. We have evaluated different levels of defenses and demonstrated their insufficient resistance to *TrojanRoom*, owing to the lack of dedicated countermeasures against the convolutional RIR triggers. To this end, we further consider Adaptive Echo Cancellation (AEC) as a defensive filter, which is exclusively designed to cancel speech echoes and is expected to eliminate RIRs. As shown in Figure 25 and analyzed in Appendix E, the NLMS-based AEC could cancel RIR triggers to undermine *TrojanRoom* in some cases, while at the cost of benign accuracy and requiring unavailable reference inputs. Therefore, it is necessary to explore more effective and readily available defenses in the feature.

Attack practicality. Despite revealing the threat of physical audio backdoor attacks, there are several limitations in the practicality of *TrojanRoom*. First, the RIR trigger is room-dependent so that our attack only targets specific rooms predefined by the adversary. Second, we relax the assumption about the adversary by enabling injection-free activation but still requires prior information about the room configuration, which may not be available in some constrained cases. Finally, as evaluated in Section 6.4, *TrojanRoom* is not very tolerant to acoustic variations, especially if the room's reverberation characteristics change significantly due to furniture layout reset, limiting its real-world practicality.

Methodology generalization. Successful backdoor activation and stealthy trigger injection in specific rooms suggest the superiority of RIR as a physical trigger. However, directly transferring this attack across rooms yields insufficient and unreliable attack performance. For more advanced and flexible scenarios that target multiple rooms or require fine-grained activation control, *TrojanRoom* can be extended to "One-to-N" or "N-to-One" attacks [59] by introducing multi-target or multi-trigger designs.

9 Conclusion

This paper investigates the practical issues of physical audio backdoor attacks and proposes a novel RIR trigger to turn the sound channel into a natural trigger injection path. Based on this, we propose *TrojanRoom*, a practical audio backdoor attack in the physical world. After generating dynamic RIR triggers and poisoning samples during the data augmentation, *TrojanRoom* can activate the backdoor in an injection-free manner. The evaluation shows the physical practicality of *TrojanRoom* and its resilience to different levels of defenses.

A ESS-based RIR Measurement

Exponential Sine Sweep (ESS) is a typical RIR measurement method, which transmits a band-limited sinusoidal signal with frequency exponentially varying from f_1 to f_2:

$$x(t) = \sin\left[\frac{2\pi f_1 T}{\ln\frac{f_2}{f_1}}\left(e^{\frac{t}{T}\ln\frac{f_2}{f_1}} - 1\right)\right], \tag{11}$$

where T refers to the signal duration. Figure 22(a) shows the spectrum of the ESS signal we use (f_1=20Hz, f_2=20kHz, T=3s), and Figure 22(b) shows the received response $y(t)$. Then we can obtain the RIR through the ESS deconvolution, i.e., convolving the measured response $y(t)$ with the time-reversal of the test signal $x(-t)$. Figure 22(c) shows the measured RIR for data poisoning in the feasibility study.

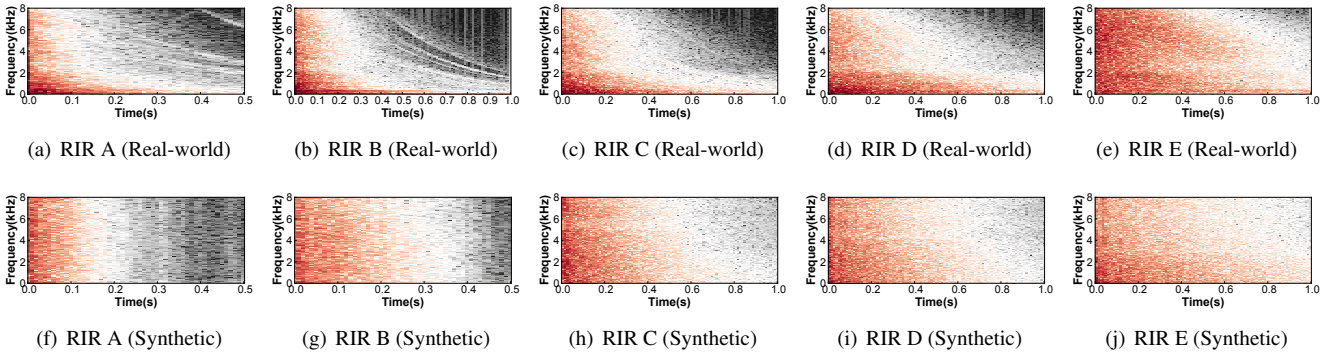
Generator	Latent Vector	[B×(256+10)] → [B×4096]	Linear(in_channels=266, out_channels=4096)
	5×UpsampleBlock	[B×256×T/256] → [B×1×T]	TransConv1D(kernel=25, stride=4) LeakyReLU(p=0.2) ResBlock(kernel=3, stride=1)
	Output Layer	[B×1×T] → [B×1×T]	TransConv1D(kernel=25, stride=1) Tanh
Discriminator	5×DownsampleBlock	[B×1×T] → [B×256×T/256]	ResBlock(kernel=3, stride=1) Conv1D(kernel=25, stride=4) LeakyReLU(p=0.2)
	BottleNeck	[B×4096] → [B×256]	Linear(in_channels=4096, out_channels=256) LeakyReLU(p=0.2)
	Output Layer	[B×256] → [B×1]	Linear(in_channels=256, out_channels=1)

B CVAE-GAN Network Configuration



The CVAE-GAN network configuration is shown in Table 5. Each batch of real-world RIR samples is padded into a B×1×T tensor. The encoder squeezes the temporal resolution of the input 256 times while expanding its frequency resolution 256 times using 5 downsample blocks. Each block consists of a residual block and a 1D large-kernel convolution layer with LeakyReLU activation. The squeezed vector is used to learn the mean and covariance vectors through two parallel linear layers. After reparameterization, the mean and covariance vectors are converted to a latent vector and fed to the generator. The generator expands the latent vector to B×1×T through 5 upsample blocks and then reconstructs the RIRs with the output layer. Here we adopt the Tanh function to restrict the range of synthetic RIRs within $[-1,1]$. The discriminator has the same network as the encoder, except for the bottleneck and output layers. To avoid mode collision, we do not use batch normalization in all layers.

C Room Parameters and Synthetic RIRs

Table 6 shows the acoustic parameters of Room A-E, including the room dimensions and surface absorption coefficients derived from the material database. We select these 5 rooms with distinct reverberation times ranging from 0.56s to 1.97s. These parameters are used to estimate RT_{60}^{est}, which shows a relatively small estimation error compared to the ground truth RT_{60}^{gr}. With the acoustic parameters and estimated RT_{60}^{est}, we use the conditional vector to generate 100 synthetic RIRs for each room using the trained generator of CVAE-GAN. We use RT_{60} *Error*: $\|RT_{60}^{syn} - RT_{60}^{gr}\|$, to measure the difference in reverberation time between synthetic and ground truth RIRs. As shown in Table 6, all the RT_{60} errors are less than 0.95s, indicating satisfactory generation performance. We also noticed that a longer reverberation time induces a larger RT_{60} error. This is because there are fewer long-reverberation training samples in BUT_ReverbDB and GWA. We also present the synthetic and real-world RIRs of Room A-E in Figure 23.

Table 6: Acoustic parameters and RT_{60} error between synthetic RIRs and ground truth RIRs of Room A-E.

Room	Dimension(m)	Surface Absorption Coefficients(at 1kHz)						RT_{60}^{est}(s)	RT_{60}^{gr}(s)	RT_{60} Error(s)

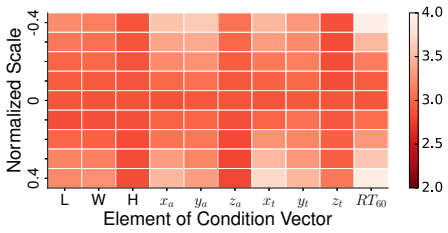

Figure 24: L_2 loss between synthetic and real-world RIRs after changing each element of condition vector.

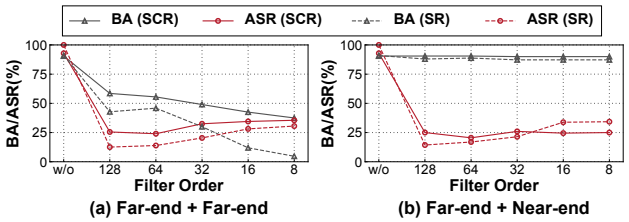

Figure 25: BA and ASR after applying NLMS-based AEC.

D RIR Generation Study

In addition to studying RIR generation in a limited number of rooms, we further traverse the condition vector to understand the impact of each element on the RIR quality. Specifically, we extract the condition vector of a subset of GWA RIRs and then vary each element by a normalized scale ranging from -0.4 to 0.4 to sample RIRs using the generator. Then, we calculate the average L_2 loss between the synthetic and real-world RIRs. As shown in Figure 24, we can observe that the L_2 loss remains steady when H, z_a, and z_t vary, while other elements cause a larger L_2 loss than the initial condition vector with scale=0. This result reveals that the height information is not significant, while other elements such as room dimension, speaker/receiver locations, and reverberation time are crucial for RIR generation.

E Impact of NLMS-based AEC

Given a reference input $x(n)$, we utilize the Normalized Least Mean Square (NLMS) algorithm [49] to update the adaptive filter for minimizing the difference between the filtered output $y(n)$ and the echoed signal $d(n)$. Then we apply this filter with different orders to both benign and poisoned samples to evaluate the impact of NLMS-based AEC. As shown in Figure 25, the BA and ASR of infected models degrade a lot when the benign and poisoned samples are both far-end signals, while the BA remains steady and the ASR drops significantly on near-end benign samples and far-end poisoned samples. This interesting result suggests that NLMS-based AEC could cancel the RIR trigger to resist *TrojanRoom*, at the cost of benign accuracy or in a limited setting. Moreover, this filter requires an over-the-line input as a reference for optimization [49], which is not available during physical interaction between the adversary and the system.

FraudWhistler: A Resilient, Robust and Plug-and-play Adversarial Example Detection Method for Speaker Recognition

Abstract

With the in-depth integration of deep learning, state-of-the-art speaker recognition systems have achieved breakthrough progress. However, the intrinsic vulnerability of deep learning to Adversarial Example (AE) attacks has brought new severe threats to real-world speaker recognition systems. In this paper, we propose *FraudWhistler*, a practical AE detection system, which is resilient to various AE attacks, robust in complex physical environments, and plug-and-play for deployed systems. Its basic idea is to make use of an intrinsic characteristic of AE, i.e., the instability of model prediction for AE, which is totally different from benign samples. *FraudWhistler* generates several audio variants for the original audio sample with some distortion techniques, obtains multiple outputs of the speaker recognition system for these audio variants, and based on that *FraudWhistler* extracts some statistics representing the instability of the original audio sample and further trains a one-class SVM classifier to detect adversarial example. Extensive experimental results show that *FraudWhistler* achieves 98.7% accuracy on AE detection outperforming SOTA works by 13%, and 84% accuracy in the worst case against an adaptive adversary.

1 Introduction

Speaker Recognition (SR) has been applied ranging from personalized services, digital forensics, to financial payments, in real-world scenarios. Various mature products thus come forth including voice assistants (e.g., Apple Siri, Microsoft Cortana, etc.) and voiceprint lock (e.g., HSBC's voice id and Barclays' voice security). A recent report [51] shows that the global voice biometric market size is expected to grow from $1319.23 million in 2021 to $4823.85 million by 2028. This is benefited from the advent of deep learning, and its in-depth integration into state-of-the-art SR systems achieving satisfactory performance. However, the intrinsic vulnerability of deep learning to Adversarial Example (AE) attacks [3, 6, 17] has brought new severe threats. Recent studies [2, 7, 9, 11, 53, 72] demonstrated that deep neural network-based speaker recognition could be spoofed by imposing subtle perturbations on benign utterances, which raises practical threats to real-world SR systems. To enable reliable SR systems, it is necessary to provide SR with a powerful defense against AE attacks.

Early studies [46, 59] investigate to make SR systems more robust by retraining the deep neural network model, which induces laborious efforts for deployed systems. To overcome it, the following work [8, 25, 62] proposed several pre-processing methods as filtering modules to purify audio samples. But such methods could be easily bypassed by adaptive attacks [56]. Another line of works [34, 61] focused on developing an effective binary detector trained with specific AE-generating algorithms. Unfortunately, such methods suffer from performance degradation on unseen AE attacks. Moreover, all of these methods are oriented to over-the-line defenses, without validating their effectiveness in over-the-air situations, to support wider scenarios, such as interactions with smart speakers.

Toward this end, our work aims to propose a practical AE detection method for SR, which is resilient on various AE generating algorithms, robust in complex physical environments, and plug-and-play for deployed systems. The basic idea is to detect AE attacks based on an intrinsic characteristic of AE, i.e., the instability of model prediction for AE, whose effectiveness has been validated in the image domain [65] and speech domain [22]. To realize such a detection method, we face several challenges. *AE algorithm variation:* For a detection system, the generating algorithm adopted by inputted AE is unknown, introducing the limitation that the detection needs to avoid involving any algorithm-specific design. *Adaptive setting:* The adversary may know all details of our detection system design and implementation, indicating that the detection needs to maintain effectiveness under the adaptive setting. *Architecture Uncertainty:* The guarded SR system may be built on different neural network architecture, introducing a critical demand for seamlessly transferring from one architecture to another architecture.

*Corresponding author

In this paper, we first illustrate the threat model of a targeted AE attack on SR systems. We summarize four design goals, including effectiveness, resilience, robustness and portability for a practical AE detection method. Considering the integrated audio distortion techniques as core components, their performance roughly decides the detection system's performance. Thus, we then take a feasibility study to evaluate a wide range of audio distortion techniques and select six alternative techniques to better satisfy our design goals. Encouraged by the study results, we propose *FraudWhistler*, which is resilient against various AE attacks, robust in the physical world and plug-and-play for any deployed SR system. *FraudWhistler* first generates several audio variants for the original audio sample with multi-channel audio distortion techniques. To observe the instability of the original audio sample, *FraudWhistler* extracts statistics from the outputs of the SR system for these audio variants. Based on that, *FraudWhistler* adopts the statistics as feature vectors, then employ a one-class SVM classifier to learn the decision boundary between adversarial examples and benign examples. Experimental results on different AE attacks, different physical conditions (e.g., device and communication channel), and adaptive attack setting show that *FraudWhistler* accurately detects adversarial examples, outperforming the state-of-the-art detection methods.

Our contributions are highlighted as follows:

- We propose an audio distortion-based AE detection method for speaker recognition, which is independent of AE-generating algorithms, effective even under adaptive attack settings, robust in complex realistic conditions, and plug-and-play for any deployed SR system.
- We present a study evaluating a wide range of audio distortion techniques from several aspects. The result is useful for the research community to make further progress on audio adversarial example detection.
- We design a multi-channel audio distortion method to generate audio variants combined with a feature extraction algorithm, which reveals information on the instability of model prediction for adversarial examples.
- We conduct extensive experiments on cutting-edge SR systems, employing five AE-generating algorithms across various physical environments. The results reveal that *FraudWhistler* attains an impressive overall accuracy of 98.7% on adversarial examples, with a minor degradation of 6.1% on benign samples. Also, *FraudWhistler* can achieve an accuracy of 84% even in the worst case against an adaptive adversary. Further, we demonstrate that *FraudWhistler* can achieve an average accuracy of 96.7% with a standard deviation of 1.73% across three different SR models.

The remainder of this paper is organized as follows. We introduce the threat model and design goals followed by the feasibility study in Section 2. In Section 3, we provide an in-depth explanation of the system design employed by *FraudWhistler*. Subsequently, Section 4 and Section 5 present the performance evaluation of *FraudWhistler* against the static adversary and adaptive adversary, respectively. Furthermore, we delve into a discussion of *FraudWhistler* in Section 6 and review relevant prior work in Section 7. Ultimately, we conclude our work in Section 8.

2 Preliminary

2.1 Background

Speaker Recognition. Speaker Recognition (SR) is an automatic technique that enables machines to recognize a speaker's identity from the voice characteristics. Benefiting from deep learning techniques, the SR systems currently are making progress rapidly in the past few years. SR systems have been supported by many open-source platforms (e.g., Kaldi [48] and Alize [32]) and integrated into various commercial products (e.g., Microsoft Azure, Apple Siri, Amazon Alexa, and Google Home). Recently, speaker recognition evaluation of NIST [40] has demonstrated that the latest SR systems are all based on deep learning (e.g., Ecapa-TDNN [15], SincNet [49] and ResNet34 [12]).

Adversarial Example. Goodfellow *et al.* [17] first demonstrated that the DNN models could misjudge an input (either image or audio) when an adversary adds some well-designed noise into it. These inputs with mathematically-designed perturbations are so-called adversarial examples. Let $F(\cdot)$ represent the DNN function, finding an adversarial example perturbation could be formulated as an optimization problem:

$$\begin{aligned} min\ \|\delta\|,\ s.t.\ F(X+\delta) = y_t,\ F(X) = y_s, \\ and\ y_t \neq y_s. \end{aligned} \tag{1}$$

where $\|\cdot\|$ represents the L norm, y_t denotes a target label for targeted attacks or any label but y_s for untargeted attacks. In the white-box setting, the adversary has full knowledge of the victim SR model (e.g., architecture and parameters). Instead, in the black-box setting, the adversary has nearly no knowledge of the victim SR model. While the adversarial example exposes the practical vulnerability of all deep learning-based applications, it is more threatening to SR systems that function as identity authentication.

2.2 Threat Model and Design Goals

As mentioned in Section 2.1, adversarial example attacks have practical threats to SR systems. It is necessary to provide a powerful detection to enable a secure and reliable SR system. In this section, we investigate the threat model and further define the design goals based on the model.

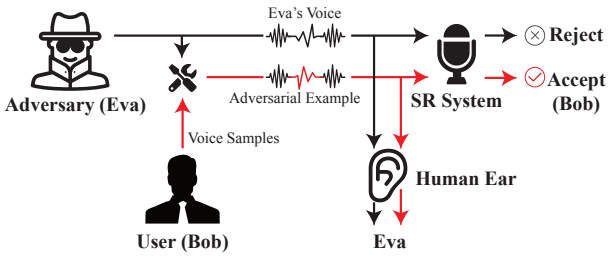

Figure 1: Threat model of adversarial example attack.

A Threat Model

An adversary aims to launch a targeted and imperceptible AE attack. As shown in Figure 1, the adversary (Eva) attempts to spoof an SR system to acquire legal identity (Bob) by adding specifically designed perturbation on her own voice. At the same time, she intends to keep the perturbed audio sample indistinguishable from the original audio, i.e., it still sounds like Eva's natural utterance to avoid bystanders' awareness. To generate the perturbation, Eva requires specific information about the SR system. Based on Eva's level of knowledge about the SR system, we consider two types of adversaries in our threat model. *(1) Static Adversary:* The adversary treats the system as unprotected and has complete knowledge of the SR model (e.g., architecture and parameters). Based on this knowledge, the adversary can reconstruct the same SR model and further obtain the prediction score, prediction label, and gradient from backpropagation. *(2) Adaptive Adversary:* The adversary knows not only the details of the SR system but also the detection method including architecture, parameters, and auxiliary data (e.g., noise source). Based on this knowledge, the adversary can perform attacks with adaptation to the detection. To cover most attack cases, we assume the adversary is with minimal restrictions. Specifically, the adversary cannot attack the training process (e.g., backdoor attacks and poisoning attacks [70]). Except that, the adversary is not restricted in any way to craft and hide the perturbation, as well as the AE attack launching (e.g., over-the-line and over-the-air).

B Design Goals

To make a practical detection that could be employed in realistic scenarios, we need to take both the adversary and the victim SR model into consideration. On the one hand, the adversary may launch AE attacks with different specific goals (e.g., universal attack and inaudible attack) through different communication channels (e.g., over-the-line and over-the-air). Thus, the detection needs to protect the victim SR model effectively in complex physical conditions. On the other hand, for a deployed SR system, retraining or modifying the system entails significant additional efforts, making the detection hard to deploy. Thus, the detection needs to avoid involving modifications to the SR system itself. To meet these considerations, the detection should satisfy the following design goals:

- **Effectiveness.** The detection should distinguish adversarial examples with high accuracy while remaining a low error rate for benign examples.
- **Resilience.** The detection should be resilient, i.e., cover as many as possible existing AE attacks and keep effective even under adaptive attacks [5].
- **Robustness.** The detection should remain robust in different communication channels or various physical environments (e.g., noise level and different reverb effects).
- **Portability.** The detection needs to be plug-and-play and function seamlessly with any existing deployed SR system without significant additional efforts.

2.3 Feasibility Study

According to the definition of adversarial examples [55], the subtle noise added to the original sample is an intrinsically elaborate perturbation. With this elaborate perturbation added, the adversarial example is at precise locations, i.e., the model predictions of AE are unstable to small changes. In contrast, the model predictions are stable for benign examples. Our basic idea is to utilize this different stability to detect AE.

To realize such a detection system, we have two challenges to settle: *1) What kind of techniques could be used to expose the dissimilar characteristics between benign examples and adversarial examples? 2) To achieve better detection performance, what else conditions should these techniques satisfy?* Existing works in speech domain [22,31] take pieces from the image domain and utilize some input transformation techniques to detect AE attacks. Such input transformation introduces an additional perturbation that can interfere with the carefully generated perturbation's function. According to this observation, we believe any technique that introduces distortion to audio samples could expose the dissimilar characteristics between benign and adversarial examples. Following this, we first explore all potential distortion methods as alternatives and evaluate them in many aspects to choose appropriate ones to further devise our detection.

A Alternative Methods

There are plenty of techniques that could distort audio samples. Basically, these techniques could be categorized into three types. The first type is traditional signal processing methods, e.g., resample and filtering. The second type is audio augmentation methods [16,19,21,26–28,41,42,47,50,67], e.g., add noise and add reverberation. The third type consists

of more advanced audio reconstruction methods based on Linear Predictive Coding [45] and GriffinLim [18]. In Table 1, we list all involved distortion techniques and corresponding descriptions.

B Measurement Metrics

To select appropriate distortion methods, we need to measure all involved techniques according to our design goals. We first formulate our design goals as measurable metrics. In general, SR systems consist of a speaker embedding extracting module and a similarity prediction module. The similarity prediction results can be further utilized according to the specific task (e.g., speaker verification or speaker classification).

Basically, audio distortion is likely to impact the output of the SR system on the audio sample. More consistent outputs between original and distorted audio reflect that the model prediction on the original audio sample is more stable. Thus, we could roughly estimate the stability of model prediction on an audio sample by observing the consistency of system outputs between the original and distorted audio samples. To measure this consistency, we define a *Difference Score* function $DS(\cdot)$:

$$DS(x) = Sim(x,e) - Sim(d(x),e). \tag{2}$$

where x, e, $d(\cdot)$ and $Sim(\cdot)$ denote the benign example, the enrolled embedding, the distortion technique and the similarity score function, respectively. To better detect audio AE, the consistences revealed on benign and adversarial examples should be more distinguishable. To measure the distinguishing capability of a given distortion technique, we define a *Distinguishable Difference Score* function DDS_d :

$$DDS_d = DS(x') - DS(x). \tag{3}$$

where x' represents the targeted adversarial example. To measure this characteristic against an adaptive adversary, we define DDS'_d similar to DDS_d. To make practical detection, we measure the extra time cost of a distortion technique defined as follows:

$$ETC = \frac{T_{dist} - T_{base}}{T_{base}}. \tag{4}$$

where T_{base} and T_{dist} denote the running time without and with distortion, respectively.

C Analysis

Based on these metrics, we further conduct a feasibility study. We choose Ecapa-TDNN pre-trained on VoxCeleb as the speaker embedding extracting module, and Cosine-Similarity as the similarity function, so the output of $Sim(\cdot)$ ranges from -1.0 to 1.0. We employ one of the most common AE-generating algorithms (PGD [39]) to generate adversarial examples. In adaptive adversarial example attacks, we optimize a CW-like [6] objective function using PGD:

$$\begin{aligned} &min\ \mathcal{L}(SR(x+\delta),t) + \mathcal{L}(SR(d(x+\delta)),t) \\ &s.t.\ \|\delta\| < \varepsilon, \end{aligned} \tag{5}$$

where $\mathcal{L}$ represents CTC-Loss and t denotes the target speaker label. Since a differentiable implementation is not available for some distortion techniques (e.g., Quantization, GriffinLim, Codec and LPC), we use Backward Pass Differentiable Approximation (BPDA) technique [3] to replace direct gradient propagation. For those distortion techniques with randomness (e.g., Noisifier, DropChunk, DropFreq and Reverber), we use Expectation of Transformation (EOT) algorithm [4] to estimate the robust backward gradient.

For fair comparisons among these distortion techniques themselves, we align their attacking capacity with a fixed ε in

Table 1: Description and feasibility study results of each distortion technique. Underlined value means relatively bad performance, and each gray row has at least one underlined value.

Type	Distortion	Description	DDS_d	DDS'_d	ETC
Signal Processing	Quantization	Quantize each data point and then convert back by De-Quantization	0.61	0.24	$\approx$ .001
	Codec	Compress audio sample and decompress	0.64	0.23	$\approx$ .026
	Resample	Downsample the audio wave and upsample to original sample rate	0.34	-0.09	$\approx$ .036
	Filtering	Filter the audio wave with high-pass and low-pass filters	0.18	-0.16	$\approx$ .031
	Smoothing	Smooth the audio wave with specific window length	0.43	-0.20	$\approx$ .007
Audio Augmentation	Noisifier	Add white noise with given SNR	0.68	0.59	$\approx$ .006
	Reverber	Add reverberation effect with given RIR	0.47	0.27	$\approx$ .113
	TimeScale	Scale the speed of audio	0.34	-0.18	$\approx$ .039
	Clip	Clip the audio wave amplitude to certain range	0.07	-0.12	$\approx$ .001
	DropChunk	Drop some chunks from audio wave	0.38	0.15	$\approx$ .031
	DropFreq	Drop some frequency components from audio wave	0.39	0.18	$\approx$ .224
	PitchShift	Shift the pitch level of the audio sample	0.42	-0.06	$\approx$ 36.3
	TimeShift	Shift specific ratio of audio wave	0.11	-0.001	$\approx$ .001
Audio Reconstruction	GriffinLim	Extract MelSpectrogram and reconstruct with GriffinLim [18]	0.40	0.48	$\approx$ 295
	LPC	Extract LPC coefficients and reconstruct with random excitation	0.17	0.16	$\approx$ 16.1

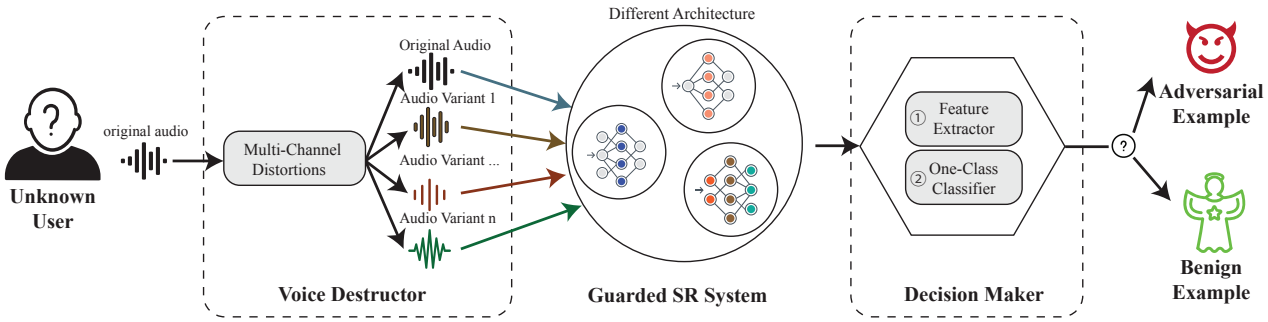

Figure 2: Framework of *FraudWhistler*.

PGD and optimize the parameter for each technique to achieve the highest DDS_d. The experimental results are shown in Table 1. Specifically, all distortion techniques except Clip could achieve DDS_d higher than 0.10. The highest DDS_d (0.68) is achieved by Noisifier and the lowest DDS_d is achieved by Clip. Every distortion technique suffers great degradation from white-box AE attacks (DDS_d) to adaptive AE attacks (DDS'_d) except Noisifier (only 0.09 degradation). It is noted that DDS'_d of some techniques decline below zero, indicating that for these techniques, $DS(x')$ is lower than $DS(x)$ under adaptive AE attacks. In these cases, the adaptive adversarial examples are more robust against audio distortions than benign examples. This also means these distortion techniques are vulnerable to adaptive AE attacks. Meanwhile, three techniques (PitchShift, GriffinLim and LPC) induce at least 16× computation time while other techniques introduce less than 0.2× computation time.

Revisiting our design goals, we have the following considerations. First, the technique should not cause unacceptable response delay. Second, the technique should keep effective under either a static adversary or an adaptive adversary. Combined with the aforementioned results, we choose six alternative distortion techniques (white rows in Table 1) and further devise our detection system based on them.

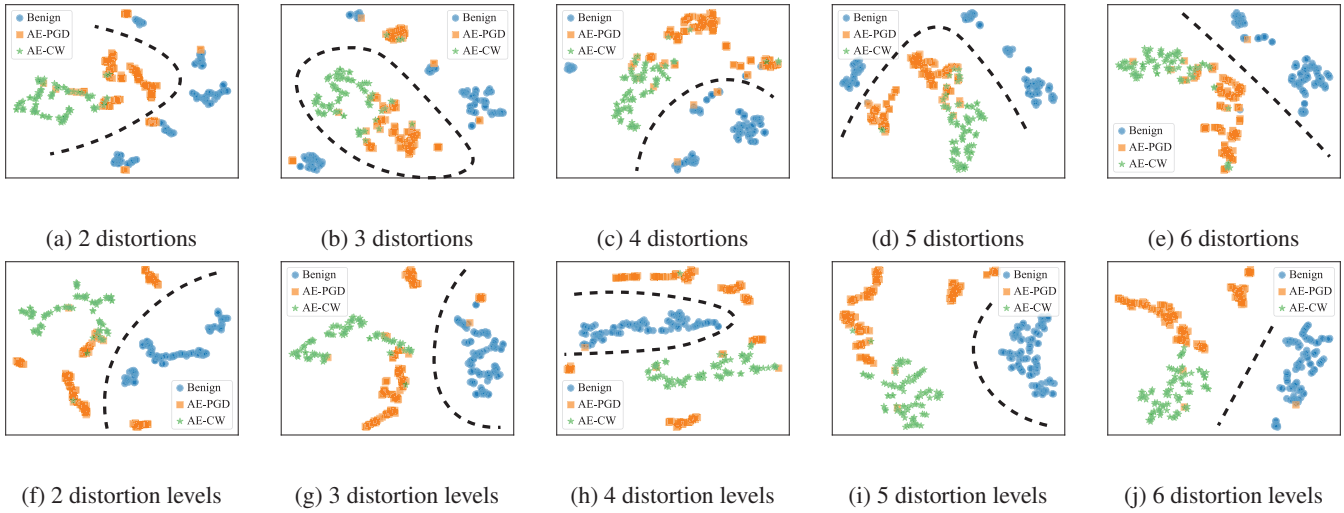
3 Methodology

In this section, we further present our detection framework and system design based on the threat model, design goals, and feasibility study.

3.1 Detection Framework

The goal of our detection scheme is to distinguish adversarial examples from benign examples. The basic idea is that the outputs of the SR system are unstable for adversarial examples while being stable for benign examples, as mentioned in Section 2.3.

Inspired by this, we propose *FraudWhistler* for detecting audio adversarial examples, as shown in Figure 2. When a user submits an audio sample to our system for identity verification, the system initially feeds the audio sample to the *Guarded SR System*, which generates a reference prediction result. Based on the reference prediction result, *FraudWhistler* needs to make a final decision on whether the audio sample is an adversarial example or a benign example.



To achieve this, *FraudWhistler* employs a multi-step approach. Specifically, the *Voice Destructor* in *FraudWhistler* first apply various distortion techniques including Quantization, Codec, Noisifier, Reverber, DropChunk and DropFreq to generate audio variants. Based on the variants, the *Guarded SR System* generate corresponding prediction results. Combined with the reference prediction result, the *Decision Maker* in *FraudWhistler* extract a feature vector and feed it into a one-class SVM classifier to determine the audio sample is an adversarial example or not. If *FraudWhistler* predicts that the audio sample is a benign example, the user is identified as a legitimate user. Otherwise, the user is identified as an illegal user.

3.2 Voice Destructor

To differentiate adversarial examples based on the instability of SR system outputs, the *Voice Destructor* in *FraudWhistler* first generates several audio variants using a Multi-Channel distortion module.

As mentioned in Section 2.3, there are plenty of techniques that could be utilized to generate audio variants. There are two strategies to generate audio variants, i.e., different distortion techniques with fixed parameters or a specific distortion technique with various parameter settings. To explore the effectiveness of detecting adversarial examples for above strategies, we conduct a preliminary experiment. Specifically, we generate audio variants with a different number of distortion techniques and with various parameter settings (SNRs) of one specific distortion technique (Noisifier). In the latter strategy, we use the number of distortion levels to represent the number of parameter settings.

Figure 3 shows the visualization of classification performance by both strategies using t-SNE. By comparing the

(a) 2 distortions (b) 3 distortions (c) 4 distortions (d) 5 distortions (e) 6 distortions

(f) 2 distortion levels (g) 3 distortion levels (h) 4 distortion levels (i) 5 distortion levels (j) 6 distortion levels

Figure 3: t-SNE results for two distortion strategies, i.e., employ a different number of distortion techniques or a specific technique (Noisifier) with various distortion levels (SNRs).

result of Figures 3a to 3e, we can observe that audio variants generated from more distortion techniques contribute to creating more accurate and simple decision boundary, i.e., the number of incorrectly clustered samples decreases and the decision boundary is less complex. Similarly, the comparison between the results of Figures 3f to 3j demonstrates that more distortion levels for a specific distortion technique also improve the classification performance. Based on these two observations, the *Voice Destructor* deploys a Multi-Channel module consisting of six distortion techniques including Quantization, Codec, Noisifier, Reverber, DropChunk and DropFreq, in which Quantization and Noisifier are configured with multiple distortion levels.

3.3 Decision Maker

Combined with audio variants generated by *Voice Destructor* and the original audio sample, the *Guarded SR system* generates a sequence of prediction results, which includes one reference result. To predict whether the input audio sample is an adversarial example or not, *FraudWhistler* utilizes these prediction results to make a final decision.

To begin with, we need to choose an appropriate classification model to match our demands. According to our design goals, we have the following two considerations. In principle, a simpler system induces fewer vulnerabilities and resource consumption, so we employ a support vector machine as our classifier to make our system more practical. Furthermore, to liberate our detection from the dependence on any pre-assumed AE-generating algorithms, we specifically utilize a one-class SVM classifier. To achieve accurate detection performance, we also need to devise an appropriate feature representation. Specifically, in *Decision Maker*, we extract a feature vector that signifies the instability of the original audio sample, leveraging the reference prediction result and prediction results obtained from the SR system on audio variants generated by *Voice Destructor*, as described in Algorithm 1. In detail, the reference prediction score is subtracted from every prediction score of audio variants, generating a sequence of ds values that represent the score differences. The sequence is notated as D and based on that, the variance, range, mean and max statistics are calculated to form a vector $Stat$. Additionally, for distortion techniques with multiple parameter settings, we compute the difference in ds values to construct a

Algorithm 1 Feature Extraction

Input: score sequence S, reference score s_{ref}
Output: feature vector F

Initialize D as size of S
Initialize Del as empty vector
for all $s \in S$ **do**
  $ds \leftarrow s - s_{ref}$
  $D \leftarrow D.append(ds)$
end for
$Stat \leftarrow [Var(D), Range(D), Mean(D), Max(D)]$
for $ds_1 \in D$ **do**
  for $ds_2 \in D - ds_1$ **do**
    if ds_1, ds_2 is from same distortion d **then**
      $Del \leftarrow Del.append(abs(ds_1 - ds_2))$
    end if
  end for
end for
$F \leftarrow Concatenation(D, Del, Stat)$
return F

vector *Del*. Finally, the three vectors, namely *D*, *Del* and *Stat*, are concatenated together to create a comprehensive feature vector F, which is further fed into the SVM classifier.

4 Evaluation

In this section, we evaluate *FraudWhistler* against a static adversary in different SR architectures with large-scale datasets.

4.1 Experimental Setup

A Dataset

We implement *FraudWhistler* based on a large-scale corpus VCTK [66], which contains speech data uttered by 110 English speakers with various accents. Each speaker reads out about 400 sentences, which were selected from a newspaper. And each speaker has a different set of newspaper texts selected based on a greedy algorithm that increases the contextual and phonetic coverage. Among them, we randomly select 10 speakers (7 males and 3 females) as target users and for each target user, we select 10 utterances as enrolled utterances for SR systems. After removing utterances used for enrollment, we select 70 utterances for each target user as the benign examples for training the SVM classifier and 30 utterances for testing. To prepare the adversarial examples, we first select another 10 speakers for each target user from the remainder of the speakers available after removing the 10 target speakers. A target user and one of its adversary speakers together constitute an adversary trial. For each adversary trial, we randomly select an utterance from the adversary's utterances as the foundation for generating adversarial examples using five attack algorithms. In sum, we have 700 benign trials as the training dataset and 800 trials that include 300 benign trials and 500 adversarial trials as the testing dataset.

B Implementation

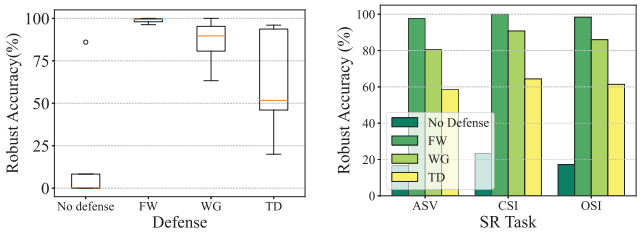
FraudWhistler is deployed on a server with 40 Intel Xeon Silver 4210R CPU, 256GB RAM, and four 48GB NVIDIA RTX A6000 GPU, running Ubuntu hirsute 21.04. In the *Voice Destructor* module, six distortion techniques are employed including noisifier, reverber, codec, quantization, dropchunk, and dropfreq. In noisifier, SNR is configured with 1 dB and 10 dB. In quantization, the parameter q is set to 7 and 8. The reverber employs Simulated Room Impulse Response (RIRs) [29]. The codec algorithm is flac, and each sample is stored in 8 bits. Within dropchunk, random dropping of 50 to 150 chunks occurs, with each chunk's length ranging from 100 to 1000 samples. In dropfreq, random dropping of 10 to 15 frequency chunks occurs, where each chunk has a range of 400 Hz. Regarding the one-class SVM classifier, we utilize the radial basis function (RBF) kernel.

Table 2: Notations used in metric definitions. AE represents Adversarial Examples, and BE represents Benign Examples. True (AE) represents the number of samples for which the true label is AE, and the same applies to the other notations.

Condition	True (BE)	True (AE)	
		Successful	Failed
Predicted (BE)	M	$P1$	$P2$
Predicted (AE)	N	$Q1$	$Q2$

C Guarded SR Systems

To evaluate the performance of *FraudWhistler*, we select the state-of-the-art SR system based on Ecapa-TDNN [15] with a Cosine-Similarity scorer. This model is pre-trained with another large-scale corpus VoxCeleb1 [44], which contains 1,251 speakers and 153,516 utterances. Based on this model, we build three SR systems for Automatic Speaker Verification (ASV), Close-set Speaker Identification (CSI) and Open-set Speaker Identification (OSI).



D Experiment Design

We evaluate *FraudWhistler* against a static adversary on three SR systems employing five AE attack methods in both the digital and physical world. In the digital world experiment, we directly use the dataset described before. For each AE attack method, we generate 100 audio adversarial examples for one given SR system. In the physical world experiment, we play the generated adversarial examples and record them in different physical conditions, varying the distance between the speaker and microphone, the background noise level, and the recording device. In sum, we evaluate *FraudWhistler* on 1500 AE attacks in the digital world and 3000 AE attacks in the physical world.

E Evaluation Metrics

For evaluations, we define the following metrics with the notations described in Table 2:

- Detect Accuracy on AEs (ACC_{ae}): $ACC_{ae} = \frac{Q1+Q2}{P1+Q1+P2+Q2}$, which is the detection rate on adversarial examples.
- Accuracy on BEs (ACC_{be}): $ACC_{be} = \frac{M}{M+N}$, which reflects the impact on benign examples.
- Robust Accuracy on AEs (ACC_{rob}): $ACC_{rob} = 1 - \frac{P1}{P1+Q1+P2+Q2}$, which stands for the whole system's robustness against AE attacks.

(a) Different algorithms (b) Different Architectures

Figure 4: Performance of *FraudWhistler* across various AE-generating algorithms and different SR architectures.

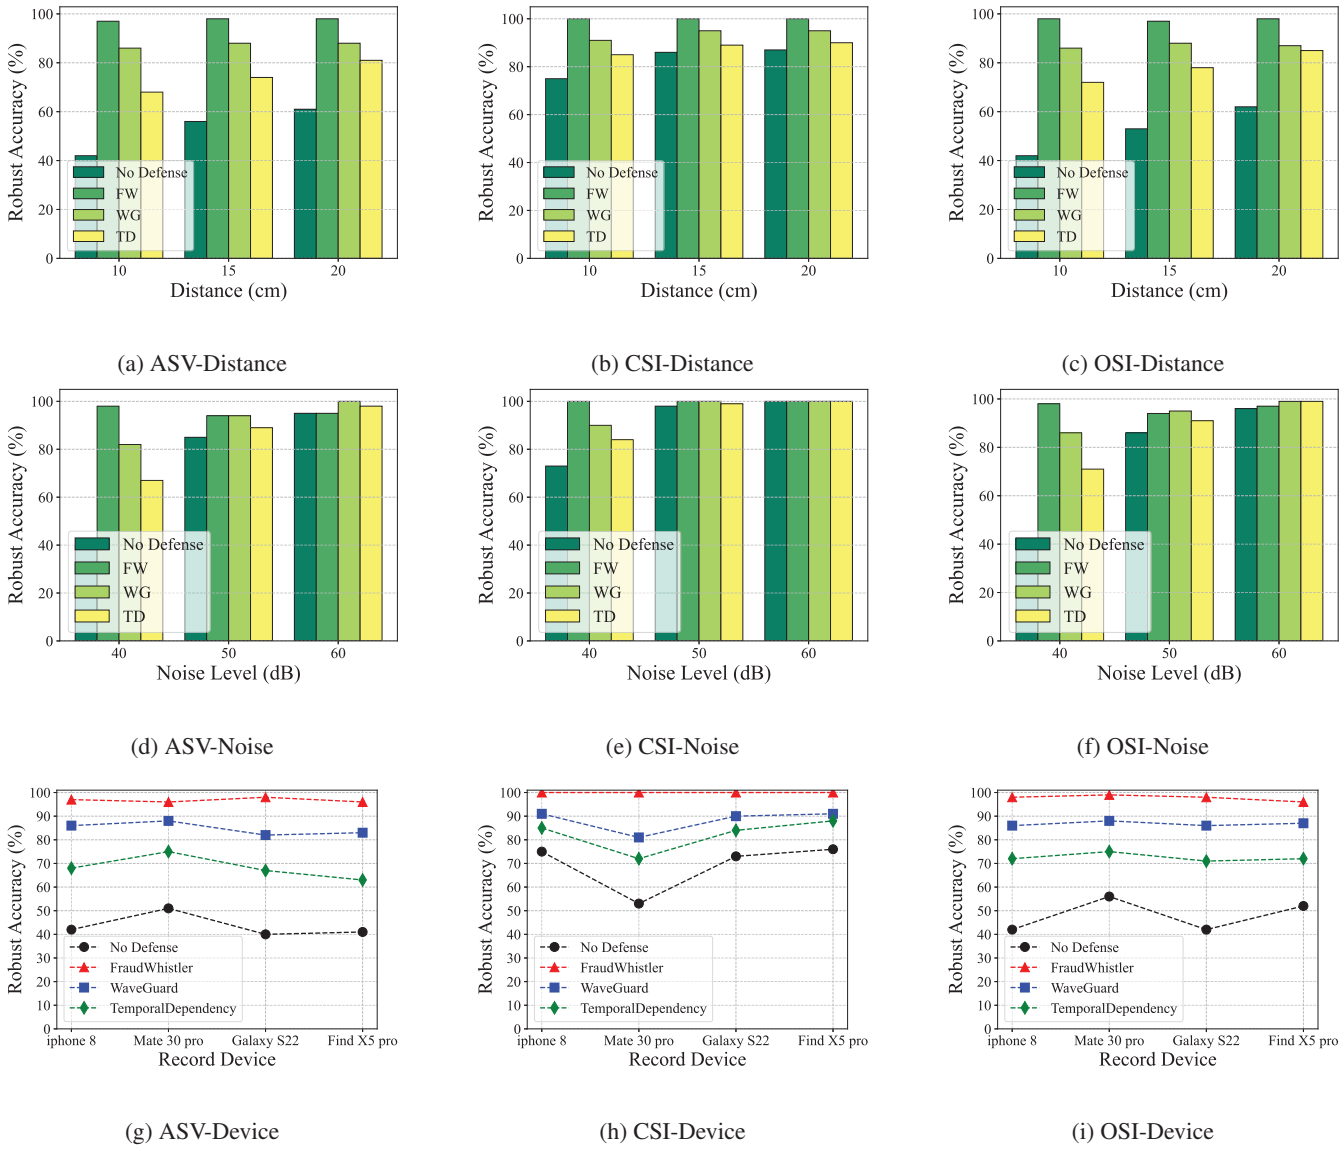
4.2 Overall Performance

We first evaluate the overall performance of *FraudWhistler* in terms of effectiveness against the static adversary. Table 3 shows the evaluation results of *FraudWhistler* (FW) and two state-of-the-art (SOTA) works WaveGuard (WG) [22] and TemporalDependency (TD) [69]. We can observe that *FraudWhistler* achieves over 40% ACC_{ae} improvement compared with TD in all SR architectures while inducing only 0.3% ACC_{be} degradation. Also, *FraudWhistler* outperforms WaveGuard with at least 7% ACC_{ae} improvement while inducing about 2% ACC_{be} degradation. With *FraudWhistler* deployed, SR systems achieve 97.6% ACC_{rob} at worst, compared to 80.6% for WaveGuard and 58.6% for TD, indicating strong defense capability against adversarial examples.

4.3 Evaluation on Resilience

As described in our threat model, the adversary is not restricted in any way on crafting and hiding the adversarial perturbations, indicating that the adversary could use any AE-generating algorithms. We take several classic algorithms in AE attack domain including FGSM [17], PGD [39] and CW [6] and two more advanced algorithms, FM [60] and UNIV [33, 37, 64, 73]. FM makes use of the psychoacoustic principle of frequency masking to generate inaudible adversarial examples, and UNIV is designated to generate universal adversarial perturbation that can be added to any speaker's speech.

Figure 4a shows the performance of *FraudWhistler* on different algorithms, we can observe that *FraudWhistler* achieves 98.7% ACC_{rob} at average, compared to 85.5% for WG and 61.5% for TD, respectively. Also, it can be observed that *FraudWhistler* achieves steady performance with the range of 3.7%, compared to 36.7% for WG and 76% for TD, respectively. Further analysis shows that, though WG achieves over 90% ACC_{rob} for FGSM, PGD, and CW, its accuracy degrades to lower than 80% for FM and UNIV. Meanwhile, TD achieves over 90% ACC_{rob} only for FGSM and CW, and its accuracy degrades to lower than 50% for PGD, FM, and UNIV.



To investigate the impact of SR architectures on the detection's performance, we further evaluate *FraudWhistler* on different SR architectures. Figure 4b shows that *FraudWhistler* achieves 97.6% ACC_{rob} at worst on three SR architectures, compared to 80.6% for WG and 58.6% for TD. Also, it can be observed that these three detection methods achieve the best performance on CSI and the worst performance on ASV. This result demonstrates that *FraudWhistler* achieves steadily high accuracy on adversarial examples across different AE generating algorithms and SR architectures, which validates its resilience in a practical scenario for deployed SR systems to defend against AE attacks.

4.4 Evaluation on Robustness

In a practical attack scenario, the adversary launch attacks in complex physical environments. Hence, we further evaluate *FraudWhistler* in the physical world. To simulate practical attacks, we employ a speaker (JBL Clip3) to play audio adversarial examples and use smartphones to record audio, as illustrated in Figure 6. The speaker and smart devices are placed on a 1.5 $m \times 3.6$ m table, in a 6 $m \times 7$ m room. We take three variables to control the physical environment condition, i.e., the distance between the speaker and the microphone of the smart device, background noise level and type of smart device. To control the background noise level, we place another smart device to play white noise and measure the noise level at the location of the recording devices' microphone, with a digital sound level meter (Smart Sensor AR844).

Table 3: Overall performance of *FraudWhistler* and SOTA works against the static adversary.

SR Architectures	$ACC_{ae}(\%)$			$ACC_{be}(\%)$				$ACC_{rob}(\%)$			
	FW	WG	TD	No Defense	FW	WG	TD	No Defense	FW	WG	TD
ASV	**87.8**	80.6	43.6	99.67	94.33	92.00	**94.67**	16.6	**97.6**	80.6	58.6
CSI	**86.2**	69.0	45.6	100.0	94.33	**96.00**	92.00	23.4	**100**	90.8	64.4
OSI	**94.0**	86.0	49.6	100.0	92.67	**94.67**	93.33	17.2	**98.4**	86.0	61.4

(a) ASV-Distance (b) CSI-Distance (c) OSI-Distance

(d) ASV-Noise (e) CSI-Noise (f) OSI-Noise

(g) ASV-Device (h) CSI-Device (i) OSI-Device

Figure 5: Performance of *FraudWhistler* and SOTA works in the physical world varying on the distance between the speaker and microphone, the background noise level or the recording devices.

Figures 5a to 5c show the performance of *FraudWhistler* varying the distance between the speaker and microphone of the recording device. We can observe that *FraudWhistler* achieves best ACC_{rob} (97% at worst) in all distance settings, compared to WG and TD. Also, it can be observed that as the distance increases, the SR system itself without defense and TD both achieve higher ACC_{rob}. Considering different SR architectures, we can observe *FraudWhistler* achieves steady performance, while WG and TD achieve higher accuracy for CSI than ASV or OSI. Figures 5d to 5f show the performance of *FraudWhistler* varying the background noise level. We can observe that when the environment is relatively quiet (e.g., with the background noise level as 40 dB), *FraudWhistler* achieves the best accuracy (above 98%) for all SR architectures. However, as the background is louder, the SR system without defense achieves 45%, 25%, and 44% ACC_{rob} improvement for ASV, CSI, and OSI respectively. When the background noise level reaches 60 dB, the SR system itself achieves at worst 95% ACC_{rob} across three architectures. Figures 5g to 5i show the performance of *FraudWhistler* and SOTA works with various record devices. We can observe that *FraudWhistler* achieves above 96% ACC_{rob} in all device settings. Also, it can be observed that *FraudWhistler* has at most 3% ACC_{rob} variation, while WG and TD have 10% and 14% variation, respectively. This result demonstrates that *FraudWhistler* could detect adversarial examples with steady

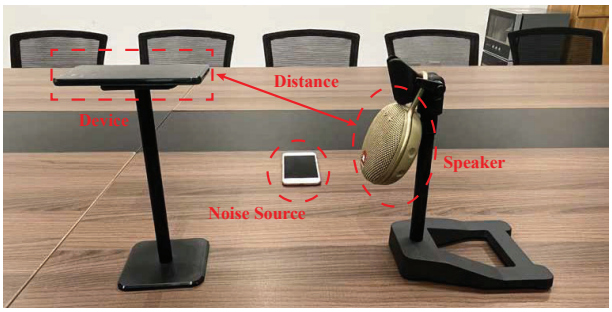


Figure 6: Physical setting to simulate practical attacks.

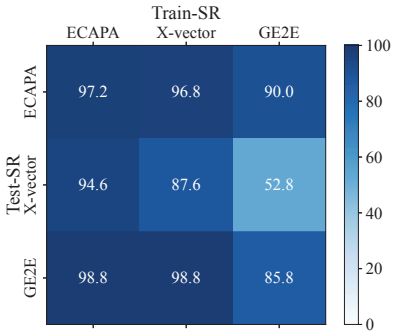

Figure 7: Performance of *FraudWhistler* when transferring among Ecapa-TDNN, X-vector and GE2E SR systems.

and accurate performance in various environmental conditions, which indicates its robustness in the complex physical world.

4.5 Evaluation on Transferability

As described in Section 3, our approach is devised to be plug-and-play for deployed SR systems whose neural network models vary in real-world scenarios. In real-world scenarios, during the training phase, *FraudWhistler* relies on an SR system for training the SVM classifier. However, *FraudWhistler* may be applied to another deployed SR system, which may have a different neural network model compared to the one used during training. Hence, it is necessary to evaluate the transferability of *FraudWhistler* across different SR models. Specifically, we evaluate *FraudWhistler* with three SR systems including Ecapa-TDNN [15], X-vector [57] and GE2E [58] which are the state-of-the-art SR model, the most classic model, and representative real-world deployed model (e.g., applied in Resemblyzer [1]), respectively. To keep consistent with a real-world deploying procedure, we did not conduct any fine-tuning operations in this experiment.

Figure 7 shows the robust accuracy (ACC_{rob}) of *FraudWhistler* across three SR models. To distinguish between the SR systems used in training and inference, we refer to them as Train-SR and Test-SR, respectively. We can observe that *FraudWhistler* trained with Ecapa-TDNN achieves the best performance across three Test-SR systems, whose accuracies are all above 94%. Instead, *FraudWhistler* trained with GE2E achieves the worst performance across three Test-SR systems, whose accuracies are all below 90%. The lowest accuracy is achieved with the Train-SR and Test-SR as GE2E and X-vector, respectively. This is because the capability of depicting a speaker's characteristics in GE2E's speaker embedding space is less powerful. This result demonstrates that *FraudWhistler* has excellent generalization capabilities when paired with an advanced SR model during the training phase, which is especially on benefits from the continuously evolving SR systems.

4.6 Performance Overhead

With *FraudWhistler* deployed, the SR systems may consume more computation resources, which induces a longer system response time and more memory usage. Hence, we evaluate the performance overhead brought by *FraudWhistler*. Table 4 shows the average Wall-Clock time and the memory usage of the SR system and *FraudWhistler*, respectively. We can observe that the average Wall-Clock time for Ecapa-TDNN SR is 178.6 ms and that of *FraudWhistler* is only 3.428 ms, indicating that *FraudWhistler* introduces approximately 1.92% additional running time only. We also evaluate the memory usage for the SR system and *FraudWhistler*. The result shows that the SR system occupies 84.647 MB memory and *FraudWhistler* occupies 2.324 KB memory, indicating that *FraudWhistler* introduces about 0.003% additional memory usage only, which is subtle compared to the original SR system. In sum, *FraudWhistler* introduces negligible performance overhead, enabling it to be a plug-and-play defense system in real-world scenarios.

4.7 Ablation Study

In this section, we investigate the impact of key components in *FraudWhistler* including Multi-Channel Distortions and Statistic Extractor. To this end, we implement two *FraudWhistler* variants FW-M and FW-S. In FW-M, we exclude both Multi-Channel Distortions and Statistic Extractor design,

Table 4: Performance overhead of *FraudWhistler*.

Process	Wall-Clock Time(ms)	Memory
Ecapa-TDNN SR	178.6	84.647MB
FraudWhistler	3.428	2.324KB
VoiceDestructor	3.160	-
DecisionMaker	0.268	-

i.e., generate audio variants in Voice Destructor using 6 distortion techniques with fixed parameter settings, and we directly use score sequences described in Algorithm 1 as a feature vector, without extracting statistics. In FW-S, we only exclude Statistic Extractor design, i.e., generate audio variants using 6 distortion techniques with various parameter settings and do not extract statistics. Besides, we also implement a variant named FW-OP with the setting that SR systems provide only predictions without similarity scores for effectiveness evaluation. In FW-OP, we set the value of ds as 1 if the predictions of the SR system for the original audio and the distorted one are different, otherwise set ds as 0, and other components are the same as in FW.

Table 5 shows the effectiveness of FW-M, FW-S, FW and FW-OP in three architectures. Comparing the first three systems, we can observe for ASV and OSI, FW achieves the best ACC_{rob} performance (98.2% at worst) while inducing 0.22% ACC_{be} degradation compared to FW-M. This result validates the effectiveness of Multi-Channel Distortions and Statistic Extractor in *FraudWhistler*. Comparing FW with FW-OP, it can be observed that with only prediction, FW-OP achieves lower accuracy in nearly all situations. The only exception is that in ASV task, it achieves higher ACC_{ae} by about 10% than FW, but at the same time, ACC_{rob} decreases to 31.11% which is unacceptable. This result validates the significance of the combination of scores and predictions in *FraudWhistler*.

5 Adaptive Attack

To enable reliable SR systems, it is important to evaluate *FraudWhistler* against the adaptive adversary. As described in Section 2.2, an adaptive adversary knows the details of the SR system, and is aware of the detection mechanism including architecture, parameters, and auxiliary data. In this section, we build an adaptive adversary and evaluate *FraudWhistler* against it.

Table 5: Performance of FW-M, FW-S, FW and FW-OP on different SR architectures.

SR Arch	Metric(%)	FW-M	FW-S	FW	FW-OP
ASV	ACC_{ae}	85.00	83.00	87.20	**98.2**
	ACC_{rob}	96.20	96.00	**98.20**	**98.2**
	ACC_{be}	92.33	93.89	**94.11**	31.11
CSI	ACC_{ae}	**88.40**	87.69	84.40	83.6
	ACC_{rob}	**100.0**	**100.0**	**100.0**	**100**
	ACC_{be}	**96.11**	94.11	95.89	87.22
OSI	ACC_{ae}	86.60	86.60	**94.60**	92.6
	ACC_{rob}	96.20	96.00	**98.40**	95.8
	ACC_{be}	92.22	93.44	**94.33**	90.89

5.1 Experimental Setup

In this experiment, we use the same dataset VCTK and Ecapa-TDNN SR system as in Section 4. To evaluate *FraudWhistler* under adaptive setting, we redefine ACC_{rob} and introduce new metrics:

- Adaptive Attack Success Rate (ASR): $ASR = \frac{N}{M}$, where N is the number of successful adversarial examples and M is the total number of attack trials.
- Robust Accuracy on adaptive AEs (ACC_{rob}): $ACC_{rob} = 1 - ASR$, which reflects the robustness of the guarded SR system against the adaptive adversary.
- Signal-to-Noise Ratio (SNR): $SNR = 10log_{10}(\frac{P_x}{P_\delta})$, where P_x and P_δ are the signal power of the original audio sample and the corresponding adversarial perturbation, respectively.
- Human Accuracy on adaptive AEs (ACC_{man}): ACC_{man} is the detection accuracy of humans on adaptive adversarial examples.

5.2 Attack Design

In this section, we introduce an adaptive AE-generating algorithm to bypass *FraudWhistler*. As motivated in Section 2.3, *FraudWhistler* detect AEs based on the model output of the AE is unstable under audio distortions. Thus, to bypass *FraudWhistler*, the adversary needs to craft the perturbation such that $SR(d(x+\delta))$ is stable when d is substituted with different distortion techniques. Meanwhile, considering the original objective to attack the SR system, the outputs of $SR(d(x+\delta))$ need to match $SR(x+\delta)$ closely. Therefore, to craft such a perturbation δ, the adversary needs to optimize a CW-like objective function as follows:

$$\begin{aligned} &min\ \mathcal{L}(SR(x+\delta),t) + \sum_{i=1}^{6} c_i \cdot \mathcal{L}(SR(d_i(x+\delta)),t) \\ &s.t.\ \|\delta\|_\infty < \varepsilon, \end{aligned} \tag{6}$$

where $\mathcal{L}$ represents CTC-loss, $epsilon$ denotes perturbation budget, and c_i is the hyper-parameter to control the weights of respective loss. Considering six distortion techniques, quantization is non-differentiable, and four techniques (Noisifier, Reverber, DropChunk and DropFreq) are with randomness. Thus, we use BPDA [3] technique to replace direct gradient propagation for quantization, and use EOT [4] algorithm to estimate robust backward gradient for the aforementioned four techniques. In our implementation, we use Project Gradient Descent (PGD [39]) to optimize the objective function. The detailed algorithm is described in Appendix A.

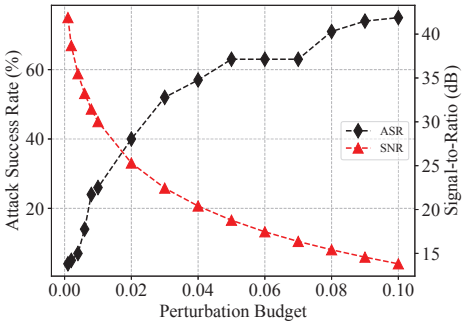

Figure 8: The attack success rate (ASR) and Signal-to-Noise Ratio (SNR) of adaptive attacks on *FraudWhistler*, while varying the perturbation budget.

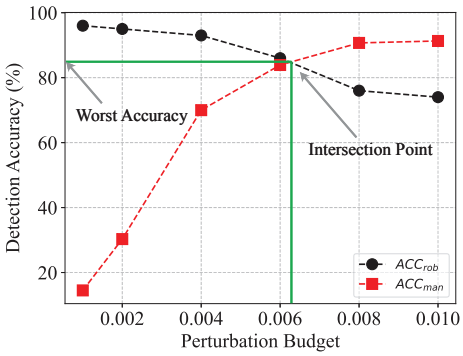

Figure 9: The detection accuracy of *FraudWhistler* and human ear on adaptive adversarial examples, while varying the perturbation budget.

5.3 Performance Evaluation

We conduct our adaptive attack evaluation in two aspects: (1) the attack success rate (ASR) and (2) the imperceptibility of adversarial examples. Toward this end, we vary the perturbation budget ε in our adaptive attacks and explore how these two sides change simultaneously. Specifically, we implement the proposed adaptive attack on three SR architectures and vary the perturbation budget from 0.001 to 0.10. The result is shown in Figure 8. Although we mentioned in Section 2.3 that these distortions could defend adaptive attacks with limited capability, i.e., a fixed parameter ε, we can observe that as the perturbation budget increases, the attack success rate could still reach higher. However, as the success rate increases, the SNR decreases. When ASR reaches approximately 75%, the SNR drops below 15 dB. This outcome suggests that *FraudWhistler* may be susceptible to adaptive attacks when the perturbation budget is relatively high. Nevertheless, maintaining the imperceptibility of adversarial examples is crucial in practical attack scenarios [11,37]. For this reason, we conduct another audibility study to evaluate *FraudWhistler*.

5.4 Audibility Study

Note that IRB approval is obtained in terms of our work involving human participants for audibility studies. In our audibility study, we recruit 31 volunteers (21 males and 10 females). We recruit volunteers on our campus forums. The recruited volunteers consist of undergraduate students, graduate students, and some faculties. We screen for hearing issues in our recruitment notice and the study was completed in the volunteers' environments. Before the start of the experiment, we prepared an informed consent form that outlines the research purpose, experimental procedures, and the usage of data. Participants may voluntarily choose whether or not to grant authorization for our audibility study. The minimum and maximum age of volunteers is 9 and 49, respectively, and most of them (24 people) are at the age of 18 to 25. The study took each volunteer about 15 minutes and every participant is compensated with $5. For each subject, we play 60 audio adversarial examples while keeping the volume to a normal level (about 60-70 dB) and let them identify whether the played audio is a benign example or an adversarial example. These 60 audio examples are randomly selected with a perturbation budget between 0.001 and 0.01.

As shown in Figure 9, we can observe that as the perturbation budget increases, the human ear could identify adversarial examples more accurately, while *FraudWhistler* achieves worse accuracy. This indicates that, though the adaptive adversary could improve the attack success rate with higher perturbation, the impact on imperceptibility would render adversarial examples failed to spoof human ears. The intersection point indicates that *FraudWhistler* and the human ear achieve the same accuracy. And when the perturbation budget is lower, *FraudWhistler* could detect adversarial more accurately. On the other hand, when the perturbation budget is higher than at this intersection, the human ear could easily identify adversarial examples. At the intersection point, the SR system achieves the worst accuracy (84%) on adversarial examples. This result indicates that *FraudWhistler* could force the adversarial examples to either fail to bypass the SR system or become noticeable to human ears, which enables a reliable SR system in the real world.

6 Discussion

In this section, we discuss the scalability of *FraudWhistler*, and possible advanced detection.

Detection Scalability: Backdoor attack [70] is another type of security threat for SR systems. We notice that in backdoor attacks, the adversary needs to contain a trigger in the audio sample which could also be perturbed by distortion techniques. Though backdoor attacks mainly focus on the training stage of SR systems, the adversary still needs to trigger the backdoor during inference time. This indicates that *FraudWhistler* may have the scalability to defend against backdoor attacks.

Possible Advanced Detections. To improve the security of the SR system, one can make possible advanced detection by modifying *FraudWhistler*. The experimental result has shown that the detection accuracy of *FraudWhistler* against static adversaries is satisfactory. On the other hand, *FraudWhistler* achieves a little lower accuracy against adaptive adversaries. One obvious strategy for better security is to introduce randomness in the multi-channel distortion component. We can use cryptographic randomness to make the distortion technique unpredictable, which complicates the task for adversaries. Further, based on the results of our transferability study, pairing the defense with a more advanced SR system during the training phase could potentially make up a more powerful defense.

7 Related Work

In this section, we discuss several key related work on adversarial example attacks over existing SR systems and corresponding defenses in the audio domain.

Adversarial Example Attacks on Speaker Recognition. We summarize existing adversarial example attacks on SR and find most of the works do not take defense into their consideration and are under white-box settings. The detailed summary is in Appendix B.

Kreuk *et al.* [30] implemented the first adversarial example attacks [55] on an end-to-end SR model [20] using *fast gradient sign method* (FGSM) [17]. Then, Li *et al.* [35] launched adversarial example attacks on GMM i-vector [14] systems and x-vector [54] systems. Villalba *et al.* [57] benchmarks adversarial examples' robustness in x-vector SR systems. The following works focus on launching practical adversarial attacks. These works [7, 36, 37, 64, 73] are mainly designated to generate robust adversarial examples to launch over-the-air attacks considering the room impulse response (RIR).

Another line of works [33, 37, 64, 73] is designated to generate universal adversarial examples that can be added to any specific speaker's speech. At almost the same time, some works intend to generate imperceptible perturbations. FoolHD [53] proposed steganography-inspired adversarial attacks to generate highly imperceptible perturbations. Wang *et al.* [60] proposed to generate inaudible adversarial perturbations based on the psychoacoustic principle of frequency masking. VoiceCloak [10] modulates perturbations into RIR. While most of the aforementioned works are under the white-box setting, FakeBob [7] conducts the first comprehensive and systematic study of the adversarial example attacks in the practical black-box setting using NES [23].

Defenses Against Adversarial Example in Audio Domain. We summarize existing defenses against adversarial example attacks on the SR model and find they can be categorized into three types. The detailed summary is in Appendix C.

The first line of works [46, 59] focuses on making SR systems more robust by retraining model with the knowledge of pre-assumed AE-generating algorithms. Wang *et al.* [59] use FGSM and *local distributional smoothness* [43] for model regularization while Pal *et al.* [46] use hybrid adversarial training considering FGSM, PGD [39], and CW [6]. The second line of works [25, 62, 71] are designated to extract benign parts from the perturbed audio example. To purify audio samples Zhang *et al.* [71] trained an adversarial separation network, Joshi *et al.* [25] proposed several preprocessing methods [13, 24, 39, 52, 68] as filtering module, and Wu *et al.* [62] use cascaded self-supervised learning models [38] to purify the adversarial perturbations. The third line of works [34, 61, 63] focuses on detecting AEs. Li *et al.* [34] introduced a VGG-like [44] binary detector while Wu *et al.* [61] adopt neural vocoders [68] to spot adversarial samples. Wu *et al.* [63] proposed a voting scheme by employing random sampling to detect AEs. Adversarial training-based and purification-based works either need extra efforts to retrain models or cause some negative effects on benign examples. The most related work [25] takes adaptive attack [56] and universal attack into consideration. Besides, almost every aforementioned work has a limited scope of attack algorithms and only one of them can resist unseen attacks successfully. Also, none of aforementioned work takes the deploying procedure in real-world scenarios into consideration.

Compared to these defenses, our work has a wide coverage of existing adversarial example attacks in both the digital world and the complex physical world. Besides, our work can defend the adaptive attacks by pushing the adversarial example either to be failed or perceptible Further, our defense can transfer well across different SR models, enabling it as a plug-and-play method in real-world scenarios. Also, our defense does not entail significant additional efforts to function seamlessly with deployed SR systems. All these features make our detection framework a practical defense for speaker recognition.

8 Conclusion

In this paper, we propose an audio distortion-based adversarial example detection method for the SR system and implement a practical detection system *FraudWhistler*. We present a study on different audio distortion techniques, and the result is helpful for the research community in developing more advanced adversarial example detection methods. Encouraged by the study result, we introduce a multi-channel distortion technique to generate audio variants. Based on the outputs of the SR system for these audio variants, we introduce an algorithm to extract features that represent the instability of the original audio sample. Further, we employ a one-class SVM classifier to learn the decision boundary between adversarial examples and benign examples. Experimental results in both the digital world and the physical world show that *FraudWhistler* can detect audio adversarial examples with steadily accurate performance and high efficiency.

A Adaptive Attack Algorithm

The algorithm of adaptive attack against *FraudWhistler* is detailed in Algorithm 2. In every iteration, we repeat the following steps. First, we obtain the gradient without distortion function by backpropagation as in a simple adversarial example attack, i.e., the defense is not considered. Second, for each distortion function employed in *FraudWhistler*, we use different gradient estimation methods to generate more gradients. Specifically, for codec, we directly use the backpropagation algorithm to obtain the gradient. For Quantization, we use BPDA to estimate the backpropagation gradient. For Noisifier, Reverber, DropChunk and DropFreq with randomness, we use EOT to estimate a robust backward gradient by internal multiple iterations of optimization. After that, all the obtained gradients are summed up and then clipped into the legitimate range of value.

Table 6: Adversarial attacks on SVs: "U/T/B" means untargeted attack, targeted attack, and both targeted and untargeted attacks. Con. Def. stands for considering detection mechanism. Optobj means optimization methods with a designed objective function. SV and SI stand for speaker verification and speaker identification.

B Adversarial Example Attacks on Speaker Recognition

Existing AE attacks on SR systems are summarized in Table 6. We can observe that all of the works' attack goals include targeted attacks except one. Besides, less than half of the works consider the over-the-air scenario or universal attacks. Also, we can observe that only two of them consider defenses in their work, which implies the necessity of an effective adversarial example defense in the audio domain. Considering the knowledge of attackers, most of the listed works are under the white-box setting and most of the victim SR systems are speaker identification systems.

C Defenses Against Adversarial Example in Audio Domain

Existing defenses against AE attacks on the SR systems are summarized in Table 7. We can observe that some of the works need to retrain the SR model, inducing additional efforts. Besides, most of the works would introduce a negative effect on benign audio examples and some of the works could be plug-and-play as preprocessing modules. However, few works consider adaptive attacks as well as advanced attacks (e.g., universal attacks) and evaluate their defense on unseen adversarial example attacks, which is necessary for a practical defense to deploy in real-world scenarios.

π-Jack: Physical-World Adversarial Attack on Monocular Depth Estimation with Perspective Hijacking

Tianyue Zheng[1], Jingzhi Hu[2], Rui Tan[2], Yinqian Zhang[1], Ying He[2], Jun Luo[2] *

[2]*Nanyang Technological University*

Abstract

Monocular depth estimation (MDE) plays a crucial role in modern autonomous driving (AD) by facilitating 3-D scene understanding and interaction. While vulnerabilities in deep neural networks (e.g., adversarial perturbations) have been exploited to compromise MDE, existing attacks face challenges in target accessibility and stealthiness. To address these limitations, we introduce π-Jack, a novel physical-world attack on MDE via *perspective hijacking*. It is based on an observation that MDE relies heavily on perspective cues to infer depth, yet these cues can be manipulated by strategically placing common 3-D objects in AD scenes. With an optimization-based approach, π-Jack "hijacks" the perspective information and alters the target pixels' depths perceived by the MDE model in a black-box manner. We also show via experiments that π-Jack is effective across various MDE models and scenarios, confirming generalizability of perspective hijacking. Our extensive evaluations demonstrate that π-Jack is effective across different target and attack vectors, and increases the mean depth error by over 14 meters. Moreover, in our end-to-end AD simulation, π-Jack results in compromised lane change, sudden braking, and life-threatening collisions.

1 Introduction

Monocular depth estimation (MDE) is a technique for estimating pixel-wise distances from a single RGB image, allowing low-cost and energy-efficient monocular cameras to sense depth and replace expensive radar and lidar sensors. Consequently, autonomous vehicles (AVs) can use MDE to facilitate downstream tasks with depth information, such as semantic segmentation [38], 3-D object detection [41], visual SLAM [69], and visual relocalization [66]. Due to its benefits and capabilities, MDE has garnered interest from both academia [21, 67, 68] and industry, including leading companies such as Tesla [1, 59], Waymo [85, 86], and Toyota [25, 84]. In particular, Tesla regards MDE as a pivotal component in their AV-AI ecosystem [1], and has already integrated MDE into their production-grade vehicles [59].

With the widespread adoption of MDE in the wake of all-vision autonomous driving (AD) solutions [1, 25, 59, 84, 85, 86], understanding its security vulnerabilities becomes increasingly important. In fact, any deficiencies in MDE could lead to AVs generating low-quality models of their surroundings (the absence of depth sensors in all-vision AD solutions renders it nearly impossible to correct such deficiencies), thereby affecting the effectiveness of their decision-making and trajectory planning. The situation could worsen significantly if an adversary targets MDE for attack, aiming to artificially deviate the inference results of MDE. Should such an attack succeed, AVs would highly likely to undertake risky maneuvers, such as improper lane changes or braking actions that may escalate into possible hazardous vehicular collisions [65]. Therefore, understanding possible attacks on MDE becomes important due to the substantial real-world consequences posed by them.

Conventional attacks on MDE are performed in the digital space [70, 74], which primarily manipulate depth perception by introducing adversarial perturbations at the *pixel level* [22, 46]. These perturbations are designed through gradient-based methods to iteratively modify pixel values in captured images to maximize depth estimation error. However, applying such attacks in real-world scenarios faces three challenges. First, it is difficult for attackers to tamper with the images during data transfer or storage due to air gap and cryptographic protection. Second, the intricate adversarial perturbations are not robust to changes in real-world lighting conditions due to shadow and weather as well as geometric variations related to view angles and object surfaces. Third, even if the pixel-level perturbations are feasible, the unnatural appearance of the perturbations can alert the AV system and the human driver, thereby triggering a fail-safe mechanism such as falling back to manual driving or emergency safe stopping.

More recent physical MDE attacks [9, 71] still act on the *pixel level*, by generating adversarial perturbations digitally and then transferring these perturbations into the physical

*This work was started when Tianyue Zheng was a PhD candidate at NTU. Open-source materials to be found at https://github.com/pi-Jack/pi-Jack

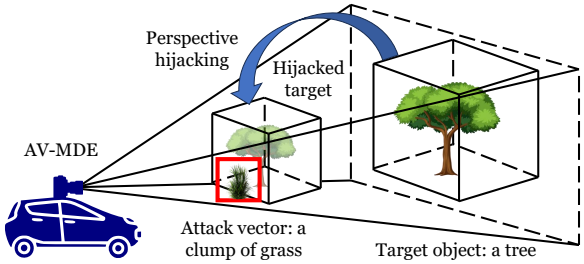

Figure 1: High-level idea of π-Jack: by strategically placing an attack vector (a clump of grass), MDE for a target object (a tree) can be hijacked.

world. They attempt to compensate for the drawbacks of digital attacks by employing methods such as style transfer [9] and Expectation over Transformation (EoT) [2, 32], as these techniques are designed to make the stickers less conspicuous and more robust to real-world conditions. However, still operating at the pixel level, these attacks remain largely impractical. For example, attaching style-transferred road markings to vehicle rears [9] still looks unnatural. Additionally, accessing the targets can be difficult due to restrictions on applying stickers on certain surfaces. Finally, the effectiveness of physical attacks is worsened by the presence of invalid colors that cannot be accurately reproduced during printing [35].

The persistent issue of adversarial perturbations (regardless of digital and physical) is their narrow focus at *pixel level* only; this calls for novel attack strategies conceived at a broader level. Inspired by the work [34] that tricks lane detection of AVs by putting markings on the road, we envision an attack operating at the *scene level*. However, designing such attacks faces two challenges. First, we need to perform an analysis of MDE's vulnerabilities and identify a scene-level depth-altering attack not achievable by previous proposals. For instance, previous physical attacks on classification tasks by using lasers [14] and projected patterns [20] are unfeasible, as they suffer from similar issues of being conspicuous and susceptible to real-world lighting conditions due to their reliance on additional light sources. Second, to achieve more practical and potent attacks, it is desirable to extend 2-D attacks (e.g., on a road sign's surface) to the 3-D physical scene. Crafting attack vectors in the 3-D scene, however, is challenging due to the difficulties in reconstructing the 3-D scene from a 2-D image and interacting with it.

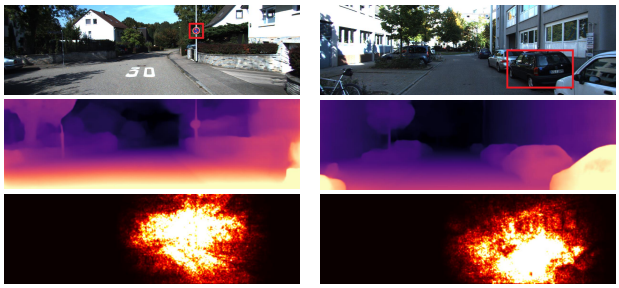
A reasonable approach to achieving *scene-level* attack on MDE involves *strategically placing 3-D objects* commonly found on the road, such as traffic signs, barrier poles, and clumps of grass, as attack vectors. These objects are readily obtainable and accessible to the attacker. Moreover, these objects are inconspicuous because traffic inspectors and drivers consider them ordinary and benign. Furthermore, the texture and placement of these objects are natural and involve no delicate adversarial perturbations, making them inherently robust to real-world lighting condition changes and geometric variations. These attack vectors manipulate visual cues on which deep learning implicitly relies for MDE. Among these cues, perspective information (i.e., the spatial attributes of geometry and texture that change with distance) is crucial because it reveals the spatial relationships among the objects.

In this paper, we introduce π-Jack, a physical-world adversarial attack that harnesses the power of *perspective hijacking*. Its basic concept is depicted in Figure 1, where we strategically position an adversarial object (e.g., a clump of grass) to manipulate the perspective relationships of targets in the scene. This approach is designed to affect or "hijack" the perspective of the target object (e.g., a tree), thereby perturbing the depth estimation of the target object. We design a 3-D modeling and rendering pipeline to place the 3-D object and create composited yet photorealistic scenes. Additionally, we implement a systematic approach to optimize the position and pose of the placed 3-D object, maximizing its effectiveness of attack. This approach also adopts a novel Expectation over Motion and Illumination (EoM&I) technique to ensure the attack's robustness to AV motion. Lastly, we conduct extensive evaluations including tests in real-world scenarios to assess π-Jack's performance. In summary, this research provides the following key contributions:

- We develop a physical-world attack on MDE termed *perspective hijacking*. To the best of our knowledge, we are the first to explicitly manipulate visual cues and mislead AV-MDE system in an effective, robust, and inconspicuous manner.
- We offer a 3-D modeling and rendering pipeline allowing the composition of the attack vector into the driving scene. This pipeline allows π-Jack to test out photorealistic perspective hijacking while considering environment illumination and shadowing.
- We propose optimization strategies to systematically optimize the position and pose of the adversarial object under the constraints of sensitive perspective region and physical realization. We also develop an EoM&I technique to make π-Jack robust to vehicle motion and illumination variations.
- We provide comprehensive evaluations conducted in both composited and real-world scenes and on different MDE models to demonstrate the effectiveness and generalizability of π-Jack.

The rest of this paper is organized as follows. Section 2 introduces the background of our work. Section 3 explains the attack goal and threat model. Section 4 presents the attack design of π-Jack, while the security analysis is postponed to Section 7 after obtaining supports from evaluation results. Section 5 provides π-Jack's implementation details, experiment setup, and evaluation metrics. Section 6 reports the evaluation results, followed by security analysis and possible defense methods in Section 7. Related works are presented in Section 8. Finally, we conclude our paper in Section 9.

2 Background



MDE is a challenging task because a single 2-D image can correspond to infinitely many 3-D scenes. However, humans can infer depth, even with one eye, based on their experience in navigating and interacting with the physical world. It has been experimentally shown that humans use visual cues such as perspective, familiar size, occlusion, shadows, and etc to make informed depth perception [57]. Drawing inspiration from this human capability, recent research has introduced deep learning-based MDE methods that uses the "experience" of sequential temporal frames as training signals [21, 67, 68]. This novel approach has been adopted by leading AV companies [1, 25, 59, 84, 85, 86], demonstrating its practical value and real-world applications.

To design an effective attack against these MDE methods, we shall identify the most vulnerable visual cues for MDE. Taking human visual perception as an analogy, it is reasonable to hypothesize that perspective cues (i.e., the spatial attributes of geometry and texture that indicate the relative locations among the objects in the scene) are essential for MDE and subject to manipulation, as there are various notable optical illusions that deceive human visual perception [23, 39]. These illusions involve parallel lines that seem to differ in length, orientation, or slope depending on the surrounding patterns, all of which distort the perspective cues. These illusions suggest that deep learning-based MDEs may also rely on perspective cues, and may be fooled by attacks with similar principles.

To have a preliminary validation of our hypothesis, we employ the widely-adopted MDE model MonoDepth2 [21] to generate a depth map with pixel values in the image representing depths, i.e., distances from the camera. We then use the saliency map [53] to understand what the depth estimation model focuses on when performing MDE. Specifically, the saliency map S is constructed by computing the gradient sum of the pixels inside the specified target region T on the depth map D, with respect to the input I as $S(u,v) = \sum_{(u_t,v_t)\in T} \frac{\partial D(u_t,v_t)}{\partial I(u,v)}$, where (u,v) represents pixel coordinates. A higher gradient means that a small change in that pixel will cause a large change in the target depth, and conversely, a lower gradient means a smaller change.

We present two example driving scenes in Figures 2(a) and 2(b), respectively. Each figure comprises three rows: an image, its estimated depth map, and its saliency map. We select a road sign and a car (two important objects in AV) as the target regions for saliency analysis in the scenes, as indicated by the red boxes. The saliency maps use brighter colors to indicate the areas most crucial for determining the depth of the selected target regions. It can be observed that, for the road sign, the sidewalk and the distant trees lining the horizon are the most salient regions; for the car, the road and the building on the side are the most salient.

All the salient regions underscore the importance of perspective cues: the parallel lines of the road converging in the distance, together with the vertical window frames of the roadside building establish a "spatial grid" that aids in perspective analysis. Additionally, the low contrast/saturation and blurred texture of the trees along the horizon indicate their remoteness and provide a reference point for perspective. This reliance on perspective cues motivates us to design the *perspective hijacking* attack: if the 3-D object we place in the scene has a similar geometric structure or texture with the target but at a different distance, the MDE model might mistakenly associate or merge our strategically-placed object with the target, thus the target perspective will be hijacked and the MDE model will output a wrong depth.

3 Problem Formulation

In this section, we present the attack goal and threat model.

3.1 Attack Goal

π-Jack aims at using 3-D physical-world adversarial objects in AV scenes to perform perspective hijacking and mislead AV-MDE model into producing incorrect depth estimation for specified target regions in the scenes. The adversarial object placement should meet the following requirements:

- *Effectiveness.* The objects should be placed in a way that they can alter the estimated target depth by the largest possible margins.
- *Accessibility.* The placed objects should be in valid and reachable areas in the scene.
- *Inconspicuity.* The objects should blend in with the environment, avoiding unusual shapes or patterns.
- *Robustness.* The attack should be robust and not affected by real-world conditions (e.g., lighting).

Given that the objects we use are ordinary 3-D objects that are generally considered benign, the inconspicuity requirement can be met. Additionally, since π-Jack does not depend on "sticker-pasting" or adversarial perturbations, it will not be influenced by environment lighting much, thus meeting the robustness requirement. Furthermore, as π-Jack does not necessitate placing objects in high-alert areas like road signs, the

accessibility requirement can also be fulfilled. Lastly, for the effectiveness requirement, we provide a comprehensive investigation of how depth estimation error can be maximized in Section 4.3 and evaluate the attack effectiveness in Section 6.

Formally, the attack objective of π-Jack can be expressed as follows. Let I be a scene image and $\theta(\cdot)$ be a depth estimation model such that $D = \theta(I)$ is the estimated depth map. Let O be a collection of ordinary 3-D objects, such as barrier poles, ladders, clumps of grass, and other similar items that can be placed into the scene. For each object $o \in O$, we define P_o as the set of coordinates and poses for o in the 3-D space corresponding to I. For each coordinate and pose $(x, y, z, \rho) \in P_o$, we obtain a modified image $I_{o,x,y,z,\rho}$ by inserting o at coordinate (x, y, z) with pose ρ. The corresponding estimated depth map is denoted by $D_{o,x,y,z,\rho} = \theta(I_{o,x,y,z,\rho})$. We then define a specific region T that contains the target to be attacked, where T can be obtained by either manual or automatic (e.g., SAM [37]) segmentation. The objective of π-Jack is to find an object $o^* \in O$ and its coordinate-pose $(x^*, y^*, z^*, \rho^*) \in P_{o^*}$ that maximize the sum of estimated depth differences between the original and compromised depth maps within the region T, i.e.,

$$o^*, x^*, y^*, z^*, \rho^* = \arg\max_{o \in O, (x,y,z,\rho) \in P_o} \sum_{(u,v) \in T} \left| D(u,v) - D_{o,x,y,z,\rho}(u,v) \right|, \quad (1)$$

where $D(u,v)$ and $D_{o,x,y,z,\rho}(u,v)$ denote the depth values at pixel location (u,v) in the original and compromised depth maps, respectively.

3.2 Threat Model

π-Jack focuses on the black-box setting, where the attacker can only query the AV-MDE system with inputs and observe the output depth map, without any knowledge of the MDE model's internals (e.g., model architecture, parameters, and other specifics of the victim's AV implementation). This scenario is more realistic and difficult than most previous works on adversarial attacks to camera-based AD perception [5, 9, 15, 75]. It is worth noting that obtaining the output depth map has been previously demonstrated possible [17]. Moreover, the attacker is assumed to have access to the camera parameters (both intrinsics and extrinsics) of the victim AV, which are likely to be public information. As shown in Section 6.4, π-Jack can transfer the attack vector optimized for a surrogate MDE model to a previously unseen MDE model, with a minor trade-off between a slight drop in attack success rate and depth difference.

In the considered threat scenario, the attacker is capable of placing new 3-D objects on accessible locations within the AV scene, including sidewalks, lawns, parking lots, and some parts of the road shoulders. This threat assumption is realistic because objects placed in these locations would not look suspicious or break traffic rules. Additionally, the attacker is assumed to has access to the 3-D models of these objects, which can be obtained using photogrammetric 3-D reconstruction techniques with smartphone photos and related software [24]. These 3-D models provide the attacker with the ability to optimize object placement and orientation in the digital space without the need to physically modify objects in the real world.

4 π-Jack Attack Design

In this section, we introduce the attack strategy of π-Jack. As shown in Figure 3, the whole workflow consists of five steps: i) 3-D object selection, ii) setting the stage for 3-D object placement, iii) object placement and rendering, iv) expectation

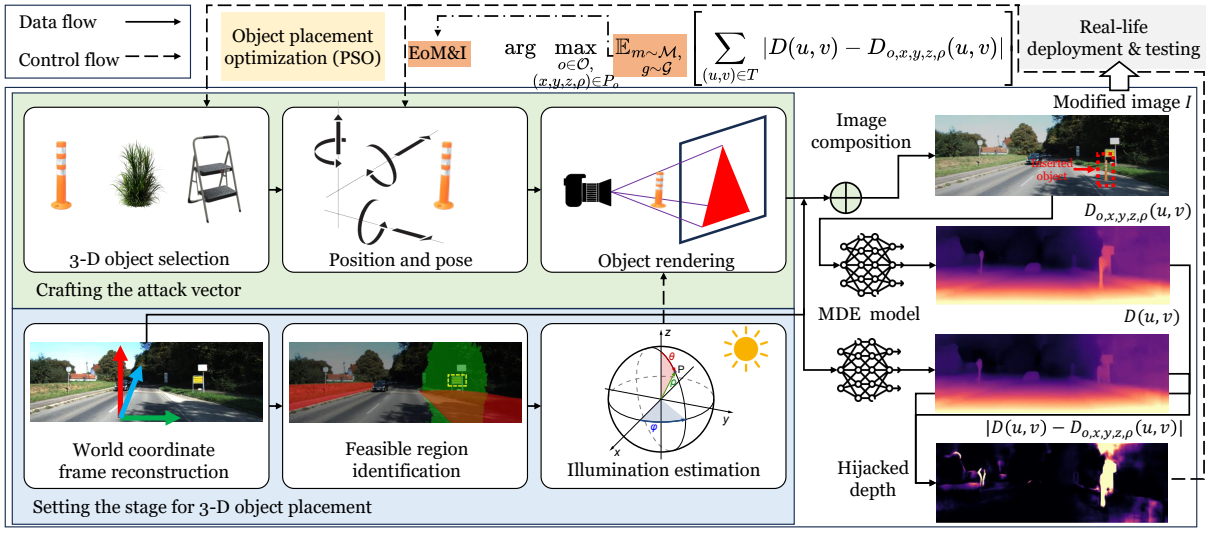

Figure 3: The workflow of π-Jack's attack strategy.

over motion and illumination to improve the robustness of π-Jack attack, and finally v) real-life deployment and testing (as evaluated in Section 6.5).

4.1 3-D Object Selection

The initial step of π-Jack involves selecting a set of 3-D objects to be positioned within the scene. As discussed in Section 2, the key to successful perspective hijacking is to create a false connection between the strategically placed object and the target at a different distance, and thus manipulate the perception of the target's depth. To accomplish this, we suggest four criteria for selecting the 3-D object: i) the 3-D object should possess structures similar to the target, ii) the 3-D object should exhibit a texture akin to the target, iii) the 3-D object should have an extended shape, ensuring its influence is not limited to a localized area, and iv) the object should be ordinary and inconspicuous, so that their existence does not raise suspicion. Note that not all of the first three criteria need to be satisfied at the same time. Based on these criteria, we choose nine types of 3-D objects as potential attack vectors. Note that there are five variants for each type of object. The detailed properties of the objects are shown in Table 1.

4.2 Setting the Stage for 3-D Object Placement

In this section, we set the stage for 3-D object placement using information obtained from AV photos. To be specific, in order to reconstruct a realistic scene, it is crucial to determine the world model for placing the object and casting the shadow, and the direction of the light source (e.g., sunlight in the outdoor driving environments) for proper illumination. Furthermore, a feasible region must also be identified for placing the 3-D object, taking into consideration perspective sensitivity and adherence to traffic rules.

4.2.1 World Coordinate Frame Reconstruction

The goal of world coordinate reconstruction is to perform the perspective projection of the 3-D coordinates of (x,y,z) in the real world to its 2-D coordinates on the image plane (u,v). This allows us to place the selected object in the AV scene, render it, and evaluate how the π-Jack attack affects the MDE model. According to the pinhole camera model [56], the projection can be formulated as follows:

$$\begin{bmatrix} u & v & 1 \end{bmatrix}^\intercal = \mathbf{K} \begin{bmatrix} \mathbf{R} & \mathbf{t} \end{bmatrix} \begin{bmatrix} x & y & z & 1 \end{bmatrix}^\intercal, \quad (2)$$

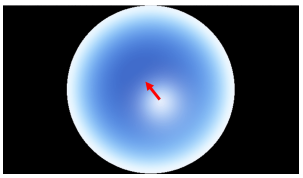
where $\mathbf{R} = \mathbf{R}_z(\psi)\mathbf{R}_y(\eta)\mathbf{R}_x(\phi)$ and $\mathbf{t} = \begin{bmatrix} t_x & t_y & t_z \end{bmatrix}^\intercal$ are the camera's extrinsic parameters that represent the rotation and translation with respect to the world coordinate system, with ψ, η, and ϕ being the Euler angles about the z, y, and x axes respectively, and (t_x,t_y,t_z) describing how the camera is translated along the three axes. $\mathbf{K}$ is the camera's intrinsic matrix that encodes the focal length f, the sensor size s, and the principal point (c_x,c_y):

$$\mathbf{K} = \begin{bmatrix} f/s_x & 0 & c_x \\ 0 & f/s_y & c_y \\ 0 & 0 & 1 \end{bmatrix}.$$

Essentially, Eqn. (2) sets the coordinate frames of showing how a strategically placed 3-D object is perceived by the AV camera.

4.2.2 Illumination Estimation

Estimation of the outdoor illumination is crucial for setting the stage for 3-D object placement, because it has been demonstrated that illumination [14] and shadow [80] can be exploited to attack AV's deep learning models. The illumination condition can be readily achieved by analyzing the photo from the AV's camera. To be specific, for a clear sky, we model the sky's illumination according to [27], and the spectral radiance L_λ in the direction $\mathbf{l}$ of the skydome can be expressed as $g(\mathbf{l},\lambda,\tau,\alpha,\mathbf{l}_s)$, where λ is the wavelength of the light, τ is atmospheric turbidity (the haziness or cloudiness), α is the ground albedo (a measure of the ground reflectivity), and $\mathbf{l}_s$ indicates the sun's position. For a diffuse overcast sky, we use the sky model $g(\mathbf{l},\lambda,L_z)$ according to [12], where L_z is the zenith luminance.



From these radiance models, we further obtain digitized RGB values by rendering at a discrete number of wavelengths ranging from 360 to 700nm. We refer to this conversion process as $g_{\text{RGB}}(\cdot)$, and express the digitized RGB color $g'_{\text{RGB}}(\mathbf{l})$ of a skydome direction $\mathbf{l}$ as $g'_{\text{RGB}}(\mathbf{l}) = \omega g_{\text{RGB}}(\mathbf{l})$, where ω is the exposure applied to the red, green, and blue channels. To

(b) Estimated skydome illumination.

Figure 4: Example AV scene and estimated illumination.

generate a map of the skydome from this model, we further discretize the skydome into several directions, and render the RGB values.

Given a skydome panorama Q and the discretized indices q corresponding to sky pixels in Q, we estimate these parameters by minimizing the least-square error of skydome reconstruction using a convolutional neural network (CNN), as demonstrated in [26]. For a clear sky, we have:

$$\mathbf{l}_s^*, \omega^*, \tau^* = \arg\min_{\mathbf{l}_s,\omega,\tau} \sum_q \left(Q(q) - \omega g_{\text{RGB}}\left(\mathbf{l}_q, \tau, \mathbf{l}_s\right)\right)^2. \quad (3)$$

For an overcast sky, we have:

$$L_z^* = \arg\min_{L_z} \sum_q \left(Q(q) - \omega g_{\text{RGB}}\left(\mathbf{l}_q, L_z\right)\right)^2. \quad (4)$$

One example driving scene and its corresponding estimated skydome illumination (clear sky) are shown in Figures 4(a) and 4(b), respectively. The skydome of Figure 4(b) is oriented such that its up direction matches the forward road direction in Figure 4(a). One may readily observe that the reconstructed sunlight corresponds with the lighting in the driving scene. In particular, the shadow of the utility pole aligns perfectly with the sun's position (as indicated by the red arrows).

4.2.3 Feasible Region Identification

To place the 3-D object properly, we need to determine the feasible region where it can fit. The feasible region should meet two requirements: i) it has an impact on the depth estimation of the target, and ii) it should respect both physical laws and traffic rules. In other words, the region should be the intersection of the salient region (as mentioned in Section 2), and the valid region without violating physical laws and traffic rules. However, due to our black-box settings explained in Section 3.2, we cannot derive the saliency map by directly calculating the gradient. Following the idea of D-RISE [47],

Figure 5: Feasible region identification.

we generate saliency maps for black-box MDE models by deleting and in-painting a region of each input image frame I. We use a binary mask B to indicate the region to be deleted, and an in-painting function χ to fill in the deleted region with a realistic context. The saliency map S' is defined as the sum of absolute differences between the original and the modified output values for all pixels in the target object T:

$$S' = \sum_{(u_t,v_t)\in T} \left|\theta(I)(u_t,v_t) - \theta(\chi(I \odot B))(u_t,v_t)\right|, \quad (5)$$

where $\odot$ denotes element-wise multiplication. We further apply a Gaussian blur using the kernel $G(u,v)$ to smooth the saliency map and remove any discontinuities. Then, we threshold the smoothed map to obtain the salient region with saliency above the threshold $\mathcal{T}$. As a result, the processed saliency region $\mathcal{F}_{\text{sal}}(u,v)$ can be expressed as:

$$\mathcal{F}_{\text{sal}}(u,v) = \mathbb{I}\left[(G * S')(u,v) > \mathcal{T}\right], \quad (6)$$

where $\mathbb{I}(\cdot)$ is the indicator function.

Subsequently, we annotate the valid region $\mathcal{F}_{\text{val}}(u,v)$ that satisfies both physical and traffic constraints (e.g., a 3-D object cannot be placed in the sky due to physical laws, nor can it obstruct the road against traffic regulations). The valid region can be obtained either by a human annotator or a semantic segmentation tool like [42]. Consequently, the feasible region can be expressed as follows:

$$\mathcal{F}(u,v) = \mathcal{F}_{\text{sal}}(u,v) \cap \mathcal{F}_{\text{val}}(u,v). \quad (7)$$

An example feasible region is shown in Figure 5. The target is the road sign highlighted by the dashed yellow box, the green color represents the thresholded salient region $\mathcal{F}_{\text{sal}}$, and the red color indicates the valid region $\mathcal{F}_{\text{val}}$. The feasible region $\mathcal{F}$ is the overlapping area containing parts from both the sidewalk and the lawn.

While the feasible region $\mathcal{F}(u,v)$ currently exists in the image space, our goal is to acquire a feasible region $\mathcal{F}(x,y,z)$ that dictates the 3-D object placement in world coordinates. To achieve this, we map the 2-D coordinate (u,v) back to the 3-D coordinate (x,y,z). This task poses an ill-posed problem since infinitely many 3-D points can project to the same 2-D point on the image plane. Nonetheless, as the 2-D plane containing the feasible region is known (typically the ground), we can compute the 3-D coordinates uniquely. This process is the inverse of the one described in Section 4.2.1 and can be performed by solving for (x,y,z) based on the equation:

$$s\begin{bmatrix} u & v & 1 \end{bmatrix}^\intercal = \mathbf{K}\begin{bmatrix} \mathbf{R} & \mathbf{t} \end{bmatrix}\begin{bmatrix} x & y & z & 1 \end{bmatrix}^\intercal, \quad (8)$$

where s is a scale factor resulting from the fact that the 2-D coordinates (u,v) are homogeneous coordinates, which means that they can be scaled by any non-zero factor while still representing the same point on the image plane. For example, although $(u,v,1)$ and $(2u,2v,2)$ represent two distinct 3-D points in the world coordinate frame, they are equivalent

homogeneous coordinates in the image. The scale factor s accounts for this ambiguity when converting from 2-D to 3-D coordinates. Take a feasible region on the ground as an example, to obtain the 3-D coordinate, we can solve for s by substituting $z = z_{\text{ground}}$ into Eqn. (8) and taking the dot product with the third row of $[\mathbf{R}\,\mathbf{t}]$, then substitute it back to get $(x, y, z_{\text{ground}})$.[1] the feasible region might reside in other planes as well.

4.3 Object Placement and Rendering

After reconstructing the world coordinate frame and identifying the feasible region, we can model the chosen 3-D object into the scene. In the modeling process, coordinate (x, y, z) in the world coordinate frame and pose ρ are obtained by the heuristic optimization method. We opt for heuristic optimization over gradient-based optimization (e.g., backpropagation) techniques because we cannot compute the gradients of black-box MDE models. We especially choose the particle swarm optimization (PSO) [36] in the family of heuristic algorithms due to its high performance. We compare PSO with other heuristic algorithms in Section **??**. PSO is inspired by the social behavior observed by a group of animals in nature, such as fish and birds, that move in the space and share information about their best position. Technically, PSO solves an optimization problem by having a population of candidate solutions, called particles that move around in the search space seeking to maximize the fitness function:

$$\zeta = \sum_{(u,v)\in T} \left| D(u,v) - D_{o,x,y,z,\rho}(u,v) \right|, \tag{9}$$

which measures the difference between the modified and original depth maps.

Each particle has a position p and velocity $\dot{p}$ in the search space P_o. Note that the position p in P_o should not be confused with the coordinate in the world coordinate frame. Rather, it is a collective term consisting of the current state of the coordinate (x, y, z) and the pose ρ of the placed 3-D object. Note that the coordinate (x, y, z) of the 3-D object is constrained by the feasible region $\mathcal{F}(x, y, z)$, as determined by Eqn. (7) and (8). As such, we represent the position and velocity of the i-th particle in the search space as $p_i = (x_i, y_i, z_i, \rho_i)$ and $\dot{p}_i = (\dot{x}_i, \dot{y}_i, \dot{z}_i, \dot{\rho}_i)$, respectively. Each particle keeps track of its best-known personal position p_i^{pbest} and the best-known position of the entire swarm p^{gbest}. The particles update their positions and velocities at each iteration based on their p_i^{pbest}, p^{gbest}, and some random factors for exploration. We provide the details of π-Jack's PSO algorithm in **Algorithm 1**.

After placement of the 3-D object, we use HDR (high dynamic range) lighting [55] with the estimated skydome illumination to cast realistic shadows of the 3-D object on the ground plane $z = z_{\text{ground}}$ or any other modeled plane in the scene. We further employ a path-tracing renderer (e.g., Cycles [31]) to render the object with appropriate shaders and materials. Then, we composite it into the original image. Finally, we perform color correction and noise reduction to make the object blend seamlessly into the background image.

[1] The ground is used only as an example here,

Algorithm 1: PSO algorithm for π-Jack.

Input: Scene image I, depth estimation model $\theta(\cdot)$, collection of 3-D objects O, target region T in I
Output: An object $o^* \in O$ and a coordinate and pose $(x^*, y^*, z^*, \rho^*) \in P_o$ that maximize fitness function ζ

Def stopping criterion ε and acceleration constants c_1, c_2
Initialize the current best fitness function $\zeta^* = -\infty$
for *each object* $o \in O$ **do**
  Initialize a population of particles with random positions $p_i = (x_i, y_i, z_i, \rho_i)$ and velocities $\dot{p}_i = (\dot{x}_i, \dot{y}_i, \dot{z}_i, \dot{\rho}_i)$ in the search space of P_o
  Evaluate i-th particle's fitness: $\zeta_i = \zeta(p_i)$
  Set the individual best position of each particle to its current position: $p_i^{\text{pbest}} = p_i$
  Set the global best position to the position of the best particle: $p^{\text{gbest}} = \arg\max_{p_i} \zeta(p_i)$
  while $|p^{\text{gbest}} - p_i| > \varepsilon$ **do**
    for *each particle* **do**
      Update the velocity of the particle : $p_i \leftarrow \omega[\dot{p}]_i + c_1 r_1 (p_i^{\text{pbest}} - p_i) + c_2 r_2 (p^{\text{gbest}} - p_i)$, where r_1, r_2 are random numbers in $[0, 1]$ and ω is the inertia weight
      Update the position of the particle using the velocity: $p_i \leftarrow p_i + \dot{p}_i$
      Evaluate the fitness of the particle: $\zeta_i = \zeta(p_i)$
      if $\zeta_i > \zeta_i^{\text{pbest}}$ **then**
        Update the personal best position of the particle: $p_i^{\text{pbest}} = p_i$
      if $\zeta_i > \zeta_i^{\text{gbest}}$ **then**
        Update the global best position: $p^{\text{gbest}} = p_i$
  if *the attack object o's best fitness is better than the current best fitness* **then**
    Store the best object, position, and pose: $o^*, x^*, y^*, z^*, \rho^* = o, x^{\text{gbest}}, y^{\text{gbest}}, z^{\text{gbest}}, \rho^{\text{gbest}}$
return $p^* = (o^*, x^*, y^*, z^*, \rho^*)$

4.4 Robust Design and Analysis

In this section, we first introduce an optimization technique called EoM&I to make π-Jack robust, then perform a mechanistic analysis to understand why π-Jack is intrinsically explainable and robust.

4.4.1 Expectation over Motion and Illumination

The above optimization of the 3-D object placement assumes a static scene. Nevertheless, the photos are dynamic and evolve over time due to the vehicle's motion and illumination variations, both being important aspects dictating image rendering and reflecting the inherent dynamics of AD systems and real-world driving conditions. Therefore, we employ the ideas in [5, 49] and formally create the expectation over motion

and illumination (EoM&I). To implement EoM&I, we first define a distribution of photos captured along the vehicle's moving trajectory $\mathcal{M}$ to model the domain shift of the image due to different viewing angles in consecutive frames as the vehicle moves. To ensure that the 3-D object we place stays at the same location across all frames, we use the Kanade-Lucas-Tomasi (KLT) algorithm [43] to track the motion of several anchor points (e.g., corners/edges with high visibility and distinctiveness) in the feasible region using optical flow, and get a solution of the camera's motion. We further use the solved trajectory of the camera to align our 3-D object at the same position in the world frame across consecutive photos.

We also consider a distribution of different illumination conditions $\mathcal{G}$ to account for the possible error of illumination estimation in Section 4.2.2, as well as the shadow and brightness variations as time elapses. These illumination conditions include different sun directions $\mathbf{l}_s$, atmospheric turbidity τ, exposure ω, and zenith illumination L_z. Collectively, these parameters encapsulate all the components necessary for the models [12, 27] described in Eqns. (3) and (4). Since the potential estimation error and parameter difference are usually small, the new illumination condition is only slightly different from the original estimated one. Based on the above analysis, we can reformulate the objective of π-Jack attack as follows:

$$\arg\max_{\substack{o\in O,\\(x,y,z,\rho)\in P_o}} \mathbb{E}_{\substack{m\sim\mathcal{M},\\ g\sim\mathcal{G}}}\left[\sum_{(u,v)\in T}\left|D(u,v)-D_{o,x,y,z,\rho}(u,v)\right|\right]. \quad (10)$$

In practice, it is unfeasible to explore all possible photos along the trajectory in $\mathcal{M}$ and illumination conditions in $\mathcal{G}$ due to high computational cost. Thus, we approximate the expectation in Eqn. (10) by averaging five consecutive frames and five randomly sampled variations of illumination conditions, resulting in $5\times 5=25$ images in total.

4.4.2 Mechanistic Analysis

The optimization goal of Eqn. (10) is to maximize the perceived depth difference before and after placing the object. Nonetheless, it is critical to understand that Eqn. (10) does not inherently predict whether the target will appear closer or further away following the optimization process. This indeterminacy is a byproduct of the optimization's heuristic nature, which introduces randomness to the attack outcome. Given these constraints, we perform a retrospective examination of the attack's impact, as opposed to making a priori predictions on the target's position. Through a careful examination of post-attack observations (refer to Figures 6 and 19 for concrete examples), we proceed with a posterior mechanistic analysis. This analysis reveals two ways in which π-Jack manipulates depth perception.

First, π-Jack is able to *creates* deceptive perspectives by establishing textural similarity between the target and inserted objects, and by blending structured lines of objects with existing linear perspectives. These approaches forge visual links between the target and the introduced objects, misleadingly suggesting *proximity* of the target. Second, π-Jack is also able to *disrupts* established perspectives by concealing critical target boundaries essential for MDE systems' depth calculations, and by disrupting the scene's natural perspective lines with contrasting linear patterns. These tactics weaken MDE's reliance on genuine perspective cues, associating the target with *distant* objects within the scene.

5 Implementation, Setup, and Metrics

In this section, we provide details on π-Jack's implementation, and introduce the experiment setup and metrics in our study.

5.1 System Implementation and Setup

We employ Blender 3.6 for 3-D modeling and rendering, and automate the modeling and rendering process with the Blender 3.6 Python API. All deep learning algorithms, including the illumination estimation and MDE models, are built upon PyTorch 1.7.1. For illumination estimation, we set $\alpha=0.3$ empirically for an urban driving environment. In feasible region identification, the standard deviation of the Gaussian kernel is set to 10 pixels, and the threshold $T=5$. For 3-D object placement, we limit the angles with respect to the three axes to less than 10° to ensure that the object appears natural and inconspicuous. We employ Python 3.7 to implement and analyze the PSO algorithm and the feasible regions, setting both acceleration constants of the PSO algorithm c_1 and c_2 to 2. For EoM&I, the turbidity variation is within a range of ± 0.5, the exposure variation is within a range of ± 0.005; the variation of the sun position is within a range of $\pm 5^\circ$ (equivalent to the sun moving 40 minutes); the variation of the zenith illumination is 100 lux. The camera-solving process is implemented by the Libmv [82] library.

5.2 Experiment Setup

We select 500 experiment AV scenes from the KITTI dataset [19], encompassing a broad spectrum of road conditions such as highways, crosswalks, and pedestrian areas. These scenes also include a variety of background objects like buildings, trees, trucks, smaller vehicles, traffic signs, and traffic lights. In addition to this, we gather our own AV scenes, both with and without strategically positioned objects, to evaluate π-Jack in real-world scenarios. For the MDE model, we choose to evaluate π-Jack using MonoDepth2 [21], Depth-Hints [67], and ManyDepth [68]. We make this selection based on their practicality, as they employ a self-supervised training strategy similar to the ones used by Tesla Autopilot [1, 17, 59] and Waymo [86], eliminating the need for ground-truth depth while achieving comparable accuracy with supervised training. Furthermore, they are open-sourced and readily available.

5.3 Metrics

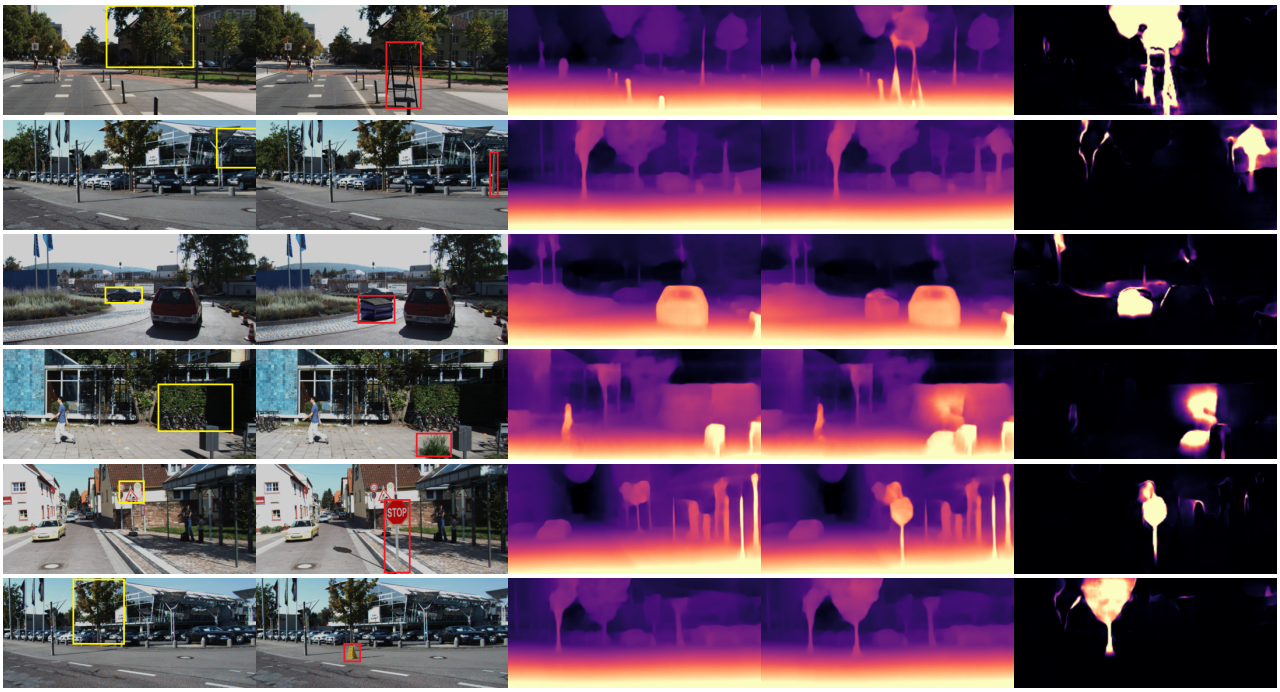
Mean depth error. For a specific target region T in the image, the mean depth error is defined as the average discrepancy

between the perceived depth of the original scene and the modified scene after π-Jack attack at each pixel $(u,v) \in T$.

Intersection over union (IoU). For the downstream task of road segmentation, we use IoU to quantify the overlap between ground truth and the prediction pixel sets as the ratio of their intersecting and union areas.

Average precision (AP). For the downstream task of 3-D vehicle detection, AP measures the accuracy of detection by averaging the precision scores at different intersections over IoU thresholds. A lower AP means that the model misses some or detects wrong vehicles due to π-Jack attack.

6 Attack Evaluation



We begin by assessing the overall performance of π-Jack. Following this, we analyze the robustness of the attack under various practical factors, such as object size, and distance attack vectors. In addition, we conduct an ablation study to examine how π-Jack performs without the EoM&I techniques. Subsequently, we compare the PSO algorithm used by π-Jack with other optimization algorithms, and investigate the generalization capability of π-Jack to other models. Finally, we evaluate π-Jack with real-world scenes and attack vectors. We postpone extended discussions of impact of π-Jack on downstream tasks such as object detection and semantic segmentation in Appendix A.

6.1 Overall Performance

Figure 6 illustrates some examples of how π-Jack can manipulate depth estimation. In each example, the original scene is shown in Figure 6(a), with the target object highlighted by a yellow box. The modified scene after π-Jack attack is shown in Figure 6(b), with the attack vector highlighted by a red box. The depth maps of the original and modified scenes are shown in Figures 6(c) and 6(d), respectively. The absolute difference between the two depth maps is shown in Figure 6(e). It is important to understand that changes in depth across the entire picture are unintended byproducts of optimizing a localized objective function. Each row of Figure 6 demonstrates a different scenario and together these scenarios illustrate the effectiveness and diversity of π-Jack attack.

The first row shows how a ladder can trick the depth estimation system into believing that a faraway tree is almost as close as the ladder. The second row presents a case where a simple barrier pole can alter the perceived depth of a large portion of a building. The third row indicates that a garbage bin can affect the depth estimation of a moving vehicle, suggesting that downstream tasks such as 3-D vehicle detection are also vulnerable to π-Jack attack. The fourth row reveals that a clump of grass can deceive the MDE into thinking that a distant bush is much closer. It also shows that the attack vector and the target object do not need to touch in the image space for the π-Jack attack to succeed. The fifth row depicts how a "stop" sign can distort the depth of more distant traffic signs. In the sixth row, it can be observed that a small 3-D object such as a safety sign can successfully hijack the perspective of a much larger target object such as a remote tree.

We further evaluate π-Jack 's performance by measuring the mean depth error for various targets and attack vectors.

(a) Original scene. (b) Attacked scene. (c) Original depth estimation (d) Attacked depth estimation. (e) Depth difference.

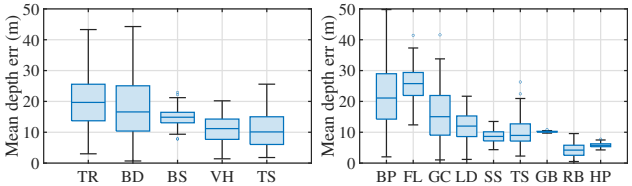


Figure 6: Example estimated depth maps before and after π-Jack attack.

The average depth error is 14.75 m, with detailed results reported in Figures 7(a) and 7(b). Figure 7(a) reveals that the medians for the mean depth errors of the target tree (TR), buildings (BD), bush (BS), vehicles (VH), and traffic signs (TS) are 19.68 m, 16.59 m, 14.87 m, 11.18 m, and 10.15 m, respectively. The reason behind the observation that trees are most vulnerable is that any pole-shaped 3-D object may hijack the depth estimation of the trunk of the tree significantly. Moreover, trees can also be attacked effectively because they have a texture that can be easily mimicked by plants such as a clump of grass. Buildings are also prone to π-Jack because they share many common structural features (e.g., parallel lines and rectangular patterns) with attack vectors. Although a bush has a similar texture to trees, its irregular shape and position make it less vulnerable to attack vectors in the feasible regions. Traffic signs and vehicles pose the most challenges for π-Jack due to their placement on perspective-rich roads, distance from feasible regions, and incongruent colors/textures with our attack vectors. Nonetheless, their median depth error exceeding 10 m represents a significant threat to AV-MDE.

Figure 7(b) shows the mean depth errors caused by different attack vectors. Barrier poles (BP), flags (FL), grass clumps (GC), ladders (LD), safety signs (SS), traffic signs (TS), garbage bins (GB), roadblocks (RB), and hydrant posts (HP) achieve medians for mean depth errors of 21.10 m, 25.77 m, 15.05 m, 12.00 m, 8.65 m, 8.973 m, 10.15 m, 4.21 m, and 5.76 m, respectively. The better performance of BP, FL, GC, and LD can be explained by Table 1. To be specific, poles and flags are the best because their superior extensibility allows them to connect and blend with distant targets; grass clump is the third best because its similar texture with distant trees and bushes enables it to blend in. Finally, ladders also perform well due to their fair extensibility and structural similarities with distant buildings.

6.2 Robustness Analysis

In this section, we analyze π-Jack's robustness to different real-life factors. These factors include the size of the 3-D object as well as the distance between the placed object and the AV camera. We postpone the robustness analysis of the vehicles displacement and sun's position to Section 6.3. We evaluate π-Jack on an Audi Q7 vehicle, utilizing a factory-installed front camera. The poses of the attack vectors are adjusted by placing foam and glue underneath.

(a) Target object. (b) Attack vector.

Figure 7: Overall π-Jack performance.

6.2.1 Effect of Object Size

We measure the planar size (height × width) of the attack vectors and investigate their impacts on depth estimation errors. The results are shown in Figure 8. Overall, object size is not strongly correlated with depth error. However, one may observe some intriguing phenomena: an object that appears smaller (0.2 m^2) to the camera may have better attack performance than an object that appears larger (1.4 m^2). This phenomenon can be attributed to the characteristics of the objects involved. For example, more extensible objects such as barrier poles, though visually smaller, demonstrated greater effectiveness in comparison to bulkier objects like garbage bins, which lack extensibility, as analyzed in Section 6.1.

6.2.2 Effect of Distance

We investigate the impact of the distance from the placed 3-D object to the camera and present the results in Figure 9. It becomes evident that when the distance to the camera falls within the range of 5 m to 20 m, the performance of the π-Jack attack remains largely insensitive to the distance, resulting in medians for mean depth estimation errors of aroufnd 20 m. However, as the distance continues to increase, the effect of the attack starts to decrease, and at a distance of 40 m from the camera, the medians for π-Jack's induced mean depth errors can be as low as 3 m. The diminishing effectiveness of π-Jack can be explained by the fact that as the distance increases, the attack vectors become smaller to the camera, thereby causing their structure and texture to become less clear and reducing their ability to hijack the perspective of the targets.

6.2.3 Effect of Object Angle

We further explore the effect of the object's azimuth angle. Given the dependency of the optimal angle on the target's position, which can significantly vary, we define the optimal angle as 0° and adjust the azimuth angle in proximity to this reference point. The robustness analysis presented in Figure 10 reveals that even within a relatively broad azimuth range of $[-3°, 3°]$, the median depth error consistently exceeds 10 m, thereby affirming the effectiveness of our approach.

6.2.4 Effect of Object Position

Object distance and azimuth angle in Section 6.2.2 and 6.2.3 are sufficient to position an object. We further examine the influence of object placement contexts, including roads (RD),

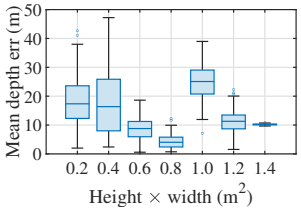

Figure 8: Impact of size.

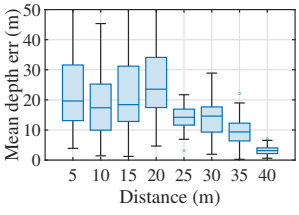

Figure 9: Impact of distance.

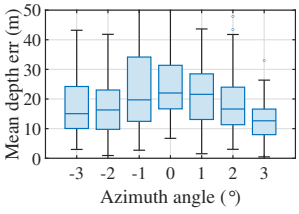

Figure 10: Impact of angle.

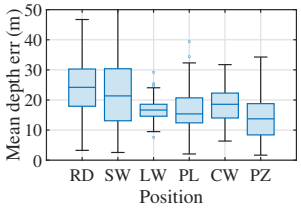

Figure 11: Impact of position.

sidewalks (SW), lawns (LW), parking lots (PL), crosswalks (CW), and plazas (PZ) in Figure 11. Our findings reveal that objects positioned on roads induce the greatest depth error. This can be attributed to the fact that roads are the most salient regions in camera views. However, while deploying attack vectors on roads might be most effective, such strategies are less feasible due to the potential for traffic disruption.

6.2.5 Effect of Illumination

We also study the impact of illumination, as shown in Figure 12. We evaluate the performance of π-Jack under environment illumination from 100 lux to 1,000 lux. The change of illumination is achieved by conducting experiments at different times of day. The results indicate that the depth errors remain relatively consistent, demonstrating limited sensitivity to changes in illumination.

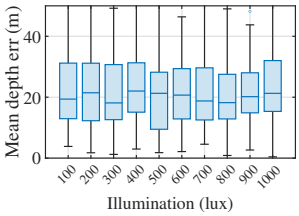

Figure 12: Impact of lux.

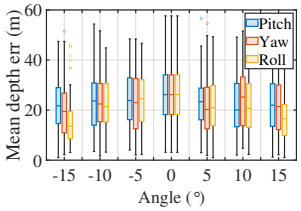

Figure 13: Impact of pose.

6.2.6 Effect of Object Pose

We also examine the effect of object pose variations (including pitch, yaw, and roll) in Figure 13. The results indicate that the system, π-Jack, sustains its high level of effectiveness across a broad range of $[-15°, 15°]$ for all three angles. Notably, changes in roll angle result in the most significant decrease in depth error, attributable to its pronounced change in the object's appearance in the camera's view.

6.2.7 Effect of Target Region Segmentation

We lastly compare the performance of manual target segmentation and SAM [37]. It turns out that the induced depth errors (on different targets and of different attack vectors) under these two segmentation methods are consistently smaller than 0.01 m, demonstrating the equivalency of these two.

6.3 Ablation Study

In this section, we conduct ablation studies on the EoM and EoI processes, comparing the results with the original π-Jack pipeline. The targets and attack vectors are the same as in Section 6.1. Figures 14,15, and16 illustrate how EoM impacts π-Jack's performance during vehicle movement. EoM consistently achieves a median depth estimation above 10 m, outperforming non-EoM cases by over 3 m on average, showcasing π-Jack's effectiveness across various velocities. Notably, EoM manages frame differences of ±2 (at a 25 m/s velocity, frame rate of 10) effectively, maintaining induced errors above 10 m, while without EoM, errors drop below 4 m. Similarly, EoM also handles lateral distances up to ±2 m effectively. Additionally, Figure 17 examines the effect of time of day on depth error estimation. Without EoI, depth error estimation decreases by 2 m under varying illuminations. However, with EoI, π-Jack's performance remains stable across the day.

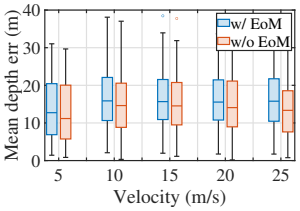

Figure 14: Velocity.

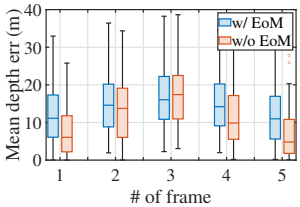

Figure 15: Number of frames.

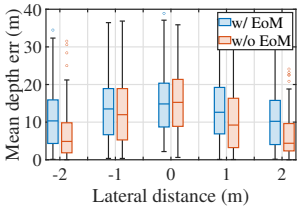

Figure 16: Lateral distance.

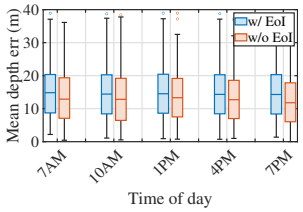

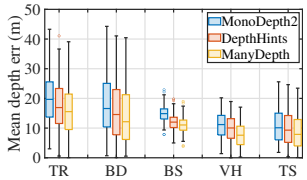

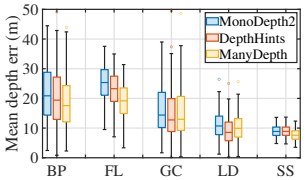

Figure 17: Time of day.

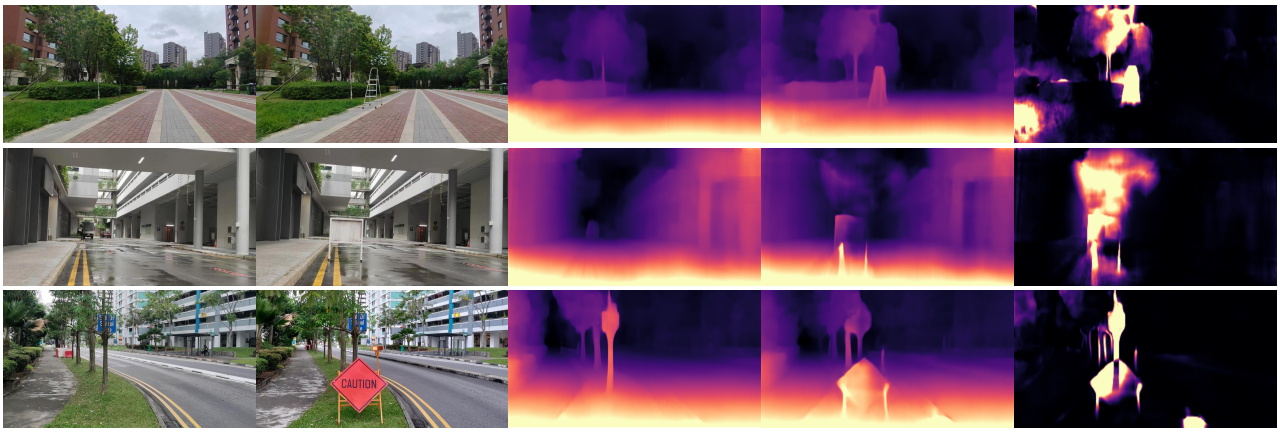
6.4 Generalization to Different MDE Models

We believe π-Jack is a general attack not limited to any specific model. To support this claim, we assess the scenes π-Jack crafts for MonoDepth2 on two other models, DepthHints and ManyDepth, and present the results in Figure 18. It can be observed that generalization to DepthHints and ManyDepth renders the attack vectors slightly less effective, with the mean depth errors decreased by an average of 2 m and 3 m, respectively. Nonetheless, even after transferring the π-Jack attack

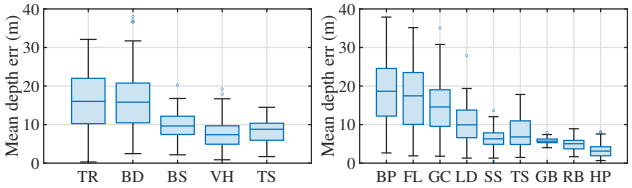


(a) Target object.

(b) Attack vector.

Figure 18: Generalizability of π-Jack to different models.

to another model, it still poses a significant threat to the safety of AD. We believe that by optimizing the attack in a model-specific manner, the performance drop can be mitigated.



(a) Original scene. (b) Attacked scene. (c) Original depth estimation (d) Attacked depth estimation. (e) Depth difference.

Figure 19: Evaluation with real-world scenes and attack vectors.

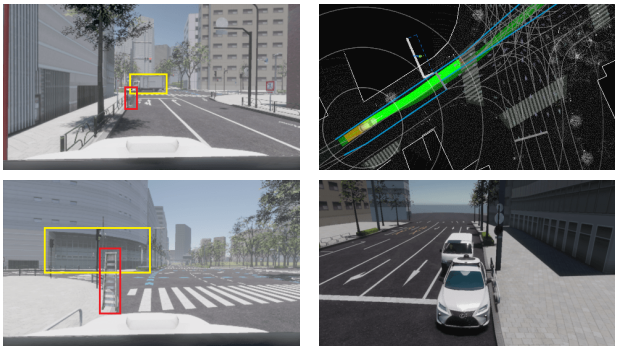
6.5 Evaluation in the Wild

To evaluate π-Jack in real life, we conduct experiments in two types of locations to ensure there's no interference from others: 1) dedicated test sites, and 2) closed roads under construction. For the latter, we have secured the necessary approvals from appropriate authorities, guaranteeing that our experiments proceed without affecting public safety or violating any regulations. We collect a total 200 scenes. Figure 19(a) shows three representative scenes for visualization purposes. Figures 19(b), 19(c), 19(d), and 19(e) show the modified scenes, the depth maps of the original and modified scenes, and the map of depth difference, respectively. In the first scene with a tree as the attack target, π-Jack selects a ladder as the attack vector. It can be observed that the target tree is "hijacked" closer to the attack vector. In the second scene with a building including its skylight as the attack target, π-Jack selects a roadblock as the attack vector. It can be observed that the affected area is much larger than the first scene, probably due to the rectangular structure shared by the roadblock and a large portion of the building body. In the third scene, the attack target is a tree, and π-Jack selects a traffic sign "caution" as the attack vector. One may readily observe that the target tree is moved further away from the attack vector in the depth map, creating an "inverse" perspective hijacking effect. Rather than creating a false perspective and makes targets appear closer, π-Jack disrupts the perspective information of the tree by obscuring its root, and makes it blend with a more distant background tree.

(a) Target object. (b) Attack vector.

Figure 20: Summary of real-world evaluations.

We further present the performance statistics in various scenes. The average mean depth error is 10.14 m, as illustrated in Figure 20. In real-world scenarios, the induced depth estimation errors are slightly smaller than those in the composited images, as shown in Figure 7. These differences can be attributed to the bias brought by a smaller number of real-world scenes requiring laborious placement. However, the results across the targets and attack vectors exhibit a similar trend and align with the outcomes obtained from composited images. The results with real-world scenes and objects show that the success of π-Jack does not stem from peculiarities or artifacts in the workflow. Instead, perspective hijacking is a feasible and effective attack in the physical world.



7 Security Analysis and Defense Discussion

7.1 Security Analysis

Since modern AVs adhere to the "Sense-Plan-Act" design paradigm [18], any malfunction occurring in the MDE module (residing in the "Sense" layer), which is targeted by π-Jack, will propagate to the upper layers. To analyze the security implications of π-Jack in the entire AD stack, we conduct end-to-end simulations using the AWSIM [83] and Autoware [60]. We employ the Tokyo West Shinjuku map and a customized Dallara AV-21R vehicle. The simulation features 30 NPCs and uses a traffic seed value of 20. Autoware employs the 3-D object detection algorithm BEVDet [28]. We implement the π-Jack attack by introducing a 3-D model of the attack vectors into the simulation environment. It is important to note that we do not aim to involve performing evaluations on a real AV in the physical world due to the associated costs and safety considerations.

Our findings from the simulation are quite concerning. Even in a traffic-free scenario, π-Jack lead to high incidences of improper lane changes and abrupt braking at rates of 63.4% and 55.0%, respectively. Furthermore, these flawed decision-makings result in a 23.9% probability of the vehicle diverting off its course and colliding with other objects. When introducing traffic into the scene, the compromised MDE results in a 42.4% likelihood of collisions with other vehicles or pedestrians. In stark contrast, the rates of improper lane changes,

abrupt stops, and collisions are all 0% in the absence of the π-Jack attack. Our observations clearly illustrate that the repercussions of the π-Jack system are not confined to the "Sense" layer alone, but extend throughout the entire stack of AD systems. This highlights the critical need for both rigorous unit testing and comprehensive strategies to address MDE-related security issues, as indicated by AD industry standards [30].

(a) AV scene. (b) π-Jack's effect.

Figure 21: Example scenes from AWSIM and Autoware.

We illustrate two example scenes from AWSIM and Autoware in Figure 21. Attack vectors and targets are highlighted with red and yellow bounding boxes, respectively. In the first scene, a garbage bin is used as an attack vector to target a distant truck. As shown in planning, the AV system erroneously perceives the truck as being on the roadside and changes its lane to avoid it. In the second scene, a ladder is employed to target a distant building. The AV system mistakenly thinks the building is blocking the road and decides to brake abruptly, resulting in a collision with another vehicle behind, as shown in the rotate-around scene.

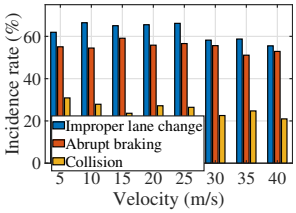


Figure 22: Impact of velocity.

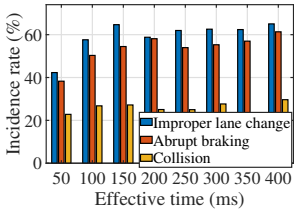

Figure 23: Impact of time.

Velocity and timing also influence the rate of flawed decision-making. In Figure 22, it is shown that the accident rate remains consistent for velocities under 35 m/s but slightly decreases at higher velocities, likely due to the diminished temporal effect of π-Jack on the AV system. Consequently, we further assess the notion of effective time, which we define as the duration an object remains within the target's salient region. The region's boundary is determined by setting a threshold at 10% of the maximum value found in the saliency map. Figure 23 illustrates that when the effective time is below 100 ms, the incidence rate decreases, probably due to the limited perception rate. We leave π-Jack's evaluation on more AD systems such as LGSVL and Apollo to future works.

Table 2: Effects of defense by adversarial training.

Mean depth error (m)	Adversarial training (conventional)	Adversarial training ([10])
MonoDepth2	13.87 (↓ 0.88)	12.33 (↓ 2.42)
DepthHints	10.93 (↓ 1.89)	9.91 (↓ 2.91)
ManyDepth	9.61 (↓ 1.69)	8.72 (↓ 2.58)

7.2 Potential Defense Methods

One potential defense method to defend against the perspective hijacking attack is conventional adversarial training. The idea is to collect AV data with adversarial examples containing 3-D objects in the model's training stage to improve the model's robustness. We follow the steps in Section 4 to place 100 effective attack vectors, and use the KLT algorithm in Section 4.4 to insert the 3-D objects into consecutive camera frames. We anticipate that this kind of training can make the MDE model less sensitive to perspective hijacking. We train the MDE model with this method and test its performance against π-Jack attacks using composited images. Table 2 indicates that this defense can improve the MDE model's robustness and raise the attack difficulty. However, the 0.88 m, 1.89 m, and 1.69 m decreases in mean depth error are not very impressive, probably because the limited number of attack vectors we craft cannot cover all vulnerabilities in the feasible region. We leave a more effective defense based on adversarial training to future work.

Besides conventional adversarial training, a novel strategy specifically tailored for self-supervised MDE is introduced by [10]. This method distinguishes itself from the conventional approach by inserting adversarial objects into only the latter of two consecutive frames during self-supervised training. This selective placement can prevent the model from converging on inaccurate yet robust depth estimations, which might occur when 3D objects are employed across all frames. By ensuring depth estimation consistency between consecutive frames with the adversarial object appearing in just the latter, this approach effectively removes the constant bias introduced by an adversarial object. Table 2 shows that this refined defense mechanism enhances the robustness of MDE models, further reducing the depth error by 2.42, 2.91, and 2.58 m for three MDE models, outperforming conventional adversarial training. It should be noted that the refined defense's success against stronger patch attacks relies on the MDE model's familiarity with the attacks, not their strength. In the π-Jack attack, only a few attributes (e.g., pose and distance) are manipulated, unlike patch attacks where every pixel can change. This limitation reduces the defense's effectiveness in adapting the MDE model to π-Jack attacks compared to patch attacks. However, the effectiveness of both adversarial training methods remain somewhat limited due to the constrained number of attack vectors available, underscoring the efficacy of the proposed π-Jack attack.

A different approach to defend against π-Jack is adversarial

detection. The method identifies and rejects adversarial inputs before feeding them to the model. For example, the AV-MDE system may use auxiliary classifiers to detect anomalous inputs that may contain perspective-hijacking patterns. Another possible defense mechanism is to use multiple sensors or modalities to estimate depth, such as lidar and radar that directly measure the distance of objects. By fusing the information from different sources, AV can reduce the dependence on a single cue and increase the robustness to perspective hijacking. However, these methods face additional challenges such as sensor calibration, data alignment, and computational cost. Moreover, they might be infeasible as some car manufacturers such as Tesla rely on the all-vision AV solution [1, 59].

7.3 Safety Considerations

Since most vision-based commercial AD/robotics systems rely on either explicit or implicit depth estimation in their object detection and segmentation modules, they should be universally vulnerable to the π-Jack attack. Testing all of these systems is beyond the capability of the authors, so we leave the case-by-case investigation to future research. Section 7.2 presents defenses that, upon enhancement, could potentially counter the π-Jack attack effectively. It is essential to emphasize that the exploration of the π-Jack attack adheres to ethical research standards, with no intention to facilitate real-world attacks against AVs. Instead, by bringing the π-Jack attack to light, we seek to alert the academic community to this vulnerability, encouraging a concerted research effort to safeguard against these threats. This proactive disclosure is intended to preemptively counteract malevolent entities from exploiting these vulnerabilities in real-world scenarios, ensuring the advancement of cybersecurity in the AV sector.

8 Related Work

8.1 Attack on Autonomous Driving Perception

AD systems rely on sensors such as camera, lidar, radar, ultrasonic, and IMU for perception [76, 78, 79]. However, these sensors are vulnerable to spoofing (i.e., broadcasting false or modified signals that cause the sensors to produce incorrect results) [3, 6, 48, 52, 64, 72, 73] and jamming (i.e., overpowering the signals with noise that overwhelm the receiver) [52, 72] attacks. These attacks target vulnerabilities at the signal processing level, without exploiting the algorithms that process the sensor information. In contrast, more recent attacks focus on higher levels (e.g., AD perception and autonomy level) by exploiting vulnerabilities intrinsic to AD software and algorithms. Some examples include attacks on camera/lidar object detection [6, 8, 54, 75], tracking [33], localization [51], lane detection [34], intrusion detection [58], steering angle detection [11], and end-to-end AD [62].

8.2 Digital Adversarial Attacks

Conventional adversarial attacks typically occur in the digital domain, where crafted perturbations are directly fed to the model. These perturbations are usually bounded by the l_p norm [7, 22, 44, 77] to remain imperceptible. Digital adversarial attacks can be either white-box or black-box, depending on the attacker's access to the model. In white-box attacks, the attacker has full knowledge of the model (e.g., input, output, weights) and can use the model's gradient to generate adversarial perturbations [7, 22, 40, 44, 46]. In black-box attacks, the attacker can only input data and observe the model's output, without knowing the model's architecture and parameters. However, even in black-box settings, attackers can exploit the transferability of perturbations to similar models [13, 45, 63] or estimate model information through multiple queries [29].

8.3 Physical-World Adversarial Attacks

In contrast to digital domain attacks, physical-world adversarial attacks on MDE are more realistic yet more challenging, as they require robust perturbations that can survive various environmental factors (e.g., lighting, weather, distance, and angle) and affect the 3D scene understanding of autonomous systems. Previous works have investigated the "sticker-pasting" strategy [15] on the *pixel level* to attach stickers on traffic signs [15], cars [8, 9, 71], and roads [71] to mislead deep neural networks such as classfiers [4, 15], object detectors [8, 8, 16, 54, 61, 75], and depth estimation networks [9, 15]. These attacks leverage techniques such as style transfer [9] and EoT [2, 32] to make the stickers less noticeable and more robust to real-world conditions.

More recent physical-world attacks exploit light and shadow phenomena to achieve non-invasive attacks without physically modifying target objects or scenes. For instance, AdvLB [14] and DoubleStar [81] use light beams directly as attack vectors, proving to be effective physical-world attacks on DNNs. OPAD [20] deceives classifiers by projecting structured illumination with a low-cost projector. Zhong et al.[80] use natural-looking shadows to mislead traffic sign classifiers without alerting humans. Sayles et al.[50] leverage the rolling shutter effect to generate desired outputs. Most of these attacks work by transferring pixel-level attacks to the physical world, except for [34], which operates on the scene level by placing line markings on the road.

9 Conclusion

In this paper, we propose π-Jack as the first physical adversarial attack on AV-MDE systems utilizing perspective hijacking. Exploiting ordinary 3-D objects as attack vectors, π-Jack offers superior effectiveness, robustness, accessibility, and inconspicuity. Our experiments validate the high attack success rate and large depth difference achieved by π-Jack, demonstrating its successful application in both composited and real-world AV scenes. We also explore π-Jack's extensions to two downstream tasks of road segmentation and 3-D vehicle detection. Our results expose critical vulnerabilities in widely-used AV-MDE models and hence underscore an urgent need for enhanced security measures against such risks.

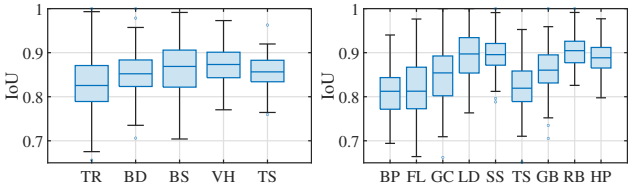
A Impact on Downstream Tasks

In this section, we evaluate π-Jack's impact on road segmentation and 3-D vehicle detection.

A.1 Road Segmentation

Road segmentation is critical for AD, enabling the vehicle's AI to distinguish drivable from non-drivable areas for safe navigation and accident prevention. Moreover, it assists in comprehending the environment for effective decision-making and planning. Attacks on depth estimation can severely affect the segmentation by misleading the vehicle on object distance and location. This can result in an erroneous interpretation of drivable areas, leading to unsafe driving conditions. To demonstrate π-Jack's impact on road segmentation, we employ the widely used fully convolutional networks to generate road segmentation before and after π-Jack attack. As illustrated in Figures 24(a) and 24(b), the introduction of a flag in

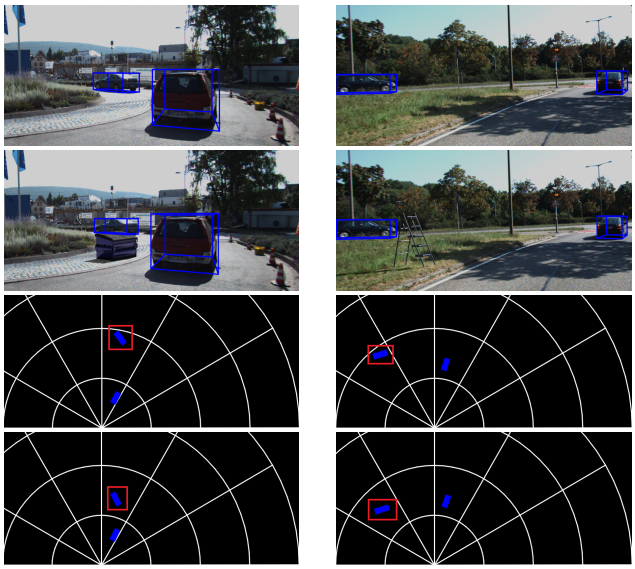


the first row of Figure 24 disrupts the perspective of a distant tree, causing a complete failure in the segmentation between the flag and the tree. Similarly, the second row demonstrates how a clump of grass disrupts the perspectives of both distant trees and nearby lawns, leading to the recognition of a large "forbidden" area on the road.

(a) Original scene. (b) Attacked scene.

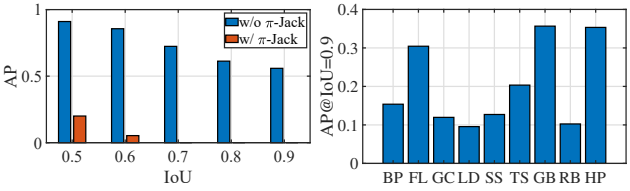
Figure 24: Road segmentation.

We further quantitatively assess how π-Jack affects road segmentation. Without the π-Jack, the average IoU between the segmented road and the ground truth is 0.942. However, upon launching the π-Jack attack, the average IoU drops significantly to 0.867. The detailed IoU values for different targets and attack vectors are illustrated in Figures 25(a) and 25(b), respectively. It becomes evident that there is a negative correlation between the IoU and mean depth error induced by the π-Jack attack (shown in Figure 7), firmly indicating that the hijacked depth disrupts the downstream task of road segmentation.



(a) Target object. (b) Attack vector.

Figure 25: IoU of segmented road before and after attack.



A.2 3-D Vehicle Detection

3-D vehicle detection is another important task of AD, as it allows the vehicle to accurately perceive and locate surrounding vehicles in 3-D space, which is essential for safe navigation and decision-making. Given that 3-D vehicle detection largely depends on depth information, a π-Jack attack can significantly compromise the accuracy and reliability of the detection system. This might lead to incorrect or incomplete object detection, thereby jeopardizing the safety of the AV and its passengers. We use the state-of-the-art MonoCon [41] to perform vehicle detection. Figure 26 illustrates the outcome of vehicle detection, with the first two rows presenting the 3-D bounding boxes before and after the attack, and the last two rows showing the detection results from a bird's-eye view. It can be clearly seen from Figure 26(a) how the introduction of a garbage bin can alter the perspective of a distant vehicle by approximately 5m. Similarly, in Figure 26(b), a ladder can distort a vehicle's perspective even without overlapping with it in the image space.

(a) Example scene 1. (b) Example scene 2.

Figure 26: 3-D vehicle detection.

(a) IoU threshold. (b) Attack vector.

Figure 27: AP of detected vehicle before and after attack.

We further evaluate how π-Jack affects 3-D vehicle detection quantitatively. As shown in Figure 27(a), without the π-Jack attack, the AP of vehicle detection at IoU thresholds from 0.5 to 0.9 are 91.04%, 85.63%, 72.38%, 61.27%, and 55.88%, respectively. However, upon launching the π-Jack attack, the AP decreases to 20.3%, 5.33%, 0%, 0%, and 0%, respectively, indicating an AP drop of more than 71%. We further analyze how different attack vectors affect the AP of vehicle detection, focusing on AP@IoU=0.5 due to the small APs at IoU thresholds from 0.5 and 0.9. As shown in Figure 27(b), we determine that the most effective attack vectors for vehicle detection are grass clump, ladder, and roadblock, with APs of 11.96%, 9.56%, and 10.25%, respectively. The prominent performance of these attack vectors can be attributed to their similar structures and locations with vehicles on the road.

AE-Morpher: Improve Physical Robustness of Adversarial Objects against LiDAR-based Detectors via Object Reconstruction

Abstract

LiDAR-based perception is crucial to ensure the safety and reliability of autonomous driving (AD) systems. Though some adversarial attack methods against LiDAR-based detectors perception models have been proposed, deceiving such models in the physical world is still challenging. While existing robustness methods focus on transforming point clouds to embed more robust adversarial information, our research reveals how to reduce the errors during the LiDAR capturing process to improve the robustness of adversarial attacks. In this paper, we present AE-Morpher, a novel approach that minimizes differences between the LiDAR-captured and original adversarial point clouds to improve the robustness of adversarial objects. It reconstructs the adversarial object using surfaces with regular shapes to fit the discrete laser beams. We evaluate AE-Morpher by conducting physical disappearance attacks that use a mounted adversarial ornament to conceal a car from models' detection results in both SVL Simulator environments and real-world LiDAR setups. In the simulated world, we successfully deceive the model up to 91.1% of the time when LiDAR moves towards the target vehicle from 20m away. On average, our method increases the ASR by 38.64% and reduces the adversarial ornament's projection area by 67.59%. For the real world, we achieve an average attack success rate of 71.4% over a 12m motion scenario. Moreover, adversarial objects reconstructed by our method can be easily physically constructed by human hands without the requirement of a 3D printer.

1 Introduction

Advancements in artificial intelligence and sensor technology have significantly accelerated the development of autonomous driving (AD) in recent years, bringing it closer to widespread adoption. Presently, a considerable number of vehicles on the road incorporate autonomous features, with their prevalence continually expanding. Systems like Tesla's Autopilot and GM's Super Cruise can even partially take over vehicle control, handling specific driving tasks. Consequently, the safety of autonomous driving systems has emerged as an increasingly critical concern.

LiDAR sensors and LiDAR-based perception models are critical components of AD systems' perception modules. However, the vulnerability of deep neural networks (DNNs) to adversarial examples (AEs) has raised concerns regarding the security of LiDAR-based perception models. Some studies [9, 12, 13, 15, 16, 40, 43, 49] have explored the use of adversarial object attacks to deceive LiDAR-based perception models to output incorrect perceptions that could potentially lead to accidents. Nevertheless, conducting an effective physical-world attack against LiDAR-based perception models is challenging. Because these models typically operate in dynamic environments, deceiving them demands more robust AEs capable of handling varying relative distances and viewing angles.

For the physical adversarial attack against camera-based perception models, many robustness improvement methods [17–19, 24, 25, 27, 29, 30, 32, 47] have been proposed. However, to the best of our knowledge, effective robustness improvement methods for physical adversarial object attacks against LiDAR-based perception models remain limited. Some approaches [20, 28, 33, 39, 44] introduce a surface smoothness function during adversarial optimization. However, these methods are designed for dense 3D scanner point clouds and are unfeasible for sparse LiDAR point clouds. Transformation-based methods [11, 45, 46], such as EOT [11], has been employed in MSF-ADV [13]. However, the effectiveness is mainly proved on small objects like traffic cones or boxes and presents additional challenges in terms of convergence.

Therefore, this paper aims to propose an effective robustness improvement method to enable more threatening and realistic physical adversarial attacks against LiDAR-based detection models. To achieve it, we need to consider the following two key questions:

Q1: What causes the loss in the robustness of physical

*The corresponding authors.

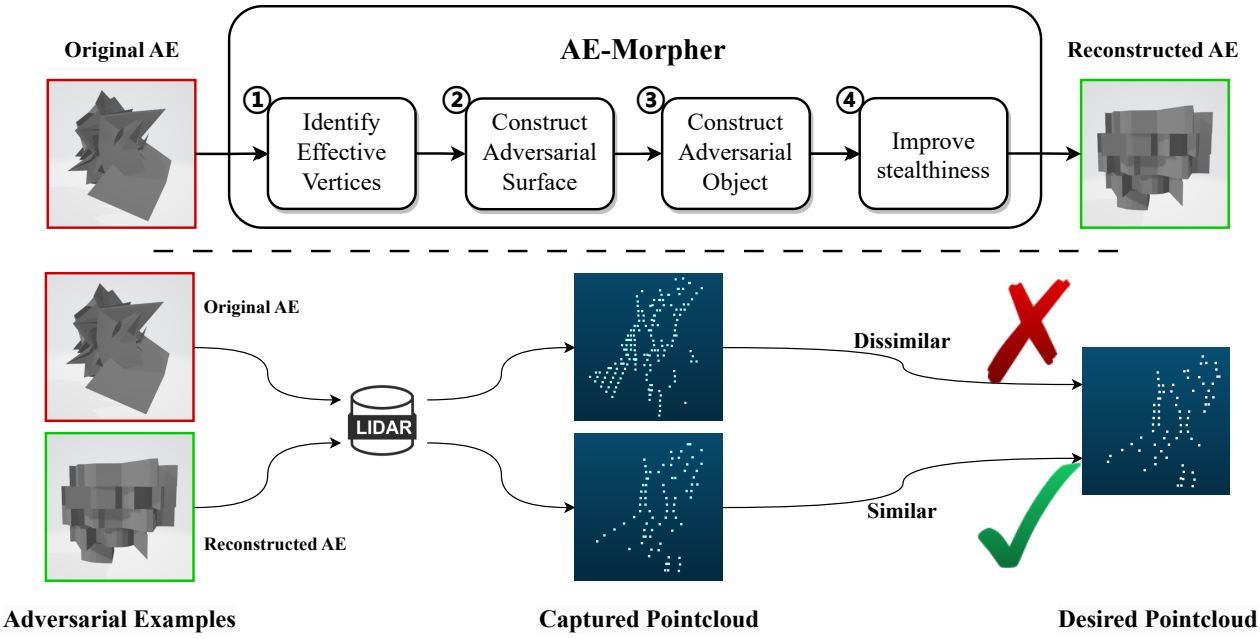

Figure 1: Overview of AE-Morpher. The desired adversarial point cloud p_{adv} can successfully deceive the target model in the digital realm, representing how the attack expects the original AE to be perceived by LiDAR. However, the captured point cloud of the original adversarial object often differs from this desired representation. Therefore, we propose AE-Morpher, a method aimed at reconstructing the original adversarial object to minimize the discrepancies between the captured point cloud and the desired point cloud.

adversarial attacks against LiDAR-based detection models?

In order to attack a LiDAR-based perception model in the real world, the attacker needs to generate an adversarial point cloud p_{adv}, transform it into a 3D object x_{3D}, and 3d print it as x'_{3D}. The LiDAR then captures the beam reflected from x'_{3D}, generating point cloud p'_{adv} and feeds it to the perception model.

Upon comparing multiple pairs of p_{adv} and p'_{adv}, we have unexpectedly found that they are likely to be quite different. According to our analysis in Section 3, the primary factor behind it is the difficulty of sparse laser beams in accurately capturing the scattered perturbations of adversarial objects, particularly those with irregular surfaces and sharp protrusions. We present an example to facilitate the initial understanding. For an object shown in Figure 2, the captured point clouds differ when the laser beams hit various locations. We also conduct a real-world experiment to confirm this insight, please refer to Appendix A.2 for more details. In a physical attack scenario, due to factors such as the location offset between the digital and physical adversarial objects during placement, and the change in relative position between the LiDAR and the physical adversarial objects, it is hard to ensure that the point cloud p'_{adv} captured by the LiDAR is the desired point cloud p_{adv}. The discrepancies between p_{adv} and p'_{adv} compromise the robustness of the adversarial object. For a more detailed analysis, please refer to Section 3.

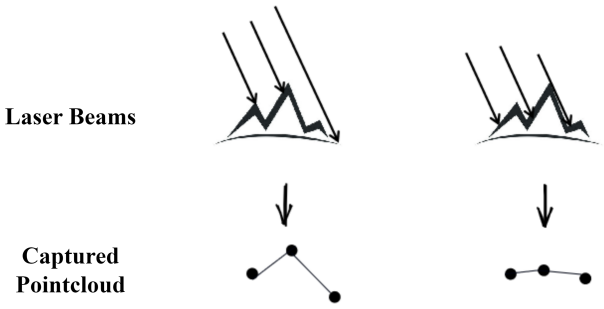

Figure 2: The LiDAR-captured point cloud differs when the hit points of laser beams change.

Q2: How can we improve the robustness of physical adversarial attacks against LiDAR-based perception models?

Based on Q1, scattered adversarial perturbations are difficult to effectively capture by sparse LiDAR signals and result in the discrepancies between p_{adv} and p'_{adv}, compromising the robustness of the adversarial object. To address it, we propose AE-Morpher, a novel AE Reconstruction method. Rather than seeking more robust adversarial perturbations, we aim to optimize the presentation of adversarial perturbations to minimize perturbation distortions during the LiDAR

capturing process. Specifically, as depicted in Figure 1, we first identify the effective perturbations of a given adversarial object, scattered points on the object. Then, we expand them by constructing adversarial surfaces for each perturbation to make them easier to capture while eliminating redundant details of the adversarial object. With adversarial surfaces, we construct a new adversarial object and enhance its stealthiness by reducing the volume at selective positions. By doing so, the captured point cloud can closely resemble the digital point cloud and maintain the adversarial attack capability in the physical world. Importantly, our method does not interfere with the adversarial optimization stage, thereby avoiding any additional challenges in model convergence.

We validate our proposed robustness improvement method with disappear attacks against LiDAR-based perception models. Specifically, we generate an adversarial ornament and attach it to a car to conceal the car from the detection of the following cars. We conduct extensive experiments in both a simulated environment and the real world. Our results show that the reconstructed adversarial ornaments achieve an attack success rate of 100% over a 20m motion scenario in Apollo. On average, our method increases the ASR by 38.64% and reduces the adversarial ornament's projection area by 67.59% compared to the original adversarial ornament. For the real world, we achieve an average attack success rate of 71.4% over a 12m motion scenario. Notably, our reconstructed objects do not require expensive 3D printing technology. While a 3D printer capable of producing an object measuring approximately 60*58*38 cm is priced at $29,999 on Amazon [5], our method can be achieved through simple manual cutting of low-cost materials, such as corrugated cardboard or wood board, and the whole cost is less than $15.

In summary, this work makes the following contributions:

- *New finding.* By delving into LiDAR capturing principles, we are the first to reveal that both the sparse LiDAR laser beams and the scattered adversarial perturbations jointly play a crucial role in the physical adversarial attack robustness against LiDAR-based perception models.
- *New technique.* We propose AE-Morpher, a novel approach to improve the robustness of AEs against LiDAR-based perception models in the physical world. AE-Morpher adjusts the geometric properties of adversarial objects to fit the discrete LiDAR signals by reconstructing their surfaces, thereby improving the physical attack robustness of AEs.
- We evaluate AE-Morpher by conducting physical disappearance attacks on cars in both SVL Simulator environments and the real world. The results show that our approach can effectively improve the attack robustness of adversarial objects. Video demonstrations can be found at https://sites.google.com/view/ae-morpher.

2 Background and Related Work

In this section, we provide a summary of LiDAR's development and applications, as well as an overview of existing attacks against LiDAR-based object detection models and related robustness improvement methods.

2.1 LiDAR Sensors and Detection Principles

LiDAR is a remote sensing technology that employs laser pulses to measure distances and generate 3D maps. It's extensively utilized in autonomous driving to provide precise information about nearby objects, including vehicles, pedestrians, road signs, and lane markings. Prominent autonomous driving platforms, including Baidu Apollo [1] and Autoware [3], incorporate LiDAR as their principal sensor for object detection. Although there are different types of LiDAR, including spinning LiDAR [2], rotating mirror LiDAR [6], and optical phased array LiDAR [23], which rely on different ways of manipulating the laser beam, they all follow a similar detection principle.

The detection principles of LiDAR. The LiDAR sensor first emits a laser beam from a transmitter, which is directed toward the target direction using a rotating mirror or scanning mechanism. When the pulse encounters an obstacle, it reflects back toward the LiDAR, where it is detected by a receiver. The time taken for the pulse to travel back and forth can be used to calculate the distance between the transmitter and the obstacle, considering the speed of light is constant, as illustrated in Figure 3.

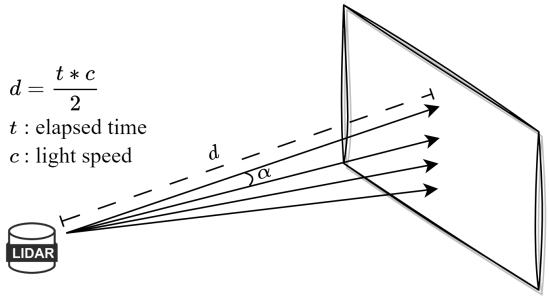

Figure 3: LiDAR detects the position of obstacles by recording the time spent on the round trip of the laser beam.

Angular (horizontal/vertical) resolution is a crucial metric of LiDAR sensors, referring to the angular interval between laser beams. To achieve a wider field of view, the laser emitter rotates horizontally and emits laser light at specific intervals, which represents the horizontal resolution. To determine the height of obstacles, LiDAR sensors adopt an x-line design, emitting multiple laser beams from top to bottom simultaneously, with a certain angle between each beam. This angle, denoted as α in Figure 3, represents the vertical resolution of

the LiDAR system. A higher angular resolution corresponds to more emitted beams and a denser point cloud. Currently, LiDAR sensors equipped on vehicles typically have an angular resolution ranging from 0.1 to 0.4 for horizontal and 0.17 to 2 for vertical. To illustrate, an angular resolution of 0.2° implies a distance of 17.5cm between two adjacent points at a range of 50 m. As a result, LiDAR is likely to acquire different point clouds for an object at a distance of 50m when its surfaces are irregular (e.g., with significant protrusions or depressions within a 17.5cm range), even with minimal movement. Therefore, the instability of point cloud acquisition may occur when the surface irregular deformation of the object is smaller than the radar's resolution, which is a primary issue our robustness improvement method aims to address in this paper.

2.2 Attacks against LiDAR-based Object Detection Models

Due to the unique scanning principles of LiDAR, several LiDAR-specific attack methods have been proposed. These attacks can be broadly divided into three categories: spoofing attacks [14, 21, 22, 34, 37, 38, 42], arbitrary object attacks [48, 49] and adversarial object attack [9, 12, 13, 15, 16, 40, 43].

In spoofing attacks, the attacker employs an additional laser emitter to project laser beams toward the LiDAR system, thereby introducing spoofed reflection points into the point cloud generated by the LiDAR to deceive the perception models. As for arbitrary object attacks, they utilize the location of the objects to mislead the models. To be specific, [49] intricately devises processes to identify the correct locations. These locations are typically distributed in the space surrounding the target vehicle, necessitating the use of drones. Conversely, adversarial object attacks use the shape of the object for this purpose. Attackers employing adversarial object attacks need to optimize the shape of the adversarial object. Each type of attack has its own set of advantages and disadvantages.

In terms of practicality, spoofing attacks require a complex attack system that includes devices such as signal generators and laser emitters. Additionally, the attacker needs to precisely aim the laser emitted by the laser transmitter at the vehicle's LiDAR. These factors introduce difficulties in launching such attacks, reducing their practicality [26, 38]. For arbitrary object attacks and adversarial object attacks. the arbitrary object attack necessitates the use of multiple extra objects, while the adversarial object attack does not. Furthermore, when the target vehicle is in motion, the drones in [49] must adjust their position according to the vehicle to successfully mislead the model, whereas an adversarial object attack does not require such adjustments. However, although adversarial objects can yield favorable results in simulators, their physical robustness is lacking [41]. This prompts us to propose robustness improvement methods.

In terms of stealthiness, spoof attacks themselves are the most stealthy since the laser beams cannot be perceived by humans. However, the required attack system has a relatively large volume and may raise suspicion when placed on the roadside. arbitrary object attacks are also stealthy as the objects are placed around the target vehicle, although the presence of multiple objects might appear unusual. These objects, however, do not directly contact the target vehicle. The stealthiness of adversarial object attacks is determined by the size of the adversarial object used, which can range from highly stealthy to very noticeable. This consideration compels us to take stealthiness into account when proposing robustness improvement methods.

2.3 Robustness-improvement Method for Attacks against LiDAR-based Object Detection Models

In recent years, several robustness improvement methods specifically designed for point clouds have been proposed [20, 28, 33, 39, 44]. These methods employ techniques such as surface smoothness loss functions or limiting the magnitude of point cloud deformation. However, they primarily focus on dense point clouds generated by 3D scanners, which are substantially different from the sparse point clouds produced by LiDAR. For instance, a 3D scanner-generated point cloud of a car may comprise more than 100k points, while LiDAR-generated point clouds typically contain only hundreds or thousands of points due to resolution differences (millimeter-level for 3D scanners vs centimeter or even ten-centimeter level for LiDAR). Sparse point clouds imply large intervals between points and a loss of detailed structural information. Assessing the smoothness of a region with insufficient proximity points is challenging, rendering these methods unsuitable for LiDAR attack scenarios.

For classical generic robustness improvement methods [11, 45, 46], exemplified by EOT [11], these methods improve the generalization of adversarial objects by applying various transformations, making them robust against small discrepancies between the original point cloud and the captured point cloud. They perform well in some situations [13], but they are initially designed for images and lack targeted optimization for LiDAR scenes, potentially causing difficulties in the convergence of adversarial objects [11].

This situation prompts us to design a robustness improvement method utilizing LiDAR's detection principles to further improve obstacle robustness beyond existing methods.

3 Preliminary Analysis

A 3D object, whether it is a benign object or an adversarial object, is typically described by two main components: vertices, which define the points in 3D space that make up the

object, and faces, which define the polygons connecting these vertices, as shown in Figure 4. Based on this background knowledge, we further discuss the three limitations that the mainstream adversarial objects may have that compromise their robustness and stealthiness.

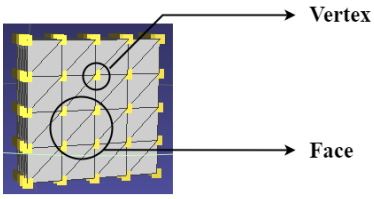

Figure 4: A 3D object consists of vertices (i.e., point clouds) and faces (i.e., polygons). And vertices here are not necessarily to be the corner of the object.

Scattered perturbations are difficult for LiDAR to capture. The adversarial perturbations are mainly introduced into the vertices of the adversarial object, which are scattered points on the object's surface. In the physical world, LiDAR captures points based on laser signals reflected from the surfaces of the object. Due to the sparsity of laser beams, they are more likely to hit the faces of the adversarial object rather than the vertices. However, these faces are not well-designed and do not carry effective perturbations. This means that many effective adversarial perturbations are missed during the LiDAR capturing process.

Irregular surfaces amplify errors during the LiDAR capturing process. Since the vertices carry adversarial perturbations, the ideal adversarial point cloud should exclusively consist of vertices. However, the captured point cloud consistently deviates from the ideal one due to discrepancies between the laser beams' hit points and the object's vertices (as shown in Figure 5). Moreover, irregular surfaces and sharp protrusions can exacerbate these discrepancies. Compared to flat surfaces, the disparity between the coordinates of two adjacent points on an irregular surface with sharp protrusions is more pronounced. Consequently, more errors are introduced when the laser beams do not hit the vertices but instead hit adjacent points on the surface. Ultimately, these discrepancies undermine the physical robustness of the adversarial object.

Figure 5: The LiDAR-captured point cloud (left) usually differs from the desired one (right).

Redundant vertices enlarge the volume of adversarial objects. During the adversarial optimization process, not all vertices of the original object are involved, which means many of these vertices are actually redundant, and carry minimal adversarial information. Nevertheless, these redundant vertices introduce additional surface details, such as sharp protrusions, on the adversarial object. While these protrusions contribute less to the effectiveness of the adversarial attack, they add unnecessary volume to the object and pose challenges during the physical creation of the adversarial object. As a result, the presence of these protrusions undermines the stealthiness and practicality of the adversarial object.

4 Approach Overview

In this section, we describe our high-level intuition for improving the physical attack robustness of adversarial objects and the threat model of our method.

Key intuition. Our approach is derived from the analysis discussed in Section 3. We recognize that the scattering of perturbations and the irregularity of surfaces play a joint role in compromising the robustness of the adversarial object in the physical world. Additionally, the presence of redundant vertices results in unnecessary volume in the adversarial object, compromising the robustness of the adversarial object in the physical world. Intuitively, if we can solve these problems, both the physical robustness and the stealthiness of the adversarial object will increase.

Firstly, we identify and remove vertices with minimal contribution to the attack efficacy from the original adversarial object in order to decrease its volume. To accomplish this, we simulate the LiDAR capture process by sampling multiple times from all vertices of the original adversarial object. We evaluate the attack performance of these sampled vertices and select the ones that are most effective.

Secondly, we incorporate adversarial perturbations from vertices into edges or surfaces, so the adversarial perturbations are not limited to discrete spots but expand to continuous lines and areas, which makes the adversarial perturbations more easily captured by LiDAR. To achieve this, we reconstruct the surface of the adversarial object using flat polygons, as illustrated in Figure 6. The coordinates of these polygons are derived from the remaining vertices, thereby inheriting the adversarial perturbations. Consequently, the new object exhibits adversarial perturbations using surfaces instead of vertices.

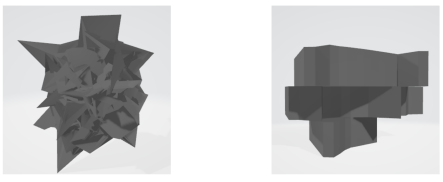

Figure 6: The original (left) and the reconstructed (right) adversarial object.

Threat Model. We assume that the attacker has successfully generated a digital adversarial object using a known method. To apply our method and enhance the object's robustness in the physical world, the attacker requires additional information. This information includes the position of the LiDAR on the victim vehicle, as well as its vertical and horizontal angle resolution. Acquiring these details is relatively straightforward since the attacker can refer to the public manual of the target LiDAR to obtain its performance parameters and examine similar vehicles to determine its installation position. Additionally, for the adversarial object to function effectively, the attacker must have the capability to physically create the object and position it as desired.

Overview. As depicted in Figure 1, AE-Morpher consists of four main steps: (1) Identifying effective adversarial vertices: Given an original adversarial object M, we identify the vertices that carry effective adversarial perturbations. (2) Constructing adversarial faces: We generate an adversarial face f_{adv} for each effective vertex, ensuring that each point on f_{adv} possesses the corresponding adversarial perturbation. (3) Constructing the adversarial object: We obtain an adversarial surface by connecting the adversarial faces into a folded surface. This surface is then translated in space to give it thickness, ultimately resulting in a 3D object. (4) Enhancing stealthiness: We fine-tune the size of the surface to strike a balance between the object's robustness and stealthiness. This enables customization of the object according to specific requirements.

5 Approach Details

5.1 Identifying Effective Adversarial Vertices

The first step is identifying effective vertices from the original adversarial object. Since not all vertices of the original adversarial object effectively attack the LiDAR-based detection model M, there is no need to generate adversarial faces for all vertices. Furthermore, by using fewer vertices, we can construct a smaller adversarial object, thereby enhancing its stealthiness. Our objective is to select a set of fewer vertices that can effectively attack M.

We utilize Ray Cast rendering [7] to help select effective vertices from all vertices of a given original adversarial object. Ray casting simulation emulates the LiDAR capture process to generate the rendered point cloud of the original adversarial object. It selectively preserves specific vertices of the 3D object and utilizes them to generate a point cloud corresponding to the 3D object. The vertex selection process primarily takes into account the object's position, angle, and occlusion. Next, we input the rendered point cloud into M and analyze the output of M. If the rendered point cloud successfully deceives M, we consider the vertices comprising the rendered point cloud as the effective vertices.

To avoid missing effective vertices and further improve the robustness of the reconstructed adversarial object, we render the original adversarial object at various distances and collect the effective vertices for each distance. More specifically, we divide the interval where we expect the adversarial object to be effective into N equal segments, determining N positions at the center of these segments. We then render the adversarial object at these N positions. At each position, we slightly move the adversarial object to generate a series of point clouds. From these, we select the point cloud that has the minimum number of points while still capable of fooling the model. By leveraging the correspondence between the points of the selected point clouds and the vertices of the object, we can identify effective vertices at each position. Then, we take the union of effective vertices at all positions to obtain a set of effective vertices, denoted as $V = \left\{v_1^{'}, v_2^{'}, ..., v_n^{'}\right\}$.

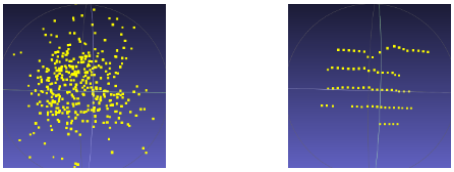

Figure 7: From all possible vertices (left), we identify the effective adversarial ones (right).

5.2 Constructing Adversarial Faces

With the set of effective vertices V, we can construct the adversarial surface to enhance the robustness of the adversarial object in the physical world. The question is, how to create a reasonable and effective adversarial surface?

Assume an ideal position for the LiDAR, where all laser beams precisely hit the effective vertices, thereby capturing an effective adversarial point cloud. However, when there is relative motion between the LiDAR and the adversarial object, such as the LiDAR approaching the object, the hit points of laser beams deviate from the effective vertices and shift towards their adjacent points, resulting in a new LiDAR reflection signal with altered coordinates. Notably, when the effective vertex is located on sharp protrusions, the disparity between its coordinates and those of its adjacent point becomes substantial. Conversely, if the effective vertex is positioned on flat surfaces, the discrepancies between its coordinates and those of its adjacent point are minimal. Therefore, we create a flat region centered around each effective vertex as an adversarial surface to reduce the discrepancies between the captured point cloud and the desired point cloud, thus improving the physical robustness.

Formally, we provide a definition for the adversarial face f_{adv}, which is represented as a rectangle. We consider f_{adv} as a rectangle because the LiDAR scans an object in rows, and using a rectangle maintains consistency in both horizontal

and vertical directions. The rectangle can be represented by its four vertices, as shown in Equation 1.

$$\begin{cases} f_{adv} & = & [v_{n1}^{'}, v_{n2}^{'}, v_{n3}^{'}, v_{n4}^{'}] \\ v_{n1}^{'} & = & t(v_n^{'}, l_1, d_1) \\ v_{n2}^{'} & = & t(v_n^{'}, l_2, d_2) \\ v_{n3}^{'} & = & t(v_n^{'}, l_3, d_3) \\ v_{n4}^{'} & = & t(v_n^{'}, l_4, d_4) \end{cases} \quad (1)$$

Here, $v_n^{'}$ denotes the original adversarial vertex, and the function $t(\cdot)$ represents the translation operation. $v_{n1}^{'}$, $v_{n2}^{'}$, $v_{n3}^{'}$ and $v_{n4}^{'}$ are the new vertices generated by translating $v_n^{'}$ in the direction of d_1, d_2, d_3 and d_4 by distances l_1, l_2, l_3 and l_4, respectively.

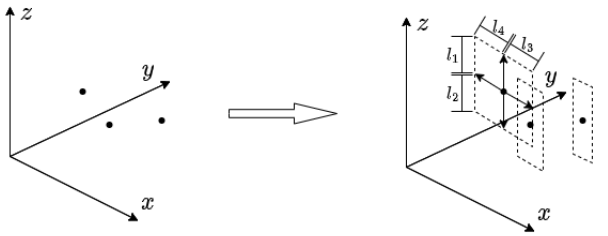

Figure 8: Translate the effective vertices to create adversarial faces.

We adopt a right-hand coordinate system, where the victim vehicle moves from the negative direction of the Y-axis to the positive direction, and the laser beams are emitted from the same negative direction of the Y-axis. As depicted in Figure 8, all effective vertices are expanded to form faces. These faces are perpendicular to the XOZ plane and oriented towards the Y-direction. In this scenario, $d_1 = [0,0,1]$, $d_2 = [0,0,-1]$, $d_3 = [1,0,0]$ and $d_4 = [-1,0,0]$. Here, l_1, l_2, l_3 and l_4 represent the translation magnitudes in the d_1, d_2, d_3 and d_4 directions, respectively. In this case, l_1 and l_2 are the same for all vertices, considering that the height of all adversarial faces should be equal. l_3 and l_4 are adjusted based on individual vertices to ensure that adjacent adversarial faces do not block each other.

5.3 Constructing Adversarial Object

In the previous step, we generate a series of adversarial faces corresponding to the effective vertices, all sharing the same orientation. Subsequently, these faces need to be connected to form a single continuous surface. As depicted in the right half of Figure 8, the adversarial faces are initially scattered. To achieve a continuous surface, we connect the two closest pairs of vertices between each pair of adjacent faces, creating new quadrilateral faces. The result is illustrated in the left half of Figure 9.

Next, we proceed to construct a 3D object using this surface. We duplicate the surface and then translate the duplicated surface along the position direction of the Y-axis by a distance d. The original surface and the duplicated surface are then connected using quadrilateral faces, which can be constructed by connecting the closest vertices on the outer edges of both surfaces. The value of d determines the thickness of the newly created 3D object and can be minimized based on stealthiness requirements.

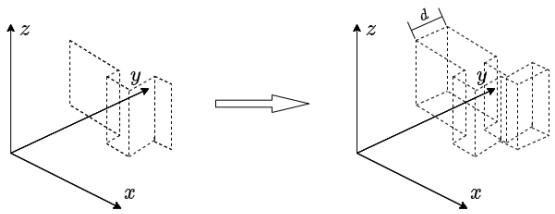

Figure 9: Transform adversarial faces into a 3D object.

As shown in the right half of Figure 7, the effective vertices are arranged in rows. Figure 9 shows the reconstruction result of one of these rows. We can reconstruct each row and stack them like layers of a cake to obtain the reconstructed adversarial object. Furthermore, we can modify the back side of the adversarial object (the side not facing the LiDAR) to enhance its practicality in the physical world. For example, we can flatten the back side to facilitate its physical production or attach hooks to it, allowing the object to be hung somewhere. These modifications are feasible because the LiDAR sensor does not capture the back of the object, ensuring that the robustness of the adversarial object remains unaffected.

5.4 Stealthiness Enhancement

To enhance the stealthiness of the adversarial object, we can adjust the height of each layer. While generating adversarial faces in Section 5.1, we establish the translation magnitude as the margin between adjacent vertices. However, as shown in the right half of Figure 7, there is a noticeable gap between two vertically adjacent vertices, allowing us to moderately reduce the value of l_1 and l_2 to improve the stealthiness of the adversarial object.

More specifically, as depicted in Figure 10, when the LiDAR approaches or moves away from the adversarial object, the hit points of the laser beams move up and down along its surface. Consequently, by maximizing l_1 and l_2 (as depicted in Figure 8) up to the full margin to enlarge the LiDAR reflection surface, we can enhance the robustness of the adversarial object. Conversely, reducing l_1 and l_2 to decrease the volume of the adversarial object improves its stealthiness.

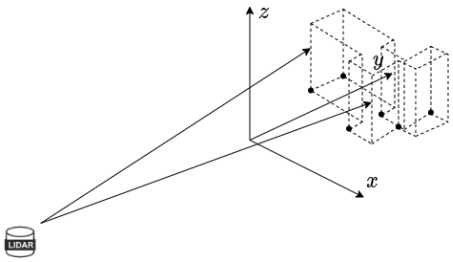

Figure 10: The hit points of the laser beams move up and down along the surface of the adversarial object.

6 Evaluations in Simulated World

In this section, we apply our method to the adversarial object generated by Tu's method [41]. The process of generating the adversarial object is discussed in detail in Section 6.2. Our method can also be employed with other attack methods, provided that an effective adversarial object is available. We evaluate the effectiveness of our method in enhancing the survival rate of digital adversarial objects, and the attack success rate in dynamic scenarios with and without deflection angles. All experiments presented in this section are conducted within a simulator environment. Furthermore, the adversarial ornaments in this section solely utilize their shape to convey adversarial information. For physical experiments, please refer to Section 8. Additionally, we assess the printability of adversarial objects both before and after applying our method, please refer to Section A.3.

6.1 Concepts in Evaluations

Before presenting our experiments, we clarify several key concepts used throughout this section:

Original adversarial ornaments: These are the adversarial ornaments directly transferred from the digital adversarial object.

Reconstructed adversarial ornaments: These adversarial ornaments are reconstructed based on the Original adversarial object.

Victim vehicle: This is the car equipped with a LiDAR and the corresponding LiDAR-based perception model, which we aim to deceive using adversarial objects.

Target vehicle: This is the car attached with an adversarial object, and we intend to make it disappear from the victim vehicle's detection results.

SVL Simulator: The SVL Simulator is an open-source autonomous vehicle simulator developed by LG Electronics America R&D Lab. Researchers can create their own maps and control cars within the simulator to obtain sensor data closely resembling real-world conditions. Numerous papers have successfully conducted their experiments using the SVL Simulator [12–14, 21]. Our experiments mentioned in this section are also performed in the SVL Simulator environment to acquire a relatively large amount of experimental data that closely approximates real-world conditions. Additionally, we showcase the results of our physical experiments in Section 8.

Apollo: Apollo is an open-source autonomous driving framework capable of receiving data from sensors and detecting vehicles, pedestrians, and other obstacles within the sensor data. We used Apollo 7.0 to conduct our dynamic experiment, as described in Section 6.4 and 6.5.

6.2 Evaluation Setup

Attack scenarios. We consider an attacker who generates an adversarial object to deceive the LiDAR-based perception model of an autonomously driving vehicle. The generated adversarial object is attached to the target vehicle as an ornament, causing the model to fail in detecting the target vehicle. The LiDAR and the target vehicle may be in a stationary position at varying distances or in motion with different angles.

Generate the adversarial object. We basically follow Tu's method [41] to construct the original adversarial ornament. After the adversarial optimization process, we obtain an effective adversarial object with a complex surface, where the coordinates of its vertices carry the adversarial information. However, LiDAR cannot accurately capture such objects, which can cause discrepancies between the LiDAR echo signals and the physical object, thereby reducing its adversarial robustness, as explained in Section 3.

Reconstruct the adversarial object. To improve the robustness of the generated adversarial object in the physical world, we apply our method described in Section 5. In practice, we find that the points of the LiDAR point cloud are relatively dense in the horizontal direction. For instance, considering the "00000.bin" file in the KiTTi dataset. At a distance of about 5.95m, the horizontal gap between adjacent points measures approximately 0.17m, while the vertical gap is around 0.49m. Therefore we set l_3 and l_4 (the horizontal translation magnitude) to zero. Under such conditions, adversarial faces are reduced to adversarial edges. Additionally, we set $l_1 + l_2$ to 50% of the margin between adjacent vertical vertices to increase the stealthiness of the adversarial object.

6.3 Efficacy in Static Attack

In this experiment, we select two widely used models: PointPillars [10] and PointRCNN [36], as our target models. These two models represent the two mainstream approaches in the field of object detection for autonomous driving systems, namely voxel-based object detection and point-based object detection. Notably, PointPillars has been adopted in Apollo and Autoware, which are among the world's leading open-source software projects for autonomous driving.

Experimental Setup. We generate 200 adversarial ornaments using Tu's method [41] for both PointPillars and PointRCNN. All of these adversarial ornaments are tested to be effective in the digital world at a distance of 15m, which is the braking distance [8] when the vehicle speed is 50 km/h, a common speed on city roads. The confidence thresholds for each model are set to their default values, i.e., 0.1 for PointPillars [50] and 0.3 for PointRCNN [35].

Subsequently, we reconstruct these adversarial ornaments with our methods and place the reconstructed ornaments at the back of the target vehicle in the SVL Simulator's map. Then, we control the victim vehicle equipped with a LiDAR to record the LiDAR signal points of the adversarial ornaments and the target vehicle from different distances, as shown in Figure 11. Finally, we export the recorded point cloud data and feed them into PointPillars or PointRCNN and observe how many adversarial ornaments can still deceive these two models.

Figure 11: Screenshot of the target and the victim vehicle. The target vehicle with an adversarial ornament is positioned at the front, and the victim vehicle is positioned at the back.

Evaluation Metrics. Considering practical application scenarios, we adopt the *survival rate* as the evaluation metric for our proposed method. The *survival rate* refers to the proportion of the 200 adversarial ornaments that maintain their effectiveness, successfully concealing the car at the specified distance, when transitioning to a more realistic environment. A high survival rate indicates that a significant portion of the adversarial ornaments maintain their effectiveness in a more realistic environment. This, in turn, enables attackers to execute large-scale attacks more easily and efficiently.

Evaluation Results. The results of this experiment are presented in Table 1. The experiment demonstrates that our method enhances the survival rate of adversarial ornaments by 38% for PointPillars and 22% for PointRCNN when they are placed at their designed distance, i.e., 15m, in the physical world. This distance is equivalent to the braking distance [8] when a vehicle's speed is 50 km/h, a common speed on city roads. Failing to detect the target car within a 15m distance leaves the victim vehicle with insufficient time to slow down and avoid a collision. In other words, the survival rate within this distance is positively correlated with the crashing rate. Furthermore, our method also improves the survival rate of the adversarial ornaments at other distances.

This experiment demonstrates the effectiveness of our proposed method across models utilizing different detection principles, further solidifying its applicability and value in enhancing the robustness of adversarial objects.

Methods	Model	Distance			
		10m	14m	15m	16m
Original	PointPillars	46.5%	45.5%	**46.0%**	34.5%
	PointRCNN	38.5%	55.0%	**58.0%**	44.5%
Reconstruction	PointPillars	51.5%	65.0%	**84.0%**	41.0%
	PointRCNN	41%	80.0%	**80.0%**	50.5%

6.4 Efficacy in Dynamic Attacks

In this experiment, we aim to evaluate the effectiveness of our methods in scenarios where there is relative motion between the victim and target vehicles. The evaluation is conducted using a combination of the SVL Simulator and Apollo.

Experimental Setup. First, we establish a connection between the SVL Simulator and Apollo 7.0. Next, we position the victim vehicle at various distances behind the target vehicle and move the victim vehicle towards the target vehicle. Finally, we analyze Apollo's detection results. We record frames every 0.13m and calculate the number of frames in which the target vehicle is detected and the number of frames in which it is not detected as the victim vehicle moves towards the target vehicle. This experiment is conducted only on PointPillars, as Apollo does not integrate PointRCNN. We test three distinct starting distances: 10m, 15m, and 20m and the ending distance is 2m.

Evaluation Metrics. To assess the effectiveness and stealthiness of our method, we employ the *attack success rate* and *projection area* as evaluation metrics, respectively. The *attack success rate* is calculated as the ratio of the number of missing detection frames to the total number of frames. The *projection area* represents the size of the adversarial ornament as viewed by the driver of the victim vehicle, and is determined by projecting the ornament onto the XOZ plane.

Evaluation Results. The results of this experiment are presented in Table 2. Our method demonstrates notable improvements in the attack success rate of adversarial ornaments at different distances. On average, the attack success rate increases by 38.64%, 21.8%, and 15.7% at each distance, respectively. Additionally, our method significantly reduces the

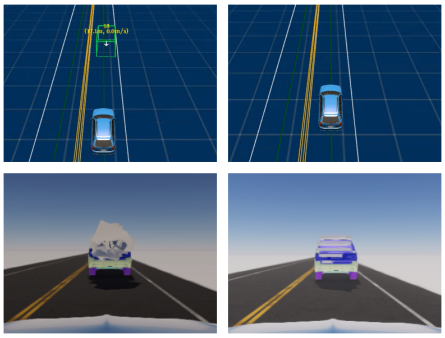

Figure 12: Visualization of Apollo's detection results: The model successfully detects the target (top left) equipped with the original adversarial ornament (bottom left), yet fails to detect the target vehicle (top right) equipped with the reconstructed adversarial ornament (bottom right).

Methods	Distance (m)			Projection (m^2)
	10m→2m	15m→2m	20m→2m	
Original	54.7%	66.4%	71.9%	2.79
Reconstruction	**100.0%**	**85.0%**	**82.2%**	**0.78** (↓72.04%)
Original	62.7%	69.0%	71.1%	2.59
Reconstruction	**97.3%**	**88.5%**	**88.9%**	**0.83** (↓67.95%)
Original	68.0%	68.1%	71.9%	2.83
Reconstruction	**92.0%**	**89.4%**	**91.1%**	**1.00** (↓64.66%)
Original	42.7%	58.4%	65.2%	3.32
Reconstruction	**100.0%**	**89.4%**	**85.3%**	**1.02** (↓69.28%)
Original	68.0%	69.9%	72.6%	2.53
Reconstruction	**100.0%**	**88.5%**	**83.7%**	**0.91** (↓64.03%)

Table 2: The attack success rates in different distances with and without our method.

projection area by 67.59% on average, thereby enhancing the stealthiness of the adversarial object. Notably, if we do not apply our method but restrict the projection area during the adversarial optimization stage, the generated adversarial ornaments cannot deceive the perception model, Consequently, achieving adversarial ornaments with such a level of stealthiness is challenging without employing our methods.

Figure 12 shows one of the screenshots during the experiment. We observe that even though the original adversarial ornament is much larger than the reconstructed one and appears to obstruct more details of the target vehicle , it fails to deceive the perception model while the reconstructed one succeeds. This is because the point cloud of the original adversarial ornament captured by the LiDAR is quite different from the effective adversarial point cloud and does not carry enough adversarial information. The captured point cloud of the reconstructed adversarial ornament, the original adversarial ornament, and the desired adversarial point cloud, are shown in our website. We observe that the shape and contour of the LiDAR signal points of the reconstructed adversarial ornament are well preserved during motion and are similar to the desired adversarial point cloud. In contrast, the LiDAR signal points of the original adversarial ornament are not.

As described in Section 5, LiDAR captures an object's information through multiple laser beams rather than providing a panoramic view like a camera. The hit points of the laser beams change as the distance between the LiDAR and the object varies, resulting in variations in the generated point cloud. The reconstructed adversarial ornament maintains a simple and smooth structure, whereas the original adversarial ornament does not. As a result, our reconstructed adversarial ornament can preserve the relative stability of the LiDAR reflection points when the distance between the object and the LiDAR changes, while the original adversarial ornament cannot. Our method demonstrates a consistent attack success rate across various distances in this experiment, indicating its robustness in different scenarios.

6.5 Efficacy in Angle Robustness

In this experiment, we aim to evaluate the effectiveness of our method in different angles. The evaluation is also conducted using a combination of the SVL Simulator and Apollo.

Experiment Setup. To simulate real driving behavior, we did not fix the relative angles of the target and victim vehicle. Instead, we control the victim vehicle to approach the target vehicle in the adjacent lane, as shown in Figure 13. The angle between the victim and the target vehicle is dynamic during this process, which is more realistic. All other settings were similar to those in Section 6.4.

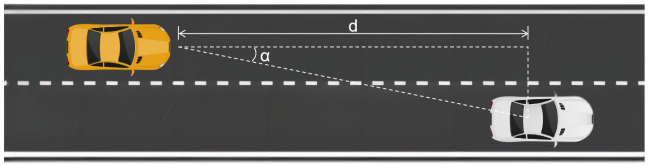

Figure 13: The angle (α) between the target vehicle (white) and the victim vehicle (yellow) dynamically changes as the distance (d) varies.

Evaluation Results. The results of this experiment are presented in Table 3. Compared to moving straightforwardly toward the target vehicle, approaching the target vehicle in the adjacent lane and deceiving the perception model is a more challenging scenario, particularly when the victim is close to the target vehicle, which implies a relatively large angle between the victim and the target vehicle. Nevertheless, our method demonstrates notable improvements in the attack suc-

cess rate of adversarial ornaments at different distances. On average, the attack success rate increases by 23.72%, 23.86%, and 23.70% at each distance, respectively. Additionally, restricting the projection area during the adversarial optimization stage still results in ineffective adversarial ornaments. This experiment showcases the robustness of our method against varying angles.

Methods	Distance (m)			Projection (m^2)
	10m (19.29°)	15m (13.13°)	20m (9.93°)	
Original	54.7%	67.3%	68.1%	2.88
Reconstruction	**80.0%**	**86.7%**	**88.9%**	**0.86** (↓70.14%)

Table 3: The attack success rates in different angles with and without our method

6.6 Efficacy Compared with Other Methods

In this experiment, we compare our proposed method with an existing attack method, denoted as **AdvLo** [49], which aims to conceal the target vehicle from the LiDAR-based perception model's detection results. The method is proposed by Miao et al., where they employ drones to fill several calculated positions around the vehicle to attack the model.

Experiment Setup. For AdvLo, we utilize the data mentioned in their paper, where they achieve a 74% success rate against PointPillars in 100 examples. Specifically, they use the algorithm AdvLo to generate adversarial locations for each example and 74% of all examples are attacked successfully. In comparison, we generate 100 adversarial ornaments following the steps outlined in Section 6.2 and reconstruct these ornaments using our method. The success rate of the adversarial ornaments before reconstruction is denoted as "Original" while the success rate after reconstruction is denoted as "Reconstruction" Since AdvLo does not specify the distance used in their experiment, we considered their 74% success rate as their best result for PointPillars and compared it with our best results.

Evaluation Results. The results of this experiment are presented in Table 4. The effective rates for the three conditions are 45.0%, 83.0%, and 74.0%, respectively. We can see that before reconstruction, the original adversarial ornament does not achieve a competitive result. However, after reconstruction, the reconstructed adversarial ornament outperforms AdvLo by 9.0%. Additionally, Our approach does not need to hover several drones exactly at some specified locations above the target vehicle, like what AdvLo does, which can facilitate the attacker when the target vehicle is in motion.

Methods	Success Rate
Original	45.0%
Reconstruction	83.0%
AdvLo [49]	74.0%

Table 4: A comparison of the attack success rate of our method and AdvLo [49].

7 Evaluations on Fusion Attack

In this experiment, we investigate the potential of employing the reconstructed adversarial object to conduct a fusion attack against both LiDAR-based and camera-based perception models simultaneously. As previously mentioned, our method generates adversarial objects with flat surfaces, which are subsequently colored to convey adversarial information to camera-based perception models. To summarize, we utilize the shape of these adversarial ornaments to carry adversarial information against LiDAR-based perception models, while their color is employed to transmit adversarial information against camera-based perception models.

Experiment Setup. The fusion attack evaluations involve both camera-based and LiDAR-based perception models. The LiDAR-based perception model used remains PointPillars, similar to the dynamic attack evaluations. As for the camera-based perception model, we choose SMOKE [31], a state-of-the-art camera-based perception model. SMOKE is also the default camera-based perception model used in Apollo 7.0. To convey adversarial information against SMOKE, we adopt an existing method [40] to optimize the texture of the adversarial ornament, resulting in a colorful adversarial ornament as shown in Figure 14. We then conduct experiments in the SVL Simulator, maneuvering the victim vehicle to approach the target vehicle. During this process, we record the number of frames in which Apollo fails to detect the target vehicle. Similar to Section 6.4, we use the *attack success rate* to measure the effectiveness of the colorful adversarial ornament. The attack success rate is calculated as the ratio of the number of missing detection frames to the total number of frames.

Evaluation Results. We observe that the flat surface generated by our method effectively serves as a carrier of adversarial information against camera-based models. During

Figure 14: The white adversarial ornament does not carry adversarial information against SMOKE, while the colorful adversarial ornament is designed to convey adversarial information specifically targeting SMOKE.

Lidar's movement from 20m away towards the target vehicle, we achieved a 75.6% attack success rate against the fusion perception module.

8 Evaluations in Real World

In this section, we evaluate the attack's effectiveness and feasibility in the physical world. The attack aims to hide the target vehicle from the LiDAR detection system.

8.1 Nighttime Experiments

Experiment Setup. We utilize the RS-LiDAR-16 to collect point clouds during the experiment. The adversarial object used in this experiment is cut from cardboard without the involvement of a 3D printer. The target model is PointPillars and the target vehicle is a Toyota Levin. The adversarial ornament is placed on the roof of the target vehicle as shown in Figure 15. We put the LiDAR around 12m away from the target vehicle and move it towards the target vehicle slowly. We record the point cloud data captured during this process and feed them to the model to calculate the attack success rate. Under the same condition, we also design a comparison experiment, i.e., placing a benign cardboard on the roof of the car. More detailed pictures can be found in our website.

Figure 15: The adversarial ornament is placed on the roof of the target vehicle.

Evaluation Results. Our method achieves a 71.4% attack success rate during this process. In contrast, when a benign cardboard is attached, the LiDAR consistently detects the car. Figure 16 illustrates the scan results of the surrounding environment by the LiDAR centered on the victim vehicle. The detection results of the model are highlighted with black bounding boxes. We observe that the model successfully detects the target car with the benign ornament (left), but fails to detect the same target car with the adversarial ornament (right). It is worth noting that the total cost of physically creating an adversarial ornament reconstructed by our method is less than $15. This implies that adversarial ornaments can be produced quickly and inexpensively in large quantities, posing a significant threat in the real world.

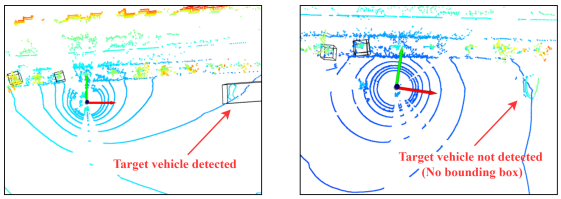

Figure 16: The detection results of the target vehicle with the benign (left) and the adversarial ornament (right).

8.2 Daytime Experiments

To comprehensively evaluate the effectiveness of our method and enhance the diversity of experimental settings, we conduct an additional real-world experiment during daylight hours. In this experiment, we target a new vehicle and place the adversarial ornament in new locations.

Experiment Setup: For this experiment, we select the Aion S as the target vehicle. The reconstructed adversarial ornaments are positioned on the trunk lid, as depicted in Figure 17. We continue to employ the RS-LiDAR-16 for collecting point clouds. All other settings remain identical to those described in Section 8.1. Extra pictures can be found in our website.

Figure 17: The adversarial ornament is placed on the truck lid of the target vehicle.

Evaluation Results. Our method achieves a success rate of 80.8% during motion from 12m to 3m right behind the target

vehicle. This value is slightly higher than that of the nighttime experiment. One possible contributing factor is the use of a greater layer height for reconstructing adversarial ornaments (about 18cm per layer in this experiment compared to about 14cm per layer in the nighttime experiment), which highlights the trade-off between robustness and stealthiness once again.

8.3 Analysis

It has been observed that there is a discrepancy between the attack success rate observed in simulated experiments and real-world experiments. We consider that the following factors contribute to this gap.

The position of adversarial ornaments. When generating and placing adversarial ornaments in the digital realm, these ornaments can be affixed to any part of the target vehicle to pursue the best performance, disregarding gravitational forces and other physical constraints. However, in the real world, adhesive tape is often insufficient for this purpose, necessitating compromises in the placement of these ornaments. Consequently, we are often unable to place the ornaments in the most optimal locations, which compromises their performance. This issue can be mitigated through the use of improved adhesive solutions.

The complexity of the environment. On the one hand, the real-world environment is significantly larger than the simulated environment (about 450,000 LiDAR reflection points versus about 7,000 LiDAR reflection points). Influencing a considerably larger environment presents greater challenges. On the other hand, the simulated environment remains relatively static, with no pedestrian or other moving vehicles present. In contrast, the real-world environment is dynamic, with passing cars and people. These factors have the potential to disrupt the effectiveness of adversarial ornaments and influence the experimental outcomes. This issue can be mitigated through the use of more realistic simulators.

The resolution of the LiDAR. The simulator employs a 64-line LiDAR, whereas the real-world LiDAR consists of 16 lines. While our method is effective for LiDARs with varying resolutions, there may be some performance differences.

9 The Effect of Reconstructed Adversarial Ornaments' Volume

In this section, we analyze the effect of the volume of reconstructed adversarial ornaments. Intuitively, increasing the volume is expected to enhance robustness while diminishing stealthiness, and vice versa. We replicate the experiments conducted in Section 6.4 and Section 6.5 to validate this intuition.

Experiment Setup. In this experiment, we utilize the same reconstructed adversarial ornaments as those employed in Section 6.4 and 6.5. Subsequently, we adjust the volume of these reconstructed adversarial ornaments by modifying the height, represented by the values of $l_1 + l_2$, for each layer. Specifically, we set the height of each layer of the reconstructed adversarial ornaments to a different percentage of the margin between the layers of the point clouds, as illustrated in Figure 18. All other configurations remain consistent with those described in Section 6.4 and 6.5.

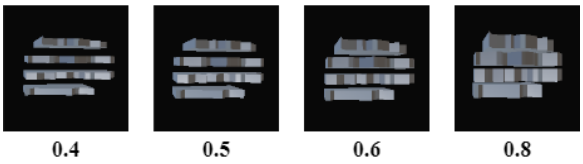

Figure 18: Reconstructed adversarial ornaments with different layer heights.

Evaluation Metrics: Two metrics, namely the *attack success rate* and the *stealthiness*, are utilized in this experiment. The definition of the *attack success rate* remains the same as the one provided in Section 6.4 and 6.5, (i.e. the ratio of the number of missing detection frames to the total number of frames). As for the *stealthiness*, it is defined as $1 - R_{area}$, where R_{area} represents the area ratio between the back view of the adversarial ornament and the back view of the target vehicle.

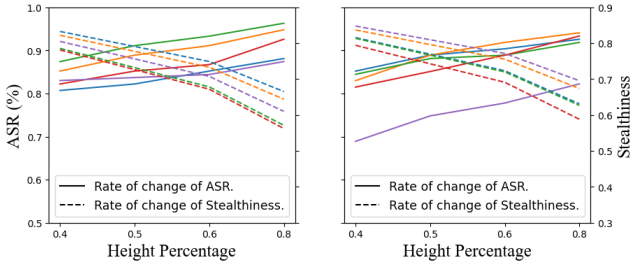

Figure 19: Trade-off between robustness and stealthiness in dynamic attacks (left) and angle attacks (right).

Evaluation Results: The results of this experiment are presented in Figure 19. Each color represents a distinct reconstructed adversarial ornament. The solid line represents the change in its attack success rate during the motion from 20m to 2m with respect to the height percentage, while the dotted line represents the change in its stealthiness with respect to the height percentage. It can be observed from both line charts that as stealthiness decreases, the attack success rate increases. In other words, there exists a trade-off between robustness and stealthiness. Decreasing stealthiness can effectively increase robustness, and vice versa. However, even with the highest observed stealthiness (83.27%, indicating that the back view of the reconstructed adversarial ornament accounts for only 16.73% of the back view of the vehicle), the ornament still achieves a dynamic attack success rate of 80.7%. Similarly, for angle attacks, the success rate with the highest stealthiness is 68.9%, which is also considered acceptable.

10 Discussion

D1: What are the differences in robustness loss of adversarial objects for LiDAR- and camera-based perception models?

Discrepancies between the captured information and the physical object are among the primary causes of robustness loss in both situations. However, the sources of these discrepancies in capture processes differ significantly between cameras and LiDAR. For cameras, discrepancies stem from occlusions, lighting conditions, printing inaccuracies, and environmental factors like weather and glare. These factors make it difficult to capture accurate color and shape information of adversarial patches, thereby compromising the effectiveness of these patches. In contrast, LiDAR-based models are less affected by environmental factors, but discrepancies occur due to missing details caused by the sparse laser beams.

Based on the above analysis, our proposed method reconstructs the surface of adversarial objects to help LiDAR capture more adversarial details, thus preserving the attack effectiveness of adversarial objects in the physical world.

D2: What are the differences between the existing robustness improvement methods and our method?

Existing robustness improvement methods aim to enhance the generalization of adversarial objects by applying transformations to the digital object to tolerate the discrepancies between the digital and the captured object, as shown in the left half of Figure 20. In contrast, our approach focuses on reducing the discrepancies between the digital and captured object by reconstructing the surface of the original object to fit the sparse laser beams, as shown in the right half of Figure 20. Our method improves the robustness of the adversarial object without interfering with the adversarial optimization stage, allowing it to be applied to various attack methods as long as a digital adversarial object is available.

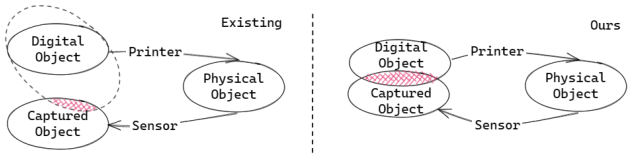

Figure 20: The red part represents the attack effectiveness of the captured object. Existing methods enhance the effectiveness by improving the generalization of the digital object, whereas our method focuses on reducing the disparities between the digital and captured objects.

D3: How do real humans perceive the stealthiness of reconstructed adversarial ornaments?

To assess the stealthiness of our physical reconstructed ornaments, we have devised a questionnaire with pictures like the ones in Section 8.2 attached. The questionnaire encompasses four aspects: 1) Does the cardboard attached to the ornament strike you as unusual or abrupt; 2) Do you think the cardboard ornament can lead to a car crash; 3) Do you perceive this ornament as a personalized decoration chosen by the car owner; 4) Would you feel compelled to notify the driver if their vehicle displayed such an ornament. We also ask participants to self-evaluate their knowledge of AI security and adversarial examples.

In total, we collect 25 questionnaires, with 28% of participants being unfamiliar with adversarial objects, 28% having some familiarity, and 44% being very familiar with adversarial objects. We observe that 84% of all participants do not think our ornaments have the potential to cause a car crash, even among those who are very familiar with adversarial objects. Furthermore, 72% of participants regard the ornaments as personalized decorations chosen by the car owner, while only 40% think it is abrupt. Through further communication with these individuals, we found that most of them believe the apparent abruptness is due to the bare cardboard being too ugly, and they think we can alleviate people's suspicion by painting and drawing on the cardboard. Finally, only 32% feel it necessary to remind the car driver. The statistical data mentioned above indicate that the majority of individuals do not exhibit excessive concern regarding our reconstructed adversarial ornaments. This finding suggests that our ornaments possess stealthiness and practical viability. Our studies receive approval from the IRB of our affiliations.

D4: What are the limitations of our method?

On one hand, our method aims to enable LiDAR to accurately capture the adversarial perturbations of the adversarial object. In other words, our goal is to ensure that the captured point clouds resemble the desired point clouds. However, the effectiveness of the desired point cloud is contingent upon other attack methods and may be compromised by certain defense methods. On the other hand, our current method only involves one LiDAR and its performance may be compromised in scenarios with multiple LiDARs. We will further investigate this aspect in future work. Additionally, the reconstructed adversarial object can only hide one vehicle at a time, and it is visible, which may raise suspicion among drivers and other pedestrians — these are also limitations.

11 Conclusion

This paper presents the first endeavor to utilize LiDAR principles to enhance the robustness of adversarial objects. We reconstruct the surface of the original adversarial object to fit the sparse laser beams, thereby reducing errors during the LiDAR capturing process and improving the robustness of the adversarial object. Experimental results demonstrate significant achievements in both simulated environments and real-world scenarios. Furthermore, our method does not rely on expensive 3D printing technology and can be implemented using simple manual cutting of affordable materials like cardboard.

A Appendix

A.1 Adaptive Defense

Our method is the first to enhance the robustness of adversarial objects by reducing the discrepancies between the digital point clouds and the captured point clouds. To the best of our knowledge, there are no existing countermeasures specifically designed for this. Therefore, we propose a potential countermeasure and evaluate its performance.

A.1.1 Point Clouds Smooth Defense

We observed that, although our reconstructed adversarial object allows for a more stable LiDAR capturing of adversarial perturbations, it exhibits irregular lines in LiDAR scans that differ from those of normal vehicles. Therefore, we naturally consider utilizing a smoothing algorithm on LiDAR scan results, which affects irregular lines more substantially than regular ones. Through the smoothing of irregular lines, we can disrupt adversarial perturbations and lead the attack to failure.

Experiment Setup. We implement a smoothing algorithm and apply it to both the point cloud files generated in Section 6.3 and the KITTI dataset. The former is utilized to assess the attack performance degradation resulting from the smoothing, while the latter is employed to evaluate the impact on AP (Average Precision) of detecting benign objects. The target model is the PointPillars.

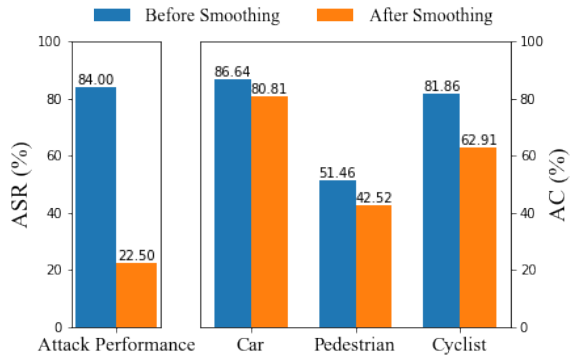

Figure A1: The ASR and the AP before smoothing (left) and after smoothing (right).

Evaluation Results. The results of this experiment are depicted in Figure A1. It is observed that the attack performance decreases from 84% to 22.5%, concurrently leading to a decline in AP for cars from 86.64% to 80.81%, for pedestrians from 51.46% to 42.52%, and for cyclists from 81.86% to 62.91%. While the smoothing algorithm effectively mitigates the impact of reconstructed adversarial objects, it does somewhat reduce the AP of detecting benign objects, especially those with complex surfaces such as pedestrians or cyclists. This trade-off between defending against adversarial attacks and the decline in AP for benign objects is non-negligible, as this reduction persists even in the absence of our reconstructed adversarial obstacles.

A.1.2 Multiple-LiDAR Defenses

As observed in the above experiments, point clouds captured at an angle exhibit a lower overall attack success rate compared to point clouds captured directly from behind. Additionally, utilizing multiple LiDAR-based perception models to detect obstacles simultaneously can help mitigate the risk of being misled. Building upon these intuitions, we propose a defense strategy: utilizing two LiDARs to capture point clouds from different perspectives and inputting these captured point clouds to separate models. This approach aims to minimize the risk of misdirection. We design an experiment to evaluate this defense strategy.

Experiment Setup. The experiment is conducted in the simulator. We utilize two LiDARs and two separate PointPillars models. If either of the two models successfully detects the target vehicle, we consider it a failure in terms of misleading the perception model. we employ the same five reconstructed adversarial ornaments as those used in Section 6.4, all other settings remain consistent with those mentioned in Section 6.4.

Evaluation Results. The results of this experiment are presented in Figure A2. It is observed that the utilization of two LiDARs reduces the attack success rate of our method by a maximum of 10.39%, thereby demonstrating the effectiveness of the adaptive countermeasure. However, this reduction is insufficient to render our method practically unexploitable. Additionally, equipping vehicles with multiple LiDARs and multiple models increases production costs for autonomous vehicles. Balancing safety and cost is a significant concern for carmakers.

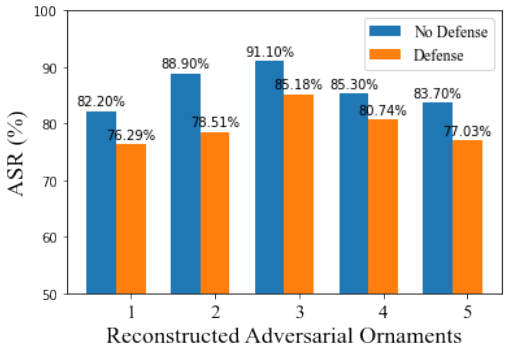

Figure A2: Evaluation results of our proposed countermeasure.

A.1.3 Other Defenses

Another potential countermeasure is to leverage the new IOV (Internet of Vehicles) and CVIS (Cooperative Vehicle Infrastructure System) technologies. With these technologies, vehicles no longer solely rely on their own obstacle-detection capabilities. Instead, they can receive obstacle information from other vehicles and even roadside streetlights. Attempting to deceive multiple sensors and models simultaneously becomes challenging, if not impossible, which limits the usage of our method. However, it is important to note that both IOV and CVIS require additional communication time, which can introduce delays.

A.2 Confirming of the Insight in the Preliminary Analysis

In this section, we compare the changes in point clouds of different objects when the LiDAR moves to confirm the insight mentioned in Section 1, namely, that it is difficult for sparse laser beams to accurately capture the scattered perturbations of adversarial objects, particularly those with irregular surfaces and sharp protrusions.

Firstly, we place an object with a complex surface - a PVC figurine - on the desk (as illustrated in the left half of Figure A3) and move the LiDAR back and forth to capture the point clouds.

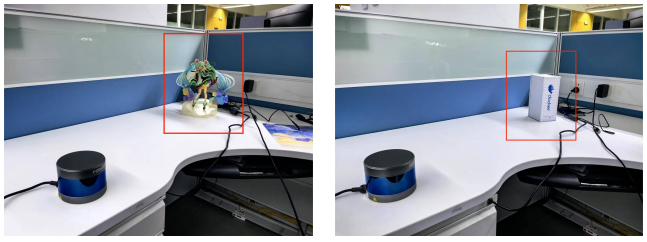

Figure A3: Different objects were considered.

The point clouds before and after the LiDAR's moving differs a lot.

Next, we position a regular object - a box - on the desk (as depicted in the right half of Figure A3) and proceed to move the LiDAR back and forth once more. This time, the point clouds captured before and after the LiDAR's movement exhibited minimal differences.

The pictures of captured points can be found in our website: https://sites.google.com/view/ae-morpher.

A.3 Printability Analysis

In this section, we assess the printability of adversarial ornaments reconstructed by our proposed method. Our evaluation focuses on two primary aspects: 1) the compatibility of these objects with widely-used 3D printers, and 2) the ease of 3D printing these objects.

Experiment Setup. To assess the printability of the adversarial object, we conducted an analysis before and after the surface reconstruction process using *PreForm* [4], a commercial tool for printability assessment. PreForm determines whether a given 3D mesh can be printed using their 3D-printing service. In addition, we utilized *watertightness* as another metric to evaluate the object. Watertightness assesses whether the object's mesh can hold water when filled, it requires the object to have a close and complete surface. That's to say, A 3D object must exhibit watertightness to have a valid volume and exist in the physical world. These two criteria are important metrics for evaluating the printability of meshes [13]. Furthermore, we computed the *self-intersection ratio* as an indicator of the ease of printing adversarial objects. The self-intersection ratio represents the proportion of all faces of an object that intersects each other. A higher surface self-intersection rate indicates a more complex surface and makes printing more challenging.

	Printable		Self-intersection
	Preform	Watertight	
Original	Error	False	1987.50%
Reconstruction	Success	True	0.00%

Table A1: The printability of the original and the reconstruction adversarial object.

Evaluation Results. The evaluation results for adversarial ornaments, with and without our method, are presented in Table A1. Before reconstruction, the adversarial ornament fails PreForm's test and is not watertight, indicating that it is difficult to 3D print. However, after reconstruction, our method not only enables the adversarial ornament to pass these tests but also reduces its self-intersection ratio from 1987.5% to 0%. Some other methods can also decrease the self-intersection ratio. For example, MSF-ADV [13] achieves a self-intersection ratio of 0.46% in their situation. However, these methods simultaneously decrease the attack success rate of the adversarial object (8% for MSF-ADV), whereas our method does not.

EaTVul: ChatGPT-based Evasion Attack Against Software Vulnerability Detection

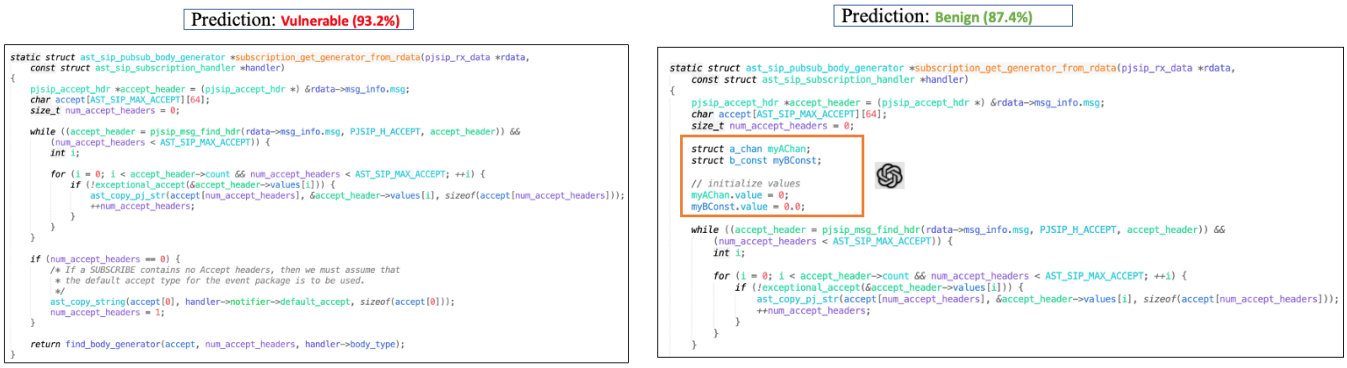
Abstract



Recently, deep learning has demonstrated promising results in enhancing the accuracy of vulnerability detection and identifying vulnerabilities in software. However, these techniques are still vulnerable to attacks. Adversarial examples can exploit vulnerabilities within deep neural networks, posing a significant threat to system security. This study showcases the susceptibility of deep learning models to adversarial attacks, which can achieve 100% attack success rate (refer to Table 5). The proposed method, EaTVul, encompasses six stages: identification of important samples using support vector machines, identification of important features using the attention mechanism, generation of adversarial data based on these features using ChatGPT, preparation of an adversarial attack pool, selection of seed data using a fuzzy genetic algorithm, and the execution of an evasion attack. Extensive experiments demonstrate the effectiveness of EaTVul, achieving an attack success rate of more than 83% when the snippet size is greater than 2. Furthermore, in most cases with a snippet size of 4, EaTVul achieves a 100% attack success rate. The findings of this research emphasize the necessity of robust defenses against adversarial attacks in software vulnerability detection.

1 Introduction

Software vulnerability detection systems play a crucial role in safeguarding computer systems and networks. Deep neural networks have made significant advancements in this field, as demonstrated by recent algorithms [6], [13]. For instance, Lin et al. [23] extract high-level function representations from the abstract syntax tree (AST) to detect function-level vulnerabilities across projects. Feng et al. [3] propose a method utilizing the AST to extract syntax features and minimize data redundancy. Yang et al. [50] leverage a deep learning-based method using the Tree-LSTM network to assess the semantic equivalence of functions across platforms. Fu and Tantithamthavorn [4] present LineVul, a Transformer-based approach for line-level vulnerability prediction. However, it is crucial to acknowledge that these systems can be susceptible to attacks, which can compromise overall security [37].

Recent studies have revealed that adversarial attacks can exploit vulnerabilities in software vulnerability detection techniques that use machine learning, particularly deep learning [38, 52]. Zhang et al. [55] proposed the Metropolis-Hastings Modifier algorithm to generate adversarial samples for attacking machine learning-based software vulnerability detection systems. Ramakrishnan and Albarghouthi [36] investigated the feasibility of backdoor attacks on deep learning-based techniques used in software vulnerability detection systems. Henkel et al. [7] assessed the current architectures of machine learning-based software vulnerability detection. However, these studies are still in the early stages of exploring adversarial attacks in machine learning-based techniques, and the security issues of these techniques have not been thoroughly evaluated. For example, the defense against the scenario of adversarial attacks has not been considered in almost all machine/deep learning-based software vulnerability detection systems [2, 13, 21, 27, 31, 33, 39]. The adversarial attacks hold significant importance as they allow attackers to modify their samples (e.g., vulnerable samples) to bypass the prediction model. By manipulating the input data, adversaries can deceive the model into making incorrect predictions (e.g., vulnerable samples predicted as non-vulnerable), compromising the overall security of the system. As the number of hackers has grown [3], there is a strong demand to evaluate the security of software analysis techniques. Therefore, this motivates us to conduct fundamental research on evasion attacks to have a thorough understanding of the security issues of machine learning-based software vulnerability detection techniques.

In this paper, we propose EaTVul (Evasion Attack Against Software Vulnerability Detection), an automatic attack strategy from the perspective of an attacker. We assume no knowledge of the target model and cannot manipulate the training data. Our experiments demonstrate that EaTVul achieves an attack success rate of more than 83% when the snippet size is greater than 2 and 100% for most cases with a snippet

(a) Vulnerable samples predicted as vulnerable

(b) Vulnerable samples predicted as non-vulnerable

Figure 1: This figure shows that a vulnerable sample can be easily bypassed by adding a precisely crafted piece of adversarial data. Left: a vulnerable function predicted as vulnerable with a high probability of 93.2%; Right: the same vulnerable function predicted as non-vulnerable with a high probability of 87.4% after adding an optimized adversarial data generated by EaTVul.

size of 4. At a high level, our approach involves using SVMs (support vector machines) to identify important vectors in non-vulnerable samples. We then employ an attention mechanism to highlight important features contributing to predictions in non-vulnerable samples. Using chatGPT, we generate adversarial data based on these important features and prepare a preserved attack pool. We use a fuzzy genetic algorithm to automatically optimize the selection of seed adversarial data and insert it into vulnerable samples, aiming to make them predicted as non-vulnerable. Figure 1 illustrates how a vulnerable function can be easily bypassed by adding precisely crafted adversarial data generated by EaTVul. The prediction changes from 93.2% vulnerable to 87.4% non-vulnerable. In summary, our main contributions are as follows:

- We propose a novel evasion attack approach, named EatVul, which produces code to evade ML-based vulnerability detectors. To achieve this, EatVul first employs SVM to identify the most important non-vulnerable samples, which will be used as important samples to identify the important features. Then, it utilizes the attention mechanism to identify the important features that have the most significant contribution to the prediction, based on the important samples identified by SVM. Afterwards, it uses ChatGPT to generate adversarial data based on the important features identified by the attention model. Finally, EatVul uses the improved fuzzy genetic algorithm (FGA) to select the optimal seed adversarial data for launching an evasion attack against machine learning-based software vulnerability detection systems.

- We have conducted an evaluation of EatVul against state-of-the-art baselines, and the experimental results demonstrated that our scheme achieved a 100% success rate for most cases (refer to Table.5 with Sni.-4). Our study presents significant findings to the software security community.

- We have made our proposed system, EatVul, available to the research community. Furthermore, we have published the datasets and code to encourage others to contribute to adversarial learning. We hope that this system will raise the attention for the security community to have good understanding the security issues of machine learning/deep learning-based systems for software security and to develop further defense strategies. The datasets and code are available at https://github.com/wolong3385/EatVul-Resources.

2 Related Work

In this section, we will only review works closely related to this study. For more comprehensive information about adversarial machine learning in other research areas such as computer vision, natural language processing, and cybersecurity, please refer to [16, 28, 29, 37].

Recent research has highlighted the vulnerability of machine learning, particularly deep learning, techniques to adversarial attacks in the field of software vulnerability detection [38, 52]. Zhang et al. [55] introduced the Metropolis-Hastings Modifier algorithm to generate adversarial samples specifically for attacking machine learning-based software vulnerability detection systems. Zeng et al. [54] developed OpenAttack, an open-source toolkit for textual adversarial attacking with unique strengths in supporting all attack types, multilinguality, and parallel processing. Yang et al. [51] further improved the strategy using a greedy and genetic algorithm with a focus on semantic preservation. Srikant et al. [43] further combined site-selection and perturbation-choice into a

joint mathematical problem, proposing a set of first-order optimization algorithms to solve the formulation. Their approach has demonstrated a 1.5x increase in attacking performance over previous adversarial generation methods [51], which we use as one of our baseline models. Yu et al. [53] presented AdVulCode, the first DL-based adversarial example generation method for vulnerability detection models, demonstrating its effectiveness through controlled perturbation and an improved MCTS search algorithm. The recently published code obfuscation tool, Milo, proposed by Song et al. [42], focuses on an elevated abstraction tier, applying the transformation to the parsed abstract syntax trees (AST).

Ramakrishnan and Albarghoutthi conducted a study on the potential of backdoor attacks targeting deep learning-based techniques used in software vulnerability detection based on source code [36]. The authors introduced additional data points containing triggers into the original training dataset, and experimental results revealed that code2seq and seq2seq-based techniques are susceptible to backdoor attacks. Henkel et al. [7] evaluated state-of-the-art machine learning-based architectures for software vulnerability detection and observed that code2seq surprisingly exhibits vulnerability to adversarial attacks. Zhou et al. [56] investigated the robustness of deep neural networks (DNNs) in generating code comments and proposed ACCENT, an identifier substitution approach that generates adversarial data. These snippets maintain syntactic correctness and semantic similarity to the original code but can mislead DNNs into producing irrelevant comments.

Moreover, efforts have been made to assess the robustness of natural language models. For instance, TextFooler [11] utilized synonyms of selected keywords combined with part-of-speech (POS) tagging information to replace original words, with the aim of minimizing alterations. BERT-Attack [17] and BAE [5] employed pre-trained masked language models to generate more fluent and natural tokens consistent with contexts. In an effort to enhance the stealthiness of attacks, Yang et al. [49] proposed a greedy search strategy with replacement operations at the character level, applicable to various state-of-the-art text classification models. However, these endeavors were found to be inadequate for programming languages, given their more structural nature and functional semantics compared to natural language.

To the best of our knowledge, few works focus on assessing the robustness of these deep-learning methods. Unlike prior works in text-based adversarial learning [5, 11, 17, 49], this paper focuses on the naturalness of adversarial statements while preserving normal execution by inserting adversarial data. Notably, this work is different from adversarial malicious learning. Generally speaking, malware detection using machine learning usually based on binaries rather than source code [12]. Therefore, a thorough discussion of adversarial malware is beyond the topic of this paper. For more information, please refer to [15, 29, 48].

3 Overview of the EaTVul

This section introduces EaTVul, an automated system designed to attack machine learning-based software vulnerability detection systems. Figure 2 provides an overview of the proposed EaTVul, which consists of two main phases: adversarial data generation (①) and adversarial learning (②).

In the first place, we train a surrogate model based on BiLSTM with an attention mechanism. To generate the adversarial data, several stages are involved in Phase 1. First, we identify important non-vulnerable samples using SVM. Then, we retrieve the averaged attention scores from the attention layer to identify the key features that contribute significantly to the prediction. These important features serve as inputs to ChatGPT, which generates adversarial data. The generated adversarial data will then be further reviewed and optimized, and ChatGPT is used again to regenerate the adversarial data. The optimized adversarial data is then added to the preserved attack pool. In Phase 2, our goal is to bypass a machine learning-based software vulnerability detection system using a vulnerable sample. To achieve this, we utilize a fuzzy genetic algorithm to select the best seed data, which is added to the vulnerable test case. The expectation is that the modified vulnerable test case will be predicted as non-vulnerable with a high probability. Details regarding the input/output of each step will be discussed in Section 3.1.

In this study, the attacker's capability, knowledge, and goal are as follows: **Attacker's capability.** The attacker is capable of perturbing the test queries given as input to pre-trained vulnerability detectors to generate adversarial samples. We follow the existing paradigm for generating adversarial examples in programming languages [51] and allow for two types of perturbations for the input code sequence: (i) token-level perturbations (for instance, variable renaming) and (ii) statement-level perturbations (for example, dead code insertion). To maintain the stealthiness and functionality of the perturbated code samples, we choose statement-level modification in this work. Specifically, the attacker is allowed to insert a certain number of non-functional statements in arbitrary locations. **Attacker's Knowledge.** Attacker's Knowledge. In the context of this study, we employ a conventional black-box framework for deep-learning-based vulnerability detection methods. Here, we presume that attackers do not have access to the architecture and parameters of target models; they are restricted to querying the deployed vulnerability detection model solely with input code sequences, receiving corresponding output probabilities or predictions. However, attackers have the capability to collect all open-source resources, including vulnerability information from NVD, to train their surrogate prediction model. Since practitioners typically utilize public vulnerability repositories to construct their training datasets, real-world vulnerable samples are limited with respect to vulnerability types. Therefore, we assume there will be overlap between the training data collected by

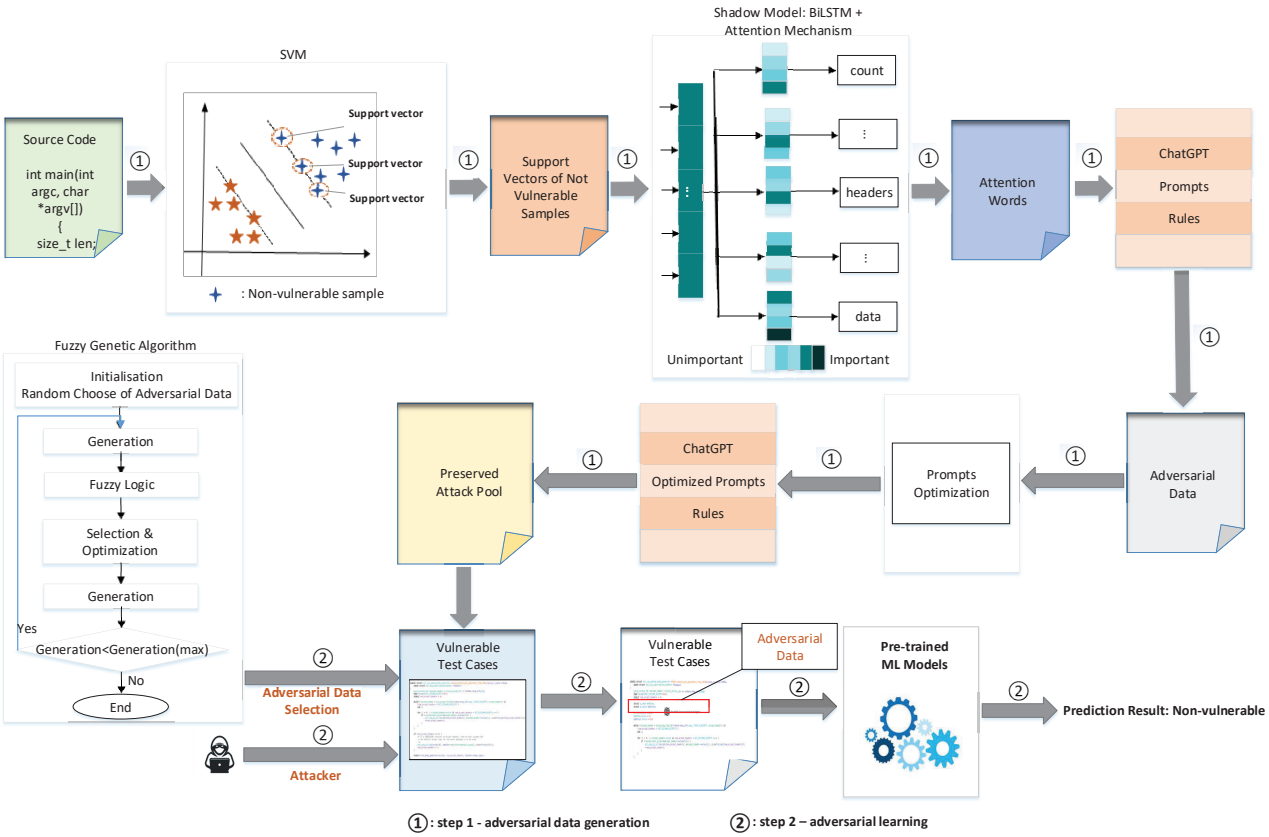


Figure 2: The framework of EaTVul.

attackers and practitioners. We maintain that this black-box setting is practical, unlike white-box or grey-box scenarios, where attackers are assumed to have access to all or part of the aforementioned facets. **Attacker's Goal.** When presented with an input code sequence or program representations from a vulnerable program, the objective of the attacker is to deceive the targeted vulnerability detection tools through imperceptible modifications to the inputs. Importantly, within the framework delineated in this paper, we formulate an additional requirement: the inserted adversarial code snippets must refrain from adversely affecting the regular execution of the code samples under examination.

3.1 Adversarial Data Generation

In this study of software vulnerability detection, adversarial data generation involves adding adversarial data in the vulnerable samples that are intentionally designed to deceive machine learning algorithms into making incorrect predictions or decisions. The goal of generating adversarial data is to identify weaknesses in the machine learning models used to detect vulnerabilities in software. Adversarial data should meet the following requirements: 1) It should include all the important features identified by the attention mechanism; 2) The adversarial data must maintain the code's functionality and should not introduce any syntactic errors or alter its operation; 3) The size of the adversarial data should be limited to less than 8 lines in this study to enhance its concealment and make it challenging to detect. To meet these requirements, we employ ChatGPT to generate adversarial data while considering all the important features (requirement 1). Subsequently, the raw adversarial data generated will undergo further optimization through prompts optimization (requirement 2) and re-generation using ChatGPT (requirement 3). The following context will provide a detailed explanation of these steps.

3.1.1 Important Samples Identification using SVM

A well-known fact is that not every sample contributes equally to the prediction. In this paper, our objective is to select the most important non-vulnerable samples and then identify the features that contribute the most to the prediction. Hence, a layered approach is essential to pick the most critical code samples and identify the most important features within those code samples. Therefore, we employ SVM, which is a low cost way to identify the important code segments (i.e., important non-vulnerable samples, which are the data points that lie closest to the decision boundary of the machine learning

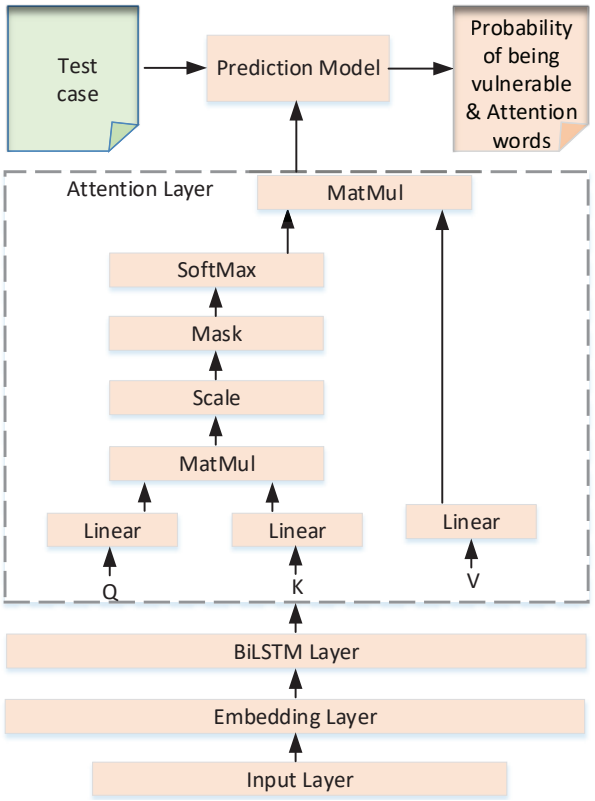

Figure 3: Framework of feature learning and attention mechanism.

model) [26]. By analyzing the properties of these support vectors, it is possible to gain insights into the most important features or characteristics of the data that the model is using to make its predictions. Once the most important samples have been identified, an attacker can then use this information to generate new data points that mimic these samples in order to manipulate the system's behavior. This could involve adding or modifying features in a way that is designed to fool the machine learning model into making incorrect predictions or decisions.

Assume a training software dataset of of n samples, $D = \{(x_i, y_i)\}_i^n$, a soft margin SVM learns the weights w and bias b by solving the following convex QP optimization problem [34]:

$$minL(w,b,\xi) = min\frac{1}{2}\|w\|^2 + C\sum_i^n \xi_i \quad (1)$$

such that

$$y_i(w^T x_i + b) \geq 1 - \xi_i,$$

and

$$\xi_i \geq 0, \quad i = 1,2,\cdots,n.$$

In the context of machine learning, let D represent the training dataset. The optimization process aims to maximize the margin by minimizing the term $\frac{1}{2}|w|^2$, where w denotes the

```
1:  static void sdp_fmtp_get(const char *attributes, const char *name, int *attr)
2:  {
3:      const char *kvp = "";
4:      int val;
5:
6:      if (attributes && !(kvp = strstr(attributes, name))) {
7:      return;
8:      }
9:
10:   if (kvp != attributes && *(kvp - 1) != ' ' && *(kvp - 1) != ';') {
11:     /* Keep searching as it might still be in the attributes string */
12:     sdp_fmtp_get(strchr(kvp, ';'), name, attr);
13:   } else if (sscanf(kvp, "%*[^=]=%30d", &val) == 1) {
14:     *attr = val;
15:   }
16: }
```

Figure 4: Important features identified by attention mechanism display. The importance decreases from red to yellow.

weight vector. The hinge loss, represented by the variable ξ_i, quantifies the classification error. The regularization parameter C controls the balance between minimizing the classification error on the training data and maximizing the margin.

In this stage, the input consists of high-level program representations from the last layer of the surrogate model, denoted as $D = (x_i, y_i)_i^n$, where y_i is the label of input samples. The output of interest in this stage is the set of support vectors. Specifically, we focus on evasion attacks given a vulnerable sample, so we only select the support vectors from the non-vulnerable class as the important samples. These support vectors are represented as $sv = (sv_1, sv_2, ..., sv_l)$, and they will be used in the subsequent subsection discussed in Section 3.1.2.

3.1.2 Important Feature Identification

Identifying the most important features is crucial for launching effective adversarial attacks. Adversaries aim to manipulate a system's decision-making process by introducing carefully crafted adversarial examples that resemble normal samples but are misclassified by the system. In this paper, we employ BiLSTM (bidirectional long short-term memory) with the attention mechanism [25] as the surrogate model and identify the most important features using the average attention scores. These features will be further utilized to generate adversarial data. In this step, we adopt the indices set from the previous stage and retrieve the weights from the attention layer. Further, the averaged attention score will be projected to the tokens in the statements. To maintain the stealthiness, we exclude low-frequency or unusual user-defined terms unique to a singular project. The outcome of this stage comprises a corpus of candidate features deemed significant.

Figure 3 illustrates the general overview of the surrogate model. The input data, which is the source program, passes through several layers including the embedding layer, BiLSTM layer, and the self-attention layer. The output of the attention layer is the prediction model, which provides the

Table 1: Categories of Keywords in C programming Language

Category	Features
Data Type	'int', 'float', 'double', 'char', etc.
Control Statement	'if-else', 'switch-case', 'for', 'while', 'do-while', etc.
Storage Classes	'auto', 'extern', 'static', 'register', etc.
Input-Output	'printf', 'scanf', etc.
Miscellancous	'sizeof', 'return', 'break', 'typeof', 'continue', etc.

probability of vulnerability and the attention words for a given test case. The succeeding component of the attention layer is the prediction module, which provides the probability of vulnerability. Figure 4 showcases an example of the important features identified by the attention mechanism, with the importance depicted through a gradient from red to yellow. In this example, the identified features include *static, const, strstr, strchr, val, sscanf*. These features will be incorporated into the generation of adversarial data.

The purpose of the self-attention mechanism is to capture the dependencies and relationships between different words in a sequence of source programs. It enables the model to assign distinct weights or attention scores to each word based on its relevance to other words in the sequence. By learning these attention weights, the model can effectively focus on important and relevant words, allowing it to capture long-range dependencies. Motivated by the previous study [45], the softmax attention function in this study is as follows:

$$attention(Q,K,V) = softmax(\frac{QK^T}{\sqrt{d_k}})V \quad (2)$$

where Q, K, V are matrices of the sets of queries, keys, and values, d_k means the dimension.

3.1.3 Adversarial Data Generation using ChatGPT

Generative AI has the potential to revolutionize various aspects of our lives, with chatbots being one of the most popular implementations. ChatGPT has been extensively used and tested in different domains, showcasing its remarkable capabilities. In our work, we digest the candidate set of significant features and leverage ChatGPT as the code generation tool to generate adversarial data. In comparison to the predefined templates, the code snippets exhibit a higher level of fluency.

To generate effective code snippets, we propose query templates as prompts to ChatGPT, incorporating the important features extracted using attention mechanisms. Especially, to better fulfill the requirement of stealthiness, we incorporate the partial codes preceding and succeeding to the inserting locations as context, following the template: <*Context*> <*Query*>< *Context*>. And the <*Context*> yields one of the following prompt variations: "Given the partial

```c
#include <stdio.h>

struct a_chan {
   int value;
};

struct b_const {
   double value;
};

static const char a_array[] = "NULL";

void myFunction() {

   struct a_chan myAChan;
   struct b_const myBConst;

   myAChan.value = 0;
   myBConst.value = 0.0;

   for (int i = 0; i < 10; i++) {
      printf("Iteration %d:\n", i);

      myAChan.value += i;
      myBConst.value += 0.5 * i;

      printf("a_chan value: %d\n", myAChan.value)
      printf("b_const value: %f\n", myBConst.value)
     }

}
```

(a) Raw data generated by ChatGPT

```c
struct a_chan { int value; } queue;
struct b_const { double value; } p_project;
static const char a_array[] = "NULL";

queue.value = 0;
p_project.value = 0.0;

for (int i = 0; i < 10; i++)
     printf("i = %d\n", i);
```

(b) Further optimized data by ChatGPT

Figure 5: Raw adversarial data and optimized adversarial data generated by ChatGPT. The top figure contains more than 25 lines of code, while the bottom one displays a more concise version with no more than 8 lines.

preceding/succeeding codes as:", "With the partial preceding/following codes provided as:", "In light of the incomplete preceding/following codes as:" and "Taking into account the limited preceding/succeeding codes as:". Prior to constructing the queries, we categorize the obtained important features based on their predefined meaning and functionality within the programming language. This allows us to select the appropriate context for each keyword. The categories of the keywords are illustrated in Table 1. For instance, let's consider the important features "for" (loop-related), "static" (storage type), and "const" (data-type related). Using our predefined templates, we can construct a query such as: "*Please generate a function in C that contains a loop, two structs named a_chan and b_const, and define a static const char named*

Algorithm 1 Adversarial Sample Generation using Fuzzy Genetic Algorithm

Input: M (DL-based vulnerability detector); D_i (a group of vulnerable programs); S_i (the set of statements for perturbations in D_i); K (the number of fuzzy clusters)

Output: A set of optimized adversarial data

1: Population $T \leftarrow$ init(s_j), where s_j is the statement in S_j ;

2: Score set $R(s_j)$(refer to Equation 3)$\leftarrow$ init (score($D_i \otimes s_j$)), where $\otimes$ represents insertion, s_j is the statement snippet in S_j.

3: Centroid set $C \leftarrow$ init (c_k), where c_k are randomly generated centroid ranging from $[0, 1)$;

4: Fuzzy cluster label set $L \leftarrow$ init(cluster label l_{jk}), where l_{jk} are randomly assigned labels;

5: **while** there is label change for the element in L or distance perturbations **do**

6: **for** t $\leftarrow 1....j$ **do**

7: calculate distance d_k to k clusters using *Equation* 4 & *Equation* 5;

8: modify the label l_{tk} in L to $k_t = argmin(d_k)$, if $l_{tk} != argmin(d_k)$ and $\Delta\, d_k <$ Threshold ε ;

9: **end for**

10: update centroid c_k in C to get $C^{'}$ with *Equation* 6;

11: **end while**

12: select Top 2 clusters based on the magnitude of the centroid and eliminate the other clusters, update T to get $T^{'}$;

13: perform crossover ($\bigoplus$ stands for concatenation operation) by picking up ancestors from Top 2 clusters with probability p_m, to create offspring o;

14: get new population $T^{''} \leftarrow T^{'} \bigcup o$;

15: update the Score set R with new population $T^{''}$ to get $R^{'}$;

16: back to **line** *5*, repeat until any element in T can have ASR = 100.00;

17: **return** T;

a_rray initialized with NULL."

To bolster the prevention of vulnerabilities stemming from the introduction of dead code in the adversarial snippet generation process, we append a suffix string indicative of functionality to the obtained significant tokens. For example, if 'variable_a' is utilized as a variable in a conditional statement, '_condition' is appended to distinguish it before inputting it into the generation module, preventing overlap with the original code. In cases where the keyword does not function as a variable name in the original code, it is nonetheless designated as such in the generated adversarial snippets. Given that the generated code segments are dead code, their operations exhibit no contextual relevance to the surrounding codes. These measures contribute to ultimately defining the generated adversarial snippets as vulnerability-free dead code.

However, the adversarial data generated by ChatGPT often contain more lines than expected, compromising their stealthiness. We aim to improve the concealment by performing in-function insertion with adversarial data. To achieve this, we introduce additional constraints to optimize the prompts. These constraints include the following: First, we define the request as "*Please generate several lines in C*". Second, to ensure better integration with the existing code context, we rename the generated structs to be more closely related to the original variable names. For example, we use the optimized query "*Defines two structs a_chan and b_const as external structures and rename them as "queue" and "p_project*". Third, to reduce the size of the code snippets, we include the condition "*Please generate the codes in dense format*". Figure 5 presents an example of the raw data generated by ChatGPT and the optimized data re-generated by ChatGPT after using optimized prompts.

3.1.4 Preserved Attack Pool Generation

We have prepared a preserved attack pool that includes meticulously crafted adversarial data generated by ChatGPT. In detail, we generate plenty of samples from ChatGPT. To guarantee the compilability and functionality preservation, we employ the public program analysis tool (i.e., Comex) to remove these code snippets that are uncompilable or possess data dependency with the original programs and preserve the remaining adversarial code snippets. These adversarial data is specifically designed for studying adversarial attacks and assessing the robustness of machine learning-based software vulnerability detection systems models.

The preserved attack pool contains all the samples generated based on five categories of important features as discussed in subsection 3.1.3. These important features are data type, control statement, storage classes, input-output, and miscellaneous. These samples will be used as seed input for the fuzzy genetic algorithm to optimize the attack strategy. In other words, by using the preserved attack pool as a source of seed samples, fuzzy genetic algorithms can leverage the knowledge and characteristics of previously crafted adversarial examples. These seed data will provide desirable properties, such as effective attack strategies or high success rates

against machine learning models.

3.2 Adversarial Learning

This subsection will discuss Step 2, which involves adversarial learning, including seed data selection and evasion attacks.

3.2.1 Seed Data Selection using FGA

To discover the optimal combination of preserved templates and enhance the success rate of evasion attacks, we employ optimized Fuzzy Genetic Algorithm (FGA) [47] (Algorithm 1). The FGA method employs a fuzzy clustering approach to ensure that all reserved members in the population have an opportunity to pass on to the next generation. Additionally, a fuzzy selection method is utilized to mitigate the drawbacks of a greedy strategy. The novel genetic algorithm consists of four major steps: initialization, clustering, selection, and crossover. Algorithm 1 provides detailed information regarding the seed data generation.

Initialization. The genetic algorithm begins by randomizing the initial population, which serves as the first step in our proposed optimization algorithm. Each sample within the randomly generated population is filled with the predefined code snippets based on the templates. The population size remains constant throughout the method. Additionally, we initialize the score set of the population by calculating the fitness scores for each member. Furthermore, we randomly sample a centroid set from a uniform distribution within the range of $[0,1)$, denoted as $C = (c_1, c_2, ..., c_k)$, where k represents the number of clusters.

Fitness Function. The design of the fitness function is a crucial step in genetic algorithms as it greatly affects the inheritance and success rate of the algorithm. In our proposed approach, we incorporate the attack success rate and the length of inserted code snippets into the fitness function. Intuitively, an effective adversarial sample should have a higher attack success rate and a lower length of inserted code snippets. Such samples are more likely to be selected as mating candidates or as the desired outcome. Based on this idea, the calculation of the fitness score for each member of the population is formulated as follows:

$$Score(s_j) = ASR(D_i \otimes s_j) - \lambda * len(s_j) \tag{3}$$

where $ASR(D_i \otimes s_j)$ is the averaged attack success rate of entities generated by inserting the statement snippets into test vulnerable programs and $len(s_j)$ is the number of lines of the sample in the population. λ controls the significance of the lengths of code snippets.

Fuzzy clustering approach. Fuzzy clustering [32] is a type of clustering algorithm that assigns each data point to multiple clusters with corresponding probabilities instead of a single cluster. In our work, we employ fuzzy clustering for further selection of the mating pool, aiming to avoid sub-optimal combinations. Compared to conventional clustering methods, where each sample in the population is assigned to a single cluster, denoted as $y = (y_1, y_2, y_3, ..., y_n)$, the fuzzy clustering algorithm defines rules to separate the data into clusters $C = (c_1, c_2, c_3, ..., c_m)$ in a way that minimizes the overall loss. The loss is defined by the following equation:

$$argmin_C = \sum_{j=1}^{n} \sum_{k=1}^{c} w_{jk}^{\alpha} |score(s_j) - c_k| \tag{4}$$

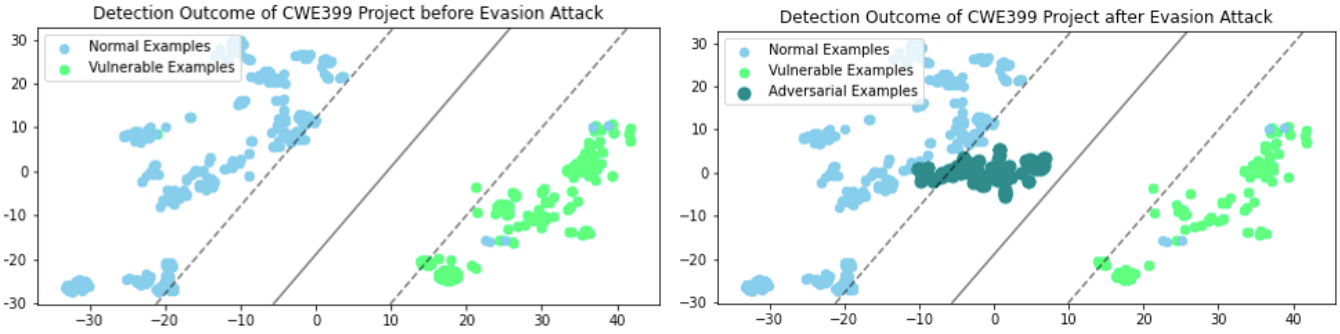
where the fuzziness is limited by the factor α. The partition matrix is denoted by $W = w_{ij}$, which indicates the probability that element y_i belongs to C_j. And w_{ij} is calculated as:

$$w_{jk} = \frac{1}{\sum_{k=1}^{c} (\frac{s_j - cj}{s_j - c_k})^{\frac{2}{C-1}}} \tag{5}$$

where C is the number of clusters.

Selection. We select the best two clusters based on the magnitude of the centroid, which is also known as the fitness score. Our intuition is that the mating candidate with a higher fitness score has a higher probability of creating high-quality and effective sub-generations. However, it is worth noting that all members in the population have a chance to participate in the reproduction process, but with a lower probability.

Crossover. The operator randomly samples two chromosomes as parents from the selected clusters, ensuring that replicated code snippet combinations are discarded. The probability of a chromosome being selected as a parent is calculated as follows:



$$p_i = \frac{e^{f_i}}{\sum_{k=1}^{n} e^{f_i}} \tag{6}$$

where $f_i = w_{ik}^{\alpha} |score(s_i) - c_k|$ and c_k denotes the centroid of the selected clusters.

3.2.2 Evasion Attack

When launching an attack on a vulnerable test case, the FGA randomly chooses a seed sample. It then produces an optimized adversarial data snippet, which is added to the vulnerable test case, which mean we add the code snippet into the vulnerable samples before feed it to the prediction model. The objective is to modify the test case in such a way that it can evade detection by the machine learning-based software vulnerability detection system. It should be emphasized that EaTVul is specifically designed for evasion attacks targeting vulnerable test cases. The consolidation of all the keywords from Figure 5a into a single function is illustrated in Figure 5, as shown in Figure 5b, while maintaining the core logic. The code depicted in Figure 5b will be incorporated into the non-vulnerable sample to initiate the attack.

In addition, it is worth noting that, for the input and output of each step in the proposed EaTVul, the generated results are consistent with expectations at each stage. Specifically, given

(a) Vulnerable and non-vulnerable (normal) samples

(b) Movement of adversarial samples

Figure 6: Visualization of Evasion Attack using EaTVul. This figure shows the distribution of vulnerable and non-vulnerable samples, as well as the adversarial samples, based on t-SNE.

the collected training data, we employ SVM to identify the most important non-vulnerable samples. SVM consistently outputs the same support vectors in this step. Subsequently, the attention mechanism is applied to identify the most important features given these crucial samples. The attention mechanism consistently produces the same important features or tokens in this step. Afterwards, we set up rules for ChatGPT to generate adversarial data. The temperature for ChatGPT is set to 0, ensuring reproducibility in the results at this step. All generated adversarial data is added to the preserved attack pool, maintaining consistency with the previous step. Next, a fuzzy genetic algorithm is applied to create the best attack strategy, consistently producing the best combination based on the samples from the same preserved attack pool. Therefore, this process is reproducible as it is automatically completed based on FGA. Finally, we launch an evasion attack based on the adversarial data created by FGA. Since each process can be reproduced, we can confirm that the generated results are consistent and reproducible, given the same training data.

3.3 Visualization of EaTVul evasion attack

In this subsection, we present the visualization of the data distribution using t-SNE [44] given vulnerable and non-vulnerable samples. Figure 6 showcases the application of t-SNE for visualizing evasion attacks, specifically focusing on the vulnerable and non-vulnerable features. The visualization presented in Figure 6a reveals interesting insights regarding the separability of vulnerable and non-vulnerable samples based on the decision boundary, with only a few vulnerable samples overlapping. By leveraging t-SNE, we can gain a deeper understanding of the effectiveness of evasion attacks and the distinguishability of vulnerable and non-vulnerable instances. The clear separation observed in the visualization indicates that the decision boundary is generally successful in classifying samples as vulnerable or non-vulnerable.

However, it is worth noting that despite the initial separation observed in Figure 6a, certain vulnerable samples may actually lie within the region classified as non-vulnerable. This discrepancy can be attributed to the presence of precisely crafted adversarial data. By strategically inserting adversarial perturbations into the vulnerable samples, we can observe a shift in their positions towards the non-vulnerable side, as depicted in the Figure6b. This demonstrates the susceptibility of vulnerable samples to manipulation and highlights the need for robust defense mechanisms capable of mitigating such adversarial attacks.

4 Experimental Setup

We will fundamentally evaluate the proposed EaTVul by answering the following research questions (RQ):

- How effective is fuzzy genetic algorithm in selecting the seed adversarial data compared with randomization?
- How effective is EaTVul based on adversarial data generated by ChatGPT originally and after optimization? To answer this question, we conducted experiments by presenting the results based on the scenario using the original adversarial data directly and optimized data.
- How effective is EaTVul with recently developed machine learning-based software vulnerability detection systems?
- How effective is EaTVul when compared with state-of-the-art large language models (LLM) and other machine learning tools that using BiLSTM for software vulnerability detection? To answer this question, we compare EaTVul with four recent large program generation models/algorithms: CodeBERT [8], CodeGen-2B [1], PosterLin [23], and MDVD [22].
- How EaTVul behaves/performs regarding obfuscation/diversification methods? To answer this question,

We conducted comparative experiments on two state-of-the-art target models, Asteria [50] and LineVul [4], which leverage different program representations.

- How effective is EaTVul when generalized to other programming languages? To demonstrate the generalizability of our proposed method, we extend the evaluation to two state-of-the-art vulnerability detection models for Java programs, namely FUNDED [46] and VDet [30].

4.1 Datasets

In this study, we consider using multiple datasets in the C/C++ programming language including the real-world Asterisk project and OpenSSL project. These two projects include multiple types of vulnerabilities and are widely used in the community [18, 19]. For the scenario of a single type of vulnerability, we reuse the datasets from [20, 31], which are CWE119 and CWE399 datasets. CWE119 is a buffer error dataset, CWE399 is a resource management errors dataset, and CWE416 is a use-after-free vulnerability dataset. Considering the SARD dataset [3], [50], [4] has been widely used in the area of software vulnerability detection, experiments based on this dataset has been conducted as well. To demonstrate the generalizability of our proposed method, we systematically assess its performance across Java code samples sourced from the National Vulnerability Database (NVD) and open-source projects on GitHub, specifically targeting those classified within the top 5 to top 30 most perilous categories as defined in the Common Weakness Enumeration (CWE) [46].

Table 2 presents the dataset information used in this paper. The first column shows the name of the dataset, the second column shows the number of vulnerable samples, followed by the number of non-vulnerable samples. In the experimental settings of training the surrogate model, we split the dataset into training (70%), evaluation (15%), and test data (15%). All the vulnerable test cases come from the test data. All the vulnerable test cases have been tested and confirmed that they are classified as vulnerable by the target model before launching adversarial attacks. The Abstract Syntax Trees (AST) feature has been considered in this paper since all the baselines use AST in their study.

Table 2: Dataset Information.

Data	#Vulnerable	#non-vulnerable	# Total
Asterisk	102	1541	1553
OpenSSL	157	788	945
CWE119	5442	6966	12388
CWE399	1232	1288	2520
SARD	64788	131792	196580
CWE416	459	1834	2293
JAVA	14756	14756	29512

4.2 Evaluation Metrics

This work only considers the attack success rate, which is defined as follows:

$$\frac{\#bypass}{\#total\ test\ cases} \times 100\% \tag{7}$$

In this study, the success rate typically refers to the percentage of attempts or instances where an adversarial attack is successful in bypassing the target model's (i.e., the vulnerable test cases misclassified as non-vulnerable). The success rate quantifies how often the attack is able to generate adversarial examples that are misclassified by the target model. It represents the proportion of crafted adversarial samples that successfully fool the model into making incorrect predictions or classifications. A higher success rate indicates a stronger attack, as it demonstrates the ability to consistently manipulate the target model's predictions.

Considering some baselines only report the top@k precision, we have also included experimental results based on top@k in our report. For instance, a success rate of 90% in Top@10 means that the attack was successful in 9 out of 10 cases when considering only the top 10 most vulnerable instances. It is important to note that reporting the top@k precision gives us insights into the attack's effectiveness in specific scenarios where only a limited number of vulnerable instances are of interest.

In this study, the snippet size [10] is an additional factor considered to improve the success rate of the attack in specific circumstances. The snippet size refers to the number of individual pieces of adversarial data that are chosen and combined to create a single adversarial sample used for launching the attack. For instance, when the snippet size is 1, it means that only one piece of adversarial data is selected and added to the vulnerable sample. On the other hand, when the snippet size is 2, two pieces of adversarial data are chosen and combined together to form a single adversarial sample. This allows for more complex modifications and combinations of multiple features or aspects in the attack process.

In addition, F1-Score [25] Without Adversarial Samples has been considered in this study as well. As stated above, the adversary's goal is to degrade the performance of the input code sequence with malicious code snippets by imperceptibly modifying the original source code, while maintaining the detection capability on the samples without adversarial code snippets. Therefore, we employ the F1-score without adversarial attack to represent the normal performance in the downstream vulnerability detection task.

4.3 Baselines

In this work, we choose the recently developed systems as the target models to show the effectiveness of the proposed

Table 3: Experimental results of attack success rate (%) based on different top@k metrics of fuzzy genetic algorithm and randomization selection.

Strategy	Top@5	Top@10	Top@15	Top@20
Randomizat.	0.533	0.475	0.464	0.454
Genetic	1.000	0.925	0.858	0.798

EaTVul scheme. The baselines include AST-EVD [3], Asteria [50], LineVul [4], Poster-Lin [23], MDVD [22], CodeBERT [8], and CodeGen-2B [1]. POSTER-Lin employs a customized bi-directional LSTM network for function-level vulnerability discovery using the AST. MDVD effectively detects function-level vulnerabilities by combining heterogeneous data sources to extract transferable vulnerability information and utilizing LSTM cells to learn unified representations of vulnerable source code patterns. AST-EVD avoids data loss by using the pack-padded method on the Bi-GRU network, achieving precise function-level vulnerability detection. Asteria utilizes the Tree-LSTM and code pairing to identify vulnerabilities in defective programs. LineVul proposes a transformer-based method with an attention mechanism for comprehensive line-level vulnerability detection, utilizing context information effectively. These approaches enhance vulnerability assessment using different techniques and data sources. CodeBERT is a pre-trained programming language model that encompasses multiple programming languages. The CodeGen-2B transformer decoder model is trained on a variety of programming languages, including C, C++, Go, Java, JavaScript, and Python, as well as natural language

Previous research treats obfuscation transformations to programs as adversarial perturbations that can affect a downstream ML/DL model like a malware detector or a program summarizer. Since our proposed attack schema operates on the natural code channel, we compare it with two state-of-the-art obfuscation techniques for a fair comparison, as they also focus on the source code: Differentiable Generator [43], which uses first-order gradient information to discover the optimal choice of sites in a program for applying perturbations and the specific perturbations to apply on the selected sites; Milo [42], which supports five obfuscation methods that alter the semantic and syntactic features of the programs. Specifically, these methods fall into two types of transformation: replacing transformation and insert transformation.

4.4 Results and Discussion

We structure our evaluation by stepping through each of our three research questions (RQ1-6).

RQ1: How effective is fuzzy genetic algorithm in selecting the seed adversarial data compared with randomization? In order to show that fuzzy genetic algorithm outperforms randomization selection, we conducted experiments on the four datasets (i.e., CWE119, CWE399, Asterisk, and OpenSSL) and report the average results. Table 3 presents the experimental results of fuzzy genetic algorithm and randomization selection. The provided results show the performance of two strategies, Randomization and Genetic, based on different top@k metrics (Top@5, Top@10, Top@15, and Top@20).

For the Randomization strategy, the success rates gradually decrease as we consider a larger number of vulnerable instances. At Top@5, the success rate is 53.3%, indicating that 53.3% of the top 5 vulnerable cases were successfully attacked. As we expand the evaluation to the top 10, 15, and 20 vulnerable instances, the success rates decline further to 47.5%, 46.4%, and 45.4%, respectively. This suggests that the Randomization strategy performs relatively less effectively as we consider a larger pool of vulnerable cases.

On the other hand, EaTVul with the Genetic strategy demonstrates high success rates across all top@k metrics. At Top@5, the success rate is a perfect 100%, indicating that all of the top 5 vulnerable instances were successfully attacked. Even as we consider a larger number of vulnerable instances, EaTVul with the Genetic strategy maintains high success rates. At Top@10, the success rate is 92.5%, which means that 92.5% of the top 10 vulnerable cases were successfully attacked. Although there is a slight decrease in the attack success rates for top@15 and top@20, with 85.8% and 79.8% respectively, the results still demonstrate the effectiveness of EaTVul with the Genetic strategy when compared to the Randomization strategy.

In summary, the results indicate that EaTVul with the Genetic strategy outperforms the Randomization strategy across all top@k metrics. It achieves higher success rates and demonstrates greater effectiveness in attacking a larger number of vulnerable instances. These findings highlight the potential of EaTVul with the Genetic strategy as a robust approach for adversarial attacks in the given context.

RQ2: How effective is EaTVul based on adversarial data generated by ChatGPT originally and after optimization? To answer this question, we conducted experiments using the

Table 4: Experimental results of the attack success rate (%) based on adversarial data generated by ChatGPT, both originally and after optimization.

Models	Data	Original data	Optimized data
AST-EVD	SARD	0.879	1.000
	OpenSSL	0.825	0.943
	CWE399	0.889	0.975
Asteria	SARD	0.902	1.000
	OpenSSL	0.854	0.980
	CWE399	0.922	1.000
LineVul	SARD	0.845	0.983
	OpenSSL	0.856	1.000
	CWE399	0.837	0.956

Table 5: Experimental results of attack success rate (%) against AST-EVD, Asteria, and LineVul. Sni.: Snippet Size.

Target Model	Dataset	Sni.-1	Sni.-2	Sni.-3	Sni.-4
AST-EVD	Asterisk	0.480	0.750	0.840	1.000
	OpenSSL	0.520	0.790	0.840	1.000
	CWE119	0.510	0.630	0.780	0.860
	CWE399	0.570	0.830	0.920	1.000
	SARD	0.460	0.650	0.840	0.920
Asteria	Asterisk	0.620	0.740	0.880	1.000
	OpenSSL	0.650	0.710	0.930	1.000
	CWE119	0.670	0.860	1.000	1.000
	CWE399	0.760	0.830	0.960	1.000
	SARD	0.640	0.840	0.950	1.000
LineVul	Asterisk	0.340	0.730	0.940	1.000
	OpenSSL	0.340	0.910	0.970	1.000
	CWE119	0.370	0.560	0.910	1.000
	CWE399	0.430	0.740	0.830	0.930
	SARD	0.450	0.670	0.870	1.000

adversarial data generated from ChatGPT directly and the optimized data by ChatGPT. We only report the experimental results based on the OpenSLL, CWE399, and SARD datasets since the experimental results are similar for the Asterisk and CWE119 datasets.

Table 4 presents the performance of attacking different models of EaTVul on various datasets using both the original data generated from ChatGPT and the re-generated optimized data by ChatGPT. The models evaluated include AST-EVD, Asteria, and LineVul, while the datasets examined are SARD dataset, OpenSSL dataset, and CWE399 dataset.

For attacking AST-EVD, EaTVul achieves an attack success rate of 0.879 on the SARD dataset when using the original data. However, this attack success rate significantly improved to a perfect 1.000 (i.e., 100%) when the optimized data was utilized. Similarly, for the OpenSSL dataset, the success rate increased from 0.825 (original data) to 0.943 (optimized data). In the case of the CWE399 dataset, the success rate improved from 0.889 (original data) to 0.975 (optimized data). These results clearly indicate that optimizing the data has a positive impact on the performance of the models. Overall, the findings demonstrate the effectiveness of data optimization in enhancing the attack success rates against the AST-EVD model across different datasets.

Similarly, for the Asteria model, EaTVul demonstrates improved attack success rates with data optimization. On the SARD dataset, the original data achieves a success rate of 0.902, while the optimized data achieves a perfect 1.000. Similarly, on the OpenSSL dataset, the attack success rate increases from 0.854 with the original data to 0.980 with the optimized data. The CWE399 dataset also shows significant improvement, with the original data achieving a success rate of 0.922, which rises to a perfect 1.000 (i.e., 100%) with the optimized data. These results highlight the effectiveness of data optimization in enhancing the attack success rates of EaTVul against Asteria model. Moreover, for the LineVul model, the attack success rate of EaTVul on the SARD dataset increases from 0.845 with the original data to 0.983 with the optimized data. On the OpenSSL dataset, the success rate improves from 0.856 to a perfect 1.000. The CWE399 dataset also shows improvement, with the success rate increasing from 0.837 to 0.956. These results emphasize the effectiveness of data optimization in enhancing the attack success rates of EaTVul against the LineVul model across multiple datasets, leading to improved attack performance in adversarial learning of vulnerability detection.

Overall, the results indicate that the optimization of data improves the performance of the models across all datasets. The higher attack success rates achieved with the optimized data demonstrate the effectiveness of the optimization process in enhancing the EaTVul models' attack capabilities. This in turn emphasized the important of our proposed optimization process.

RQ3: How effective of EaTVul towards recently developed machine learning-based vulnerability detection systems? To answer this question, we have conducted experiments with baselines AST-EVD [3], Asteria [50], LineVul [4].

Table 5 presents the results of experiments conducted on different target models using various datasets and snippet sizes. The target models include AST-EVD, Asteria, and LineVul. The datasets used in the experiments are Asterisk, OpenSSL, CWE119, and CWE399. It is worth noting that the dataset SARD has been considered in this experiment given that all three baselines have used SARD dataset in their study. For each target model and dataset combination, the table provides the success rates of the attack for different snippet sizes, ranging from 1 to 4. A higher success rate indicates a greater effectiveness of the attack in deceiving the target model.

Generally speaking, the success rates of the EaTVul attack strategy on the different target models vary depending on the dataset and snippet size. For example, for the Asterisk dataset of AST-EVD, Asteria, and LineVul models, the attack success rates of EaTVul range from 48.0%, 62.0% and 34.0% for snippet size -1 to a perfect 100.0% for snippet size -4 for all the target models. Similar results happens to scenarios except for AST-EVD on CWE-119 and SARD datasets, and LineVul on the CWE399 dataset. Looking at the overall trends in the table, it can be observed that higher snippet sizes generally lead to higher success rates. This suggests that incorporating multiple modifications or combinations of adversarial data enhances the effectiveness of the EaTVul. For some combinations, the success rates reach 100%, indicating a complete success in evasion attack.

Overall, the table provides valuable insights into the performance of the EaTVul attack strategy across various target models, datasets, and snippet sizes. It helps in understanding

Table 6: Experimental results of attack success rate (%) against Poster-Lin, MDVD, CodeBERT, and CodeGen.

Target Model	Data	Snippet Size = 2				Snippet Size =3

	CWE399	1.000	0.899	0.867	0.767	1.000	0.950	0.917	0.880

the effectiveness of the proposed EaTVul attack in different scenarios and can guide researchers and practitioners in optimizing their strategies for adversarial attacks.

RQ4: How effective is EaTVul when compared with State-of-the-art large language models (LLM) and other machine learning tools that using BiLSTM for software vulnerability detection? To answer this question, we conducted experiment based on the datasets of CWE119, CWE399, Asterisk and OpenSSL. We report the top-k precision to keep the same performance measure as used in the baselines.

Table 6 presents the results of an attack strategy on different target models using specific datasets and two different snippet sizes: Snippet Size = 2 and Snippet Size = 3. The performance is evaluated based on the top@5, top@10, top@15, and top@20 metrics.

For the target model "Poster-Lin," with the Asterisk dataset, the attack success rates of EaTVul range from 90.0% to 75.8% for snippet size 2, and from 100.0% to 85.8% for snippet size 3. When applied to the OpenSSL dataset, the attack success rates range from 100.0% to 71.7% for snippet size 2 and from 100.0% to 87.5% for snippet size 3. Similarly, for the CWE119 dataset, the attack success rates range from 93.3% to 86.7% for snippet size 2, and from 100.0% to 92.5% for snippet size 3. The CWE399 dataset yields success rates of 100.0% to 76.7% for snippet size 2 and 100.0% to 91.7% for snippet size 3. In the case of the "MDVD" target model, using the Asterisk dataset, the attack success rates of EaTVul range from 100.0% to 78.4% for snippet size 2 and from 100.0% to 97.5% for snippet size 3. With the OpenSSL dataset, the attack success rates remain consistently high at 100.0% across all metrics and snippet sizes. The CWE119 dataset produces success rates ranging from 100.0% to 82.5% for snippet size 2, and from 100.0% to 95.8% for snippet size 3. Finally, the CWE399 dataset demonstrates high success rates ranging from 100.0% to 76.7% for a snippet size of 2, and from 100.0% to 95.0% for a snippet size of 3. Despite the variation in attack success rates, the attacks of EaTVul consistently maintain a high level of effectiveness.

For the target model "CodeBERT model", there's a consistent trend indicating improved performance with larger snippet sizes. For instance, in the Asterisk dataset, the success rates for top@5, top@10, top@15, and top@20 increase from 90.0%, 85.0%, 80.3%, and 74.0%, respectively, for Snippet Size = 2, to 90.0%, 88.5%, 84.5%, and 83.2%, respectively, for Snippet Size = 3. This trend persists across different datasets like OpenSSL, CWE119, and CWE399, where larger snippet sizes consistently lead to higher success rates. For instance, in the CWE119 dataset, the success rates for top@5, top@10, top@15, and top@20 improve from 90.0%, 84.0%, 83.4%, and 78.5%, respectively, for Snippet Size = 2, to 100.0% across all metrics for Snippet Size = 3. The "CodeGen" model exhibits similar trends, with varying success rates across datasets and snippet sizes.

The results presented in the table showcase the effectiveness of the EaTVul attack strategy. Across various target models and datasets, the attack success rates achieved are generally high, indicating the strategy's ability to compromise the security of the models under attack. These results suggest that the attack strategy is capable of effectively bypassing the defenses of the target models and exploiting vulnerabilities in the datasets. The high attack success rates across different scenarios and snippet sizes further emphasize the robustness and versatility of the strategy. These findings have significant implications for improving security measures and understand-

Table 7: Experimental results of ASR and F1-Score against Asteria and LineVul with obfuscation techniques. ASR:Attack Success Rate (%); F1-Score: F1-Score of Target Model Without Adversarial Samples (%).

Dataset	Target Model	Attack Model	ASR	F1-Score
CWE119	Asteria	Differentiable Obfuscator	66.40	81.45
		Milo	35.80	
		EaTVul	**99.50**	
	LineVul	Differentiable Obfuscator	63.50	83.45
		Milo	44.30	
		EaTVul	**92.30**	
CWE399	Asteria	Differentiable Obfuscator	58.80	82.60
		Milo	26.30	
		EaTVul	**89.50**	
	LineVul	Differentiable Obfuscator	62.80	83.50
		Milo	28.70	
		EaTVul	**89.20**	
CWE416	Asteria	Differentiable Obfuscator	52.50	80.40
		Milo	20.35	
		EaTVul	**84.30**	
	LineVul	Differentiable Obfuscator	58.60	81.70
		Milo	19.80	
		EaTVul	**87.50**	

ing potential vulnerabilities. By identifying weaknesses in the target models, researchers and practitioners can enhance their defense mechanisms and develop more resilient systems against similar attack strategies. Overall, the experimental results observed in the table demonstrate the efficacy and potential of the attack strategy in compromising the target models, shedding light on the need for further research and mitigation efforts in the field of cybersecurity.

RQ5: How EaTVul behaves/performs regarding obfuscation/diversification methods? To answer this question, we have conducted comparative experiments on two state-of-the-art target models with different vulnerability types. The target models include Asteria and LineVul because these two methods are representative techniques that leverage different ways of program representations and they were demonstrated to have high precision in detecting software vulnerabilities. For the data, we use three vulnerability types with different triggering mechanisms in the augmented Juliet C/C++ Test Suite Datasets. The baseline methods are Differentiable Obfuscator [43] and Milo [42]. To guarantee the optimal performance of baseline models, we set the perturbation strength to be 8.

Table 8: Experiment results of ASR and F1-Score against two SOTA vulnerability detectors (i.e., FUNDED and VDet) on Java. ASR:Attack Success Rate (%); F1-Score: F1-Score of Target Model Without Adversarial Samples (%).

Target Model	Attack Model	ASR	F1-Score
FUNDED	Differentiable Obfuscator	53.50	85.35
	Milo	42.70	
	EaTVul	**88.60**	
VDet	Differentiable Obfuscator	63.50	86.60
	Milo	62.80	
	EaTVul	**87.30**	

And the perturbation strength represents the number of sites to transform.

Table 7 displays the comparison results of evasion attacks on different datasets, CWE119, CWE399, and CWE416, using various target models (Asteria and LineVul) and attack models (our proposed EaTVul, and baseline obfuscation techniques such as Differentiable Obfuscator, Milo) with metrics such as Attack Success Rate (ASR) and F1-Score. We can see that all the target models of Asteria [46] and LineVul demonstrate a high F1-Score of more than 80%. Since the F1-Score reflects the balance between precision and recall, this means all the target models have fairly good performance before the evasion attack. Results show that when targeting the Asteria model in the CWE119 dataset, Differentiable Obfuscator achieves an ASR of 66.40%, indicating its success in evading the detection mechanisms of the Asteria model. In contrast, Milo has a lower ASR of 35.80%, suggesting a lower success rate in evading detection. EaTVul, on the other hand, demonstrates a remarkably high ASR of 99.50%, which corresponds to improvements of 33.10% and 63.70% over Differentiable Obfuscator and Milo, respectively, showcasing its effectiveness in successfully evading the Asteria model's detection mechanisms. The same trend is observed when targeting the LineVul model within the CWE119 dataset, with Differentiable Obfuscator achieving a 63.50% ASR, Milo achieving 44.30%, and EaTVul achieving a high 92.30% ASR. These results provide insights into the relative effectiveness of different attack models in evading detection on the specified dataset and target models. EaTVul stands out as particularly potent in achieving high ASR, suggesting its efficacy in crafting adversarial examples that successfully deceive the target models. In the case of CWE399 and CWE416 datasets, EaTVul consistently shows high ASR values across different attack models, underscoring its effectiveness in evading detection.

In summary, the outcomes demonstrate that our proposed EaTVul significantly enhances attack performance on state-of-the-art vulnerability detectors across various vulnerability types.

RQ6: How effective is EaTVul when generalized to other programming languages? To prove the generalizability of our proposed method, we extend the evaluation to two SOTA vulnerability detection models designed for Java programs. Specifically, we choose FUNDED [46] and VDet as the victim models [30]. Following the previous experimental settings, we compare two obfuscation techniques with our proposed method on the Java dataset [46].

Table 8 presents a comprehensive comparison of evasion attacks on two target models, FUNDED and VDet, using Differentiable Obfuscator, Milo, and our proposed EaTVul as attack models, with metrics including Attack Success Rate (ASR) and F1-Score. We can see that all the target models of FUNDED [46] and VDet demonstrate a high F1-Score of 85.35% and 86.60%, this means all the target models have fairly good performance before the evasion attack. Notably, our proposed method, EaTVul, consistently demonstrates superior performance in evasion attacks. Specifically, when FUNDED is chosen as the victim model, *EaTVul* outperforms the Differentiable Obfuscator by 35.1% and Milo by 45.9% in terms of attack success rate. Likewise, EaTVul achieved much better attack performance than the Differentiable Obfuscator and Milo by 23.8% and 24.5% on VDet. This finding further substantiates the susceptibility of deep-learning-based vulnerability detectors to adversarial attacks, especially when considering semantic information alone, emphasizing the need to incorporate additional control flow and data flow information for method resilience.

In summary, the experimental outcomes with the Java dataset substantiate the broad applicability of our proposed method in executing evasion attacks within real-world project contexts.

4.5 Limitations

EaTVul system has several limitations. We plan to address the following issues in the future.

This study focuses on evasion attacks. From a defence perspective, it would be great to automatically recognize an adversarial sample and tell if it is actually an adversarial sample or not. However, this is a research topic in itself, and this topic is outside the scope of this work at the current stage. We believe the effectiveness of evasion attacks can be influenced by defense mechanisms. If the vulnerability detection system implements robust defense techniques such as input sanitization, anomaly detection, or ensemble models, the success rate of evasion attacks may significantly decrease. We leave this as future work.

The proposed EaTVul relies on the important samples (i.e., support vectors) identified by SVM. In this case, the number of important samples is limited to the number of support vectors. We would like to explore other methods, such as information retrieval [24] method, to further identify important samples based on the probability of being non-vulnerable and to enlarge the sample space in the next work.

EaTVul is currently limited to utilizing an attention model to identify the most important features. However, our future plans involve incorporating other interpretation models such as LIME and SHAP [40, 41] and exploring the use of these approaches. By incorporating these techniques, we aim to enhance the effectiveness and versatility of EaTVul in evading machine learning-based vulnerability detection systems.

In this study, we employ a fuzzy genetic algorithm to select attack samples and enhance the success rate. However, the applicability of FGA is constrained by the inherent attacking effectiveness of the constructed adversarial code snippets. FGA primarily endeavors to hunt for the optimal combination of pre-existing fragments, a process significantly influenced by the quality of the adversarial code snippets, particularly their naturalness. In the future, we plan to explore other large language models to automatically generate adversarial samples to launch an attack

Moreover, this study assumes attackers have knowledge of training data, which may not always be true in real-world scenarios. However, there are studies showing that one can get knowledge of the training data by using recently developed technologies [9, 14], therefore, it would be interesting to explore the training data by considering these technologies.

EaTVul has been focused on the scenario of adversarial learning at source code level software vulnerability detection. However, software vulnerability detection at the binary level is a hot topic recently, and we plan to further apply and develop our proposed scheme to binary code in the future. Especially, the comparison with adversarial malware detection in binaries will be an interesting research direction.

In this study, EaTVul has restricted the size of the adversarial data to less than 8 lines to ensure its concealment based on our historical study. In future research, we aim to investigate this further by incorporating knowledge from natural language processing [35]. Our expectation is that the size of the adversarial data can be further optimized and reduced.

5 Conclusion

In conclusion, the rapid advancement of technology and the increasing complexity of cyber threats have made cybersecurity a critical concern in today's digital world. While deep learning techniques have shown promise in detecting vulnerabilities and improving the accuracy of software vulnerability detection systems, they are not immune to attacks themselves. Adversarial examples can exploit vulnerabilities in deep neural networks, compromising the security of the entire system.

This paper has addressed the issue of adversarial attacks on machine learning-based software vulnerability detection systems. It has introduced a novel attack strategy called EaTVul, which successfully generates adversarial examples to evade detection. The proposed strategy utilizes support vector machines, attention mechanisms, chatGPT, and a fuzzy genetic

algorithm to identify important samples, key words, generate noise data, and select optimal seed adversarial data. Extensive experiments have demonstrated the efficacy of EaTVul in bypassing machine learning detection systems and altering the prediction outcomes.

FVD-DPM: Fine-grained Vulnerability Detection via Conditional Diffusion Probabilistic Models

Miaomiao Shao
Harbin Institute of Technology, Shenzhen

Yuxin Ding*
Harbin Institute of Technology, Shenzhen

Abstract

Software vulnerabilities pose a significant threat to software security. Nevertheless, existing vulnerability detection methods still struggle to effectively identify vulnerabilities and pinpoint vulnerable statements. In this paper, we introduce FVD-DPM: a novel Fine-grained Vulnerability Detection approach via a conditional Diffusion Probabilistic Model. FVD-DPM formalizes vulnerability detection as a diffusion-based graph-structured prediction problem. Firstly, it generates a new fine-grained code representation by extracting graph-level program slices from the Code Joint Graph. Then, a conditional diffusion probabilistic model is employed to model the node label distribution in the program slices, predicting which nodes are vulnerable. FVD-DPM achieves both precise vulnerability identification (slice-level detection) and vulnerability localization (statement-level detection). We evaluate FVD-DPM on five collected datasets and compare it against nine state-of-the-art vulnerability detection approaches. Experimental results demonstrate that FVD-DPM significantly outperforms the baseline approaches across various evaluation settings.

1 Introduction

Software vulnerabilities (or vulnerabilities for short) are security flaws resulting from errors in software design, development, or configuration, rendering them a primary source of software security issues. These vulnerabilities can be exploited by attackers to carry out malicious actions, posing risks to the privacy and property security of software users. Despite collaborative efforts from academia and industry to enhance software security, vulnerabilities remain a significant challenge [5]. One effective strategy for addressing vulnerabilities is the development of detection models. An ideal detection model should exhibit both robust identification and localization capabilities. This entails the detection model not only determining whether a code fragment is vulnerable but also predicting the specific code lines (i.e., statements) that are vulnerable. In this paper, *vulnerable* describes the status of a code fragment, such as a vulnerable function, a vulnerable statement. A vulnerable function represents a vulnerability, while a vulnerable statement is part of a vulnerability. A vulnerable function contains at least one vulnerable statement.

Many traditional static analysis-based methods have been proposed to detect vulnerabilities, showcasing their effectiveness. These methods encompass symbolic execution-based approaches [29], rule-based techniques [9, 19], and code similarity-based methods [16, 28, 36]. The intricate programming logic present in real-world software projects poses a challenge for manually identifying detection rules or patterns, significantly hampering the performance of traditional static analysis-based methods. In recent years, the wealth of data derived from open-source code has provided a favorable environment for constructing deep learning-based vulnerability detection models. Leveraging the feature extraction capabilities of deep learning facilitates the automatic identification of latent vulnerability patterns, offering a novel approach to vulnerability detection. Numerous studies [15, 17, 26, 32, 39] have demonstrated that deep learning-based methods outperform traditional static analysis-based methods. However, existing deep learning-based vulnerability detection approaches still exhibit some limitations, as outlined below.

The program semantics have not been fully leveraged. On one hand, some approaches [17, 26] convert source code into token sequences and employ language models to detect vulnerabilities. However, in contrast to natural language, source code contains rich structural information. Consequently, these approaches struggle to achieve good performance due to their inability to capture the structural information of the program. On the other hand, some works [21, 32, 33, 39] transform functions into graph-structured representations, e.g., Abstract Syntax Tree (AST), Control Flow Graph (CFG), Data Flow Graph (DFG), and Program Dependency Graph (PDG). While these graph-structured representations can capture structural information about certain aspects of the program, they often cannot obtain comprehensive and

*Corresponding author: yxding@hit.edu.cn

precise vulnerability semantics. Specifically, these methods typically extract program semantics from individual functions, disregarding call relationships between functions. In other words, these approaches lack the capability to perform inter-procedural analysis for source code.

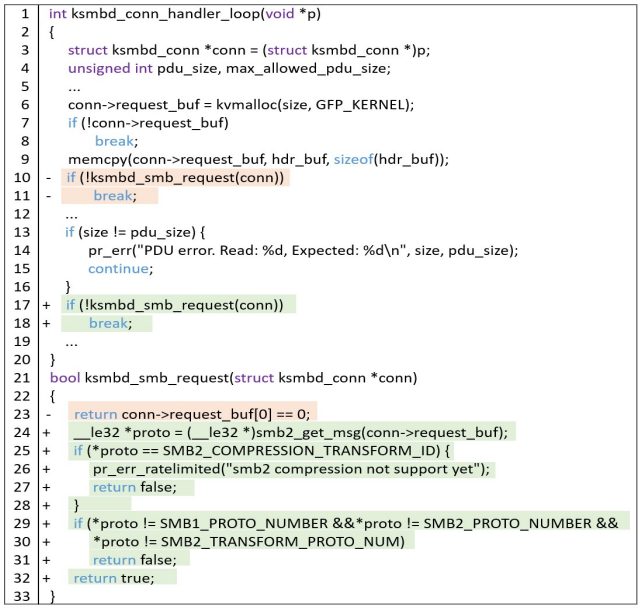
The detection granularity is coarse-grained. The detection granularity of existing deep learning-based approaches is mostly at the file-level [6, 24], function-level [21, 26, 32, 39], or slice-level [2, 15, 17, 18]. Upon analyzing a considerable number of vulnerable samples, we observe that vulnerabilities typically involve only a few statements. This implies that software developers still need to invest a significant amount of time manually scanning numerous statements to identify vulnerable ones. Hence, it is crucial to devise a more fine-grained vulnerability detection approach capable of pinpointing vulnerable statements (i.e., vulnerability localization). However, constructing a fine-grained detection approach that covers the majority of vulnerabilities is challenging due to the substantial semantic differences between various vulnerabilities.

In this paper, we present a novel Fine-grained Vulnerability Detection approach based on a conditional Diffusion Probabilistic Model (FVD-DPM) to alleviate the aforementioned limitations.

Fully leveraging program semantics. To extract comprehensive and precise semantic features, we combine control flow, data flow, function calls, and code sequences to construct a joint code representation, i.e., Code Joint Graph (CJG). Firstly, we augment CFG with data flow based on the variable `define-use` relations to generate PDG, enabling the analysis of control and data dependencies within the function. Next, we extend the PDG using Call Graph (CG) to facilitate inter-procedural analysis. Furthermore, we incorporate code sequence information into the extended graph to capture the programming logic in the source code. CJG preserves both structural and unstructured program semantics. Overall, CJG enables both intra-procedural and inter-procedural control and data flow analysis, capturing richer vulnerability semantics.

Fine-grained vulnerability detection. To train a fine-grained vulnerability detection model, we initially generate graph-level program slices from CJG. Subsequently, we formulate vulnerability detection as a diffusion-based graph-structured prediction problem. Specifically, we identify vulnerable statements by predicting node labels in the graph-level slices using a conditional diffusion probabilistic model. Diffusion probabilistic models (DPMs) belong to a class of generative models known for their ability to produce high-quality images [12, 22]. The main idea of DPMs is to iteratively add noise to an image and train a neural network to learn the noise and restore the image. Motivated by that, we treat the node label in each graph as an image in our vulnerability detection task. Leveraging the graph information (nodes and edges), we train a conditional diffusion probabilistic model by utilizing the probabilistic diffusion of node labels to identify vulnerable nodes. Previous studies have demonstrated that DPMs excel at modeling complex image domains, describing the distribution of neighboring pixels in the image and generating diverse high-quality images. Hence, we are confident that our FVD-DPM can effectively model node labels, extracting implicit patterns of various vulnerabilities and achieving high-performance fine-grained vulnerability detection.

Additionally, training deep learning-based models for fine-grained detection requires large-scale datasets. Existing datasets primarily fall into two categories: synthesized and real-world. The granularity of real-world datasets [26, 38, 39] is consistently coarse-grained (e.g., file-level or function-level), making them unsuitable for training fine-grained detection models. In this paper, based on the utilization of existing datasets in [15, 17], we construct a real-world, fine-grained dataset. This dataset includes vulnerability labels at function, slice, and statement levels. The datasets and source code presented in this paper are available online. [1]



To the best of our knowledge, this paper makes the following contributions:

- We propose a novel fine-grained code representation that extracts graph-level program slices from CJG. The CJG is obtained by integrating CFG, DFG, CG, and code sequence, enabling it to capture comprehensive and precise vulnerability semantics within the source code.
- We formalize fine-grained vulnerability detection as a diffusion-based graph-structured prediction problem. We build a conditional diffusion probabilistic model to predict node labels. With this approach, we achieve vulnerability detection at both slice-level and statement-level.
- We employ Graph Attention Network (GAT) with hybrid time encoding to predict noisy label at each timestep during the diffusion process. Moreover, we enhance the model by concurrently learning the mean and variance of the noisy label distribution, and modifying loss function.
- We evaluate our FVD-DPM approach on collected datasets, demonstrating its effectiveness in detecting vulnerabilities compared to state-of-the-art methods.

2 Motivating Examples

To highlight the motivation behind FVD-DPM, we use a typical vulnerability in the Linux Kernel as an example. Figure 1 presents the simplified vulnerable function `ksmbd_conn_handler_loop` for clarity. We observe that `ksmbd` fails to validate the `SMB` request protocol ID at line 23, resulting in an out-of-bounds read vulnerability. Exploiting this vulnerability successfully could lead to sensitive information leakage or denial of service (DoS). The fix for this vulnerability involves adding validation for the `SMB` request

25 +    if (*proto == SMB2_COMPRESSION_TRANSFORM_ID) {
26 +        pr_err_ratelimited("smb2 compression not support yet");
27 +        return false;
28 +    }
29 +    if (*proto != SMB1_PROTO_NUMBER &&*proto != SMB2_PROTO_NUMBER &&
30 +        *proto != SMB2_TRANSFORM_PROTO_NUM)
31 +        return false;
32 +    return true;
33 }
```

Figure 1: An out-of-bounds read vulnerability (CVE-2023-38430) in Linux Kernel.

protocol ID, as demonstrated in lines 24-32. This example provides the following observations:

Observation 1. Comprehensive and precise program semantic extraction is necessary. As illustrated in Figure 1, the semantics of vulnerable code and non-vulnerable code are different. Traditional static analysis-based detection methods [4, 9, 19] may not capture this semantic difference adequately because predefined rules or patterns are often simplistic and incomplete. Furthermore, we observe that this vulnerability involves multiple statements in two functions. It cannot be easily detected by some existing deep learning-based methods [21, 32, 39] because they may ignore the call relationships between functions. Additionally, the change from lines 10-11 in the vulnerable code to lines 17-18 in the non-vulnerable code underscores the significance of the natural order of code statements in identifying vulnerable code.

In this paper, we combine control flow, data flow, function calls and code sequence to construct a joint code representation (CJG). This graph not only denotes the control and data dependencies among statements within and between functions, but also captures the natural order of the source code.

Observation 2. Detection models must identify global contextual information of nodes in the CJG. As shown in Figure 1, only three statements are vulnerable. This emphasizes the necessity of building a fine-grained detection model. Existing GNN-based detection approaches [2,8,32,39] typically propagate a node's information to its first-order or second-order adjacent nodes. However, in a vulnerable sample, different vulnerable statements may be separated by dozens of non-vulnerable statements. This indicates that vulnerable nodes in graph-level code representations may not be in each other's first-order or second-order neighborhood. Consequently, these GNN-based models may struggle to infer whether a potential vulnerable node directly affects another, as they often ignore the global contextual information of nodes, thereby hindering their ability to detect vulnerabilities.

Based on the above observations, we formalize vulnerability detection as a diffusion-based graph-structured prediction problem to enhance the detection of fine-grained vulnerabilities. We extract graph-level program slices from CJG and then construct a conditional diffusion probabilistic model to predict node labels within these graph-level slices. This model considers all nodes in the entire graph as a whole, and then models the joint distribution of node labels, which can effectively capture the global contextual information of nodes.

3 Methodology

In this section, we introduce our vulnerability detection framework, FVD-DPM. As illustrated in Figure 2, FVD-DPM extracts Graph-based Vulnerability Candidate slices (GrVCs) and introduces a conditional diffusion probabilistic model for detecting vulnerabilities. The framework comprises two stages: 1) Generate CJG from source code and utilize program slicing technology to extract GrVCs from the CJG, thereby obtaining fine-grained vulnerability representations. 2) Construct a conditional diffusion probabilistic model to predict node label distribution for GrVCs, thereby achieving precise identification and localization of vulnerable code.

3.1 Feature Extraction

To capture comprehensive and precise program semantics, we introduce a novel graph-level code representation: Code Joint Graph (CJG). We construct the CJG by integrating CFG, DFG, CG, and the code sequence. The CJG not only incorporates control and data flows within and between functions but also preserves the natural sequential order of the code. However, a function typically comprises dozens or even hundreds of statements, with vulnerabilities concentrated in only a few of them. Training a detection model on the entire graph might diminish the ability to extract significant vulnerability features, making it challenging to precisely locate vulnerable statements. Consequently, our approach involves extracting graph-level program slices from the CJG to obtain a more fine-grained vulnerability representation.

3.1.1 Generating Code Joint Graph

We combine multiple code representations, including CFG, DFG, CG, and code sequence, to generate the CJG. Next, we will briefly introduce each type of code representation and explain how we integrate them into the CJG.

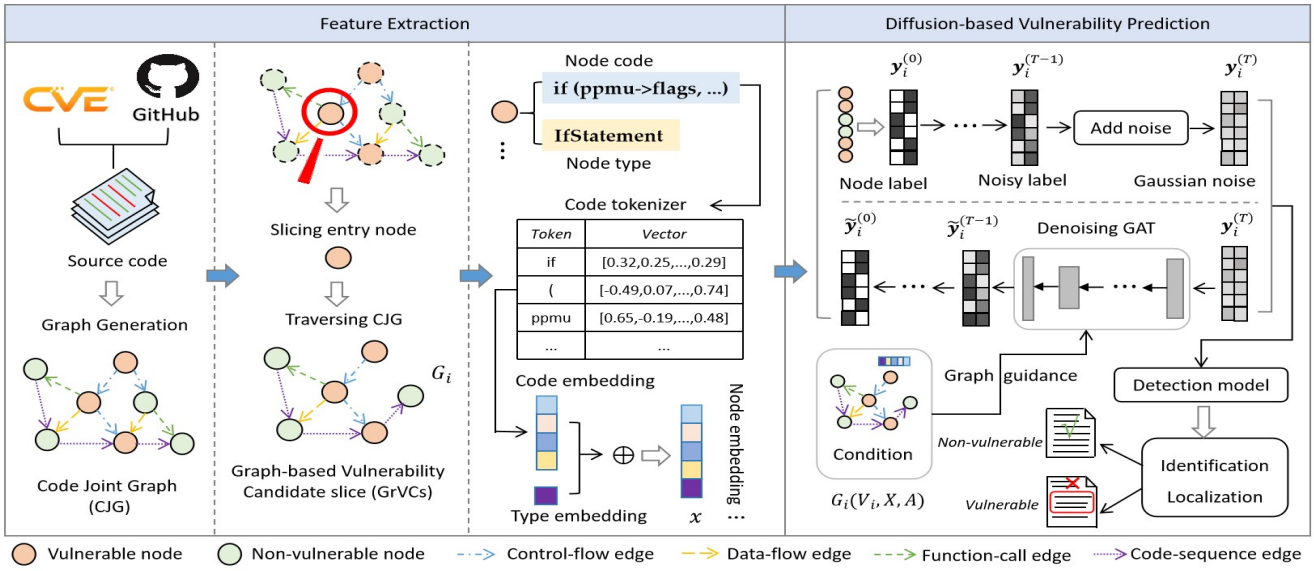

Figure 2: Overview of FVD-DPM.

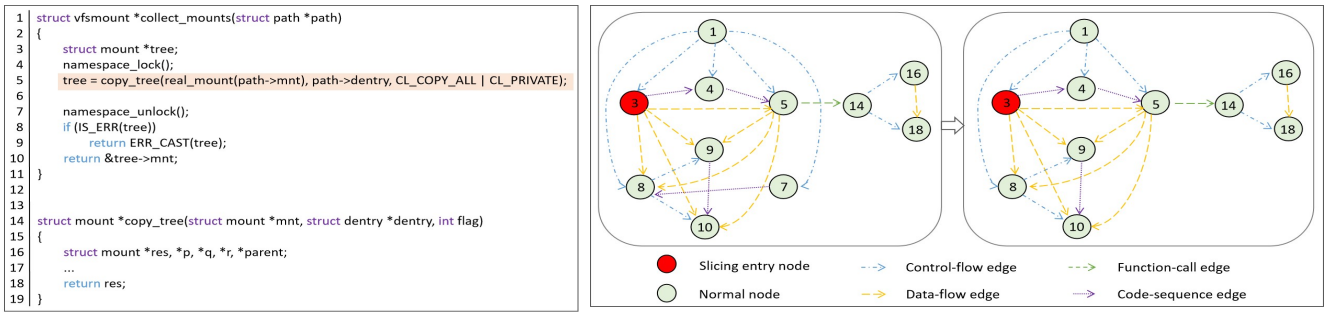
Control Flow Graph (CFG). CFG explicitly delineates all paths a program will take during execution. Path selection is influenced by conditional statements such as `if`, `for`, and `switch`. In the CFG, nodes are linked by directed edges to signify the transfer of control.

Data Flow Graph (DFG). DFG monitors variable usage across the program. Any data flow entails accessing or modifying specific variables. An edge in the DFG signifies subsequent access or modification of related variables.

Call Graph (CG). Call Graph illustrates the relationships between function calls, tracing from the caller to the callee. Integrating the Call Graph allows for inter-procedural analysis, enabling the capture of more comprehensive control and data flow information.

Code Sequence (CS). To preserve the inherent order of the source code, we introduce CS edges to sequentially connect each statement. The inclusion of these edges serves to maintain the programming logic conveyed by the source code.



Specifically, we utilize the static analysis tool Joern[2] to automatically generate CFG and DFG for each function. By combining CFG and DFG, we can generate PDG. All generated graphs are stored in the database Neo4j[3]. Subsequently, we conduct data flow inspection via reaching definition analysis. This analysis tracks the definitions and uses of variables in the function to determine which definitions lead to a given point of use. To generate CG, we query all nodes related to functions from the database, which are named as function nodes and constitute the nodes of the CG. We can generate a callee list (the *type* of node is `Callee` in it) for each function node. If a function name in the callee list corresponds to a node in the CG, then an edge is added from the caller to the callee. Consequently, the CG can be constructed.

A function f can be denoted by a CJG $G = (V, E)$, where four distinct attribute edges (control-flow edges, data-flow edges, function-call edges, and code-sequence edges) share the same node set V. Each node $v \in V$ possesses two attributes: *code* signifies a statement in the source code, and *type* indicates specific node type. The edge set E comprises a set of directed edges, where each edge symbolizes a particular dependency relationship between a pair of nodes. Specifically, the node's *type* in CJG includes the following 23 types: `Function`, `ExpressionStatement`, `Label`, `Condition`, `CFGEntryNode`, `IdentifierDeclStatement`, `UnaryExpression`, `GotoStatement`, `Parameter`, `Callee`, `CallExpression`, `BreakStatement`, `InfiniteForNode`, `ContinueStatement`, `ClassDefStatement`, `Statement`, `IncDecOp`, `ReturnStatement`, `Expression`, `CFGExitNode`, `ForInit`, `AssignmentExpr`, and `IfStatement`. These node types are defined internally by the Joern. We list the most common eight node types and the average number of nodes of each type per function in the appendix (see Table 9).

3.1.2 Extracting Slicing Entry Nodes

To achieve a more fine-grained representation of vulnerable code, we perform program slicing to extract graph-level program slices, i.e., GrVCs, from the CJG. During program slicing execution, a starting node is necessary to extract general program's characteristics from the CJG. In this context, we introduce the concept of slicing entry nodes. The slic-

[2] https://joern.io/
[3] https://neo4j.com/

(a) Source code (b) Program slicing

Figure 3: An example of generating Graph-based Vulnerability Candidate slices (GrVCs).

ing entry node is an entry point to extract features that may be associated with a vulnerability, but it cannot conclusively identify the presence of a vulnerability.

Through the analysis of numerous vulnerable codes, we observe that the majority of vulnerabilities are closely linked to API/library function calls, sensitive variables (array and pointer variables), and arithmetic expressions. Concurrently, many existing studies [2, 17, 18] highlight the misuse of API/library functions as a major vulnerability cause. Moreover, various vulnerability types (e.g., null pointer dereference, double free, buffer overflow) are frequently associated with array and pointer variables, extensively utilized in traditional static analysis methods [4, 9]. Furthermore, arithmetic expressions often contribute to vulnerabilities such as integer overflow. Hence, we select slicing entry nodes by matching these three types of characteristics that may be related to vulnerabilities.

In total, we selected 762 API/library function calls, all of which come from several static vulnerability detectors [3,4,9]. These functions primarily encompass input validation, encryption and decryption, access control and authorization, file and directory operations, and sensitive data processing. More details of these functions are available in our online dataset. We select slicing entry nodes based on the node's *type* and *code* attributes within CJG. For instance, if a node has the *type* `ExpressionStatement` and its *code* contains the character '=', it can be considered an arithmetic expression-related node, and thus, we consider it as a slicing entry node. According to our statistics, an average of 4% of the nodes in a CJG are slicing entry nodes.

3.1.3 Program Slicing

After selecting the slicing entry nodes, we extract GrVCs from the CJG. Specifically, starting from the slicing entry node, we iteratively perform forward and backward slicing until all nodes in the CJG are traversed, thus finding all nodes that are reachable from the slicing entry node. Finally, all reachable nodes are connected based on their dependency edges to generate the GrVCs. The GrVCs is essentially a subgraph of the CJG.

Figure 3 provides an example to illustrate the process of generating GrVCs. As shown in Figure 3a, the function `collect_mounts()` fails to adequately consider the possibility of execution after a path has been unmounted. This fault allows local users to exploit user-namespace root access for a `MNT_DETACH umount2` system call, causing a denial of service (DoS). There is only one slicing entry node in this example, represented by the red circle in Figure 3b. In our approach, we first extract the control flow, data flow, and code sequence information of the vulnerable code to construct the CJG, as depicted in Figure 3b. We then introduce function-call edges (i.e., Edge 5 $\rightarrow$ 14) through inter-procedural analysis. To reduce irrelevant nodes, we designate Node 3, associated with sensitive variables, as the slicing entry node for forward and backward slicing. After slicing, Node 7 is removed since there is no reachable path between Node 7 and Node 3.

3.1.4 Initial Node Embedding

After generating GrVCs, we convert all nodes in the graph into low-dimensional vectors to obtain acceptable inputs for deep learning models. We derive an initial node representation based on the *code* and *type* attributes. For *code*, we transform it into a token sequence and employ Word2Vec to train a token embedding model. Specifically, we use our training dataset to train a specific Word2Vec model for each dataset, ensuring that the vector representation is derived from domain-specific vocabulary. Subsequently, we obtain the code representation of each node by averaging the vectors of all tokens. Regarding the node *type*, we employ label encoding. Finally, we concatenate the vector representations of the *code* and *type* to obtain the initial node embedding.

3.2 Diffusion-based Vulnerability Prediction

In the following, we describe the detailed implementation process of using a conditional diffusion probabilistic model

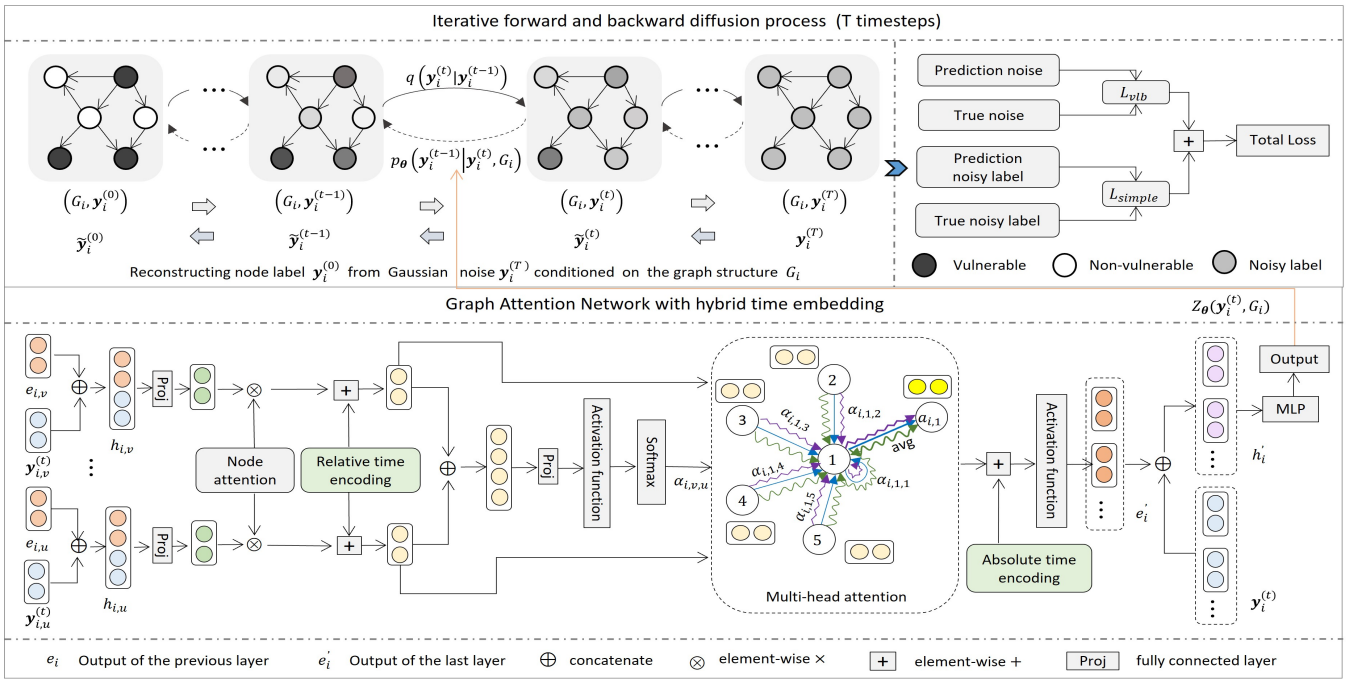


Figure 4: Illustration of FVD-DPM training on GrVCs.

for fine-grained vulnerability detection. Our goal is to develop a diffusion-based vulnerability detection method that captures the node label dependencies characterized by a graph.

Specifically, we formalize this diffusion process using a GrVCs, denoted as $G_i(V_i, E_i)$. The graph $G_i(V_i, E_i)$ consists of a node set V_i and an edge set E_i. The node label of the graph $G_i(V_i, E_i)$ is represented by y_i, with values of 0 (vulnerable) and 1 (non-vulnerable). We perform supervised learning on $G_i(V_i, E_i)$ to predict the node label y_i. Additionally, given that the node label y_i is discrete, we relax it into an one-hot vector to yield continuous values. The initial node feature matrix X and adjacency matrix A of $G_i(V_i, E_i)$ have been obtained. Thus the formal representation of the graph can be denoted as $G_i(V_i, X, A)$, abbreviated as G_i.

As depicted in Figure 4, the training process of FVD-DPM comprises two sub-processes: forward diffusion and reverse diffusion. Forward diffusion involves gradually injecting Gaussian noise into the node labels until converging to a standard Gaussian distribution. In contrast, reverse diffusion entails progressively denoising from the standard Gaussian distribution, conditioned on the graph structure of GrVCs, thereby reconstructing node labels. Within each GrVCs, we anticipate the presence of similar features between adjacent nodes. Graph Attention Network (GAT) is suitable for capturing the structural information of these graphs. Therefore, we employ GAT to learn the abstract features of GrVCs. Additionally, we aim to predict the noisy label distribution at each timestep based on the GAT.

3.2.1 Forward Diffusion Process

Following the models of [12, 13], the specific process of forward diffusion is as follows. Given the node label $y_i^{(0)} = y_i$ and the number of diffusion timesteps T, we assume that $y_i^{(0)}$ conforms to the initial data distribution $q(y)$. Gaussian noise is continuously injected into the data distribution during the forward diffusion process. The variance of the Gaussian noise injected at each timestep is fixed, and the mean depends only on the noisy label at the previous timestep. The forward diffusion process is defined as a Markov process, where $y_i^{(t)}$ depends only on $y_i^{(t-1)}$. Therefore, the forward diffusion process can be defined as follows:

$$q\left(y_i^{(1)}, \cdots, y_i^{(T)} \middle| y_i^{(0)}\right) = \prod_{t=1}^{T} q\left(y_i^{(t)} \middle| y_i^{(t-1)}\right). \quad (1)$$

$$q\left(y_i^{(t)} \middle| y_i^{(t-1)}\right) = N\left(y_i^{(t)}; \sqrt{1-\beta_t} y_i^{(t-1)}, \beta_t I\right). \quad (2)$$

where I is an identity matrix, and $\beta_t \in [0,1]$ is the fixed variance schedule for the noise injected at the timestep t. The variance schedule β_t increases linearly with the increase of t, and $\beta_T = 1$. If we sample from the Gaussian distribution $N(\mu, \sigma^2)$ and the parameters μ and σ are learned from the neural network, there is a risk of gradient vanishing during the back-propagation process because the sampling process is non differentiable. To address this issue, we exploit the reparameterization technique [14]. Specifically, we sample z from

a standard Gaussian distribution and calculate $\mu + \sigma * z$. This operation is equivalent to performing an affine transformation, transferring randomness to the constant z. Given the notion $\alpha_t = 1 - \beta_t$ and $\bar{\alpha}_t = \prod_{s=1}^{t} \alpha_s$, we have:

$$q\left(y_i^{(t)} \middle| y_i^{(0)}\right) = N\left(y_i^{(t)}; \sqrt{\bar{\alpha}_t} y_i^{(0)}, (1-\bar{\alpha}_t) I\right). \quad (3)$$

When $t = T$, the final noisy label obtained from the forward diffusion process confirms to a standard Gaussian distribution, i.e., $q\left(y_i^{(T)} | y_i^{(0)}\right) \approx N\left(y_i^{(T)}; 0, I\right)$.

3.2.2 Conditional Reverse Process

The reverse diffusion process is essentially a conditional probabilistic diffusion process, involving the reconstruction of the node label $y_i^{(0)}$ from Gaussian noise conditioned on the graph structure G_i and $y_i^{(T)}$. The $y_i^{(T)}$ is sampled from the standard Gaussian distribution $N(0, I)$. The reverse diffusion process can be defined as the conditional probability distribution $p_\theta\left(y_i^{(0)}, \cdots, y_i^{(T-1)} \middle| y_i^{(T)}, G_i\right)$, learning to reconstruct the forward diffusion process given by $q(\cdot)$. It is also a Markov process and can be defined as:

$$p_\theta\left(y_i^{(0)}, \cdots, y_i^{(T-1)} \middle| y_i^{(T)}, G_i\right) = \prod_{t=1}^{T} p_\theta\left(y_i^{(t-1)} \middle| y_i^{(t)}, G_i\right). \quad (4)$$

$$p_\theta\left(y_i^{(t-1)} \middle| y_i^{(t)}, G_i\right) = N\left(y_i^{(t-1)}; \mu_\theta(y_i^{(t)}, G_i), \Sigma_\theta\right). \quad (5)$$

3.2.3 Learning the Mean μ_θ and the Variance Σ_θ

To estimate the mean μ_θ and the variance Σ_θ, we first calculate the inverse distribution $q\left(y_i^{(t-1)} \middle| y_i^{(t)}, y_i^{(0)}\right)$. Based on equations (2), (3) and Bayes theorem, we can calculate $q\left(y_i^{(t-1)} \middle| y_i^{(t)}\right)$, which is also a Gaussian distribution denoted as $N\left(\hat{\mu}_t, \hat{\Sigma}_t\right)$. Assuming $\bar{Z}_t \sim N(0, I)$, the calculation for the mean $\hat{\mu}_t$ and variance $\hat{\Sigma}_t$ are as follows:

$$\hat{\mu}_t = \frac{1}{\sqrt{\alpha_t}}\left(y_i^{(t)} - \frac{\beta_t}{\sqrt{1-\bar{\alpha}_t}} \bar{Z}_t\right). \quad (6)$$

$$\hat{\Sigma}_t = \frac{1-\bar{\alpha}_{t-1}}{1-\bar{\alpha}_t} \beta_t. \quad (7)$$

Then we employ GAT to parameterize the distribution $p_\theta\left(y_i^{(t-1)} \middle| y_i^{(t)}, G_i\right)$, and apply it to match the data distribution $q\left(y_i^{(t-1)} \middle| y_i^{(t)}\right)$, gradually reconstructing the target distribution from the standard Gaussian distribution. The mean μ_θ can be calculated based on the following equation:

$$\mu_\theta(y_i^{(t)}, G_i) = \frac{1}{\sqrt{\alpha_t}}\left(y_i^{(t)} - \frac{\beta_t}{\sqrt{1-\bar{\alpha}_t}} Z_\theta\left(y_i^{(t)}, G_i\right)\right). \quad (8)$$

In the limit of infinite diffusion timesteps, the mean μ_θ is more effective in determining the distribution than the variance Σ_θ. However, Nichol and Dhariwal [22] pointed out that the first few timesteps of the diffusion process contribute the most to the variational lower bound of the log-likelihood. Therefore, it appears that we could improve the log-likelihood by selecting a better Σ_θ. To achieve this, we set Σ_θ to the weighted sum of β_t and $\hat{\Sigma}_t$ as follows.

$$\Sigma_\theta = \exp\left(\kappa \log \beta_t + (1-\kappa) \log \hat{\Sigma}_t\right) \quad (9)$$

Here, κ is a learnable parameter vector.

As the number of diffusion timesteps T is usually large, FVD-DPM needs to sequentially calculate dozens or even hundreds of timesteps to obtain an accurate node label distribution in the reverse diffusion process. This results in training one graph taking several tens or even hundreds of times longer than general deep learning models, significantly reducing the training speed of the model. To address this issue, we sample timestep T during the model training process. Detailed description is in Appendix A.

3.2.4 GAT with Hybrid Time Encoding

Due to the randomness of sampling timesteps, we may not effectively predict the noise at each sampled timestep t using GAT. To enhance noise prediction, we aim to make the GAT model remember the noise level at the timestep t. Therefore, we follow the position encoding method in Transformer [30] and inject time encoding information into the learning process of GAT. However, absolute time encoding alone cannot estimate the relative positions between sampled timesteps. To overcome this limitation, we combine relative time encoding and absolute time encoding to construct hybrid time encoding. As shown in Figure 4, for absolute time encoding, we directly concatenate the time encoding with the input embedding of GAT. For relative time encoding, we incorporate it into each layer of GAT by modifying the self attention calculation process. Both the absolute time encoding $abs(t)$ and relative time encoding $rel(t)$ consist of sine and cosine functions of different frequencies and fully connected layers. Thus, we parameterize $Z_\theta\left(y_i^{(t)}, G_i\right)$ using an improved GAT as follows:

$$\alpha_{i,v,u}^m = \frac{\exp\left(\phi(\omega^\top[(W^m h_{i,v} \oplus W^m h_{i,u}) + rel(t)])\right)}{\sum_{l \in N_v} \exp\left(\phi(\omega^\top[(W^m h_{i,v} \oplus W^m h_{i,l}) + rel(t)])\right)}. \quad (10)$$

$$a_{i,v} = \sigma\left(\frac{1}{M}\sum_{m=1}^{M}\sum_{u \in N_v} \alpha_{i,v,u}^m \left(W^m h_{i,u} + rel(t)\right)\right). \quad (11)$$

$$h'_{i,v} = \varphi\left(a_{i,v} + abs(t)\right) \oplus y_{i,v}^{(t)}. \quad (12)$$

$$Z_\theta(y_i^{(t)}, G_i) = \mathrm{MLP}(h'_i). \quad (13)$$

where M is the number of attention heads, $\alpha_{i,v,u}^m$ is the weight coefficient calculated by the m-th attention head, W^m is a learnable weight matrix, and ω is a learnable weight vector. The $\phi(\cdot)$ and $\varphi(\cdot)$ represent the LeakyReLU and ELU activation functions, respectively. The N_v denotes the first-order

neighboring node set of node v. Here, $h_{i,v}$ is initialized by concatenating the node feature $x_{i,v} \in X$ and the noisy label $y_{i,v}^{(t)}$. Additionally, the symbol $.^{\top}$ represents transposition. After learning the graph representation using the GAT model, we apply an MLP to map the graph representation onto a final two-dimensional output vector to estimate the noise $Z_\theta\left(y_i^{(t)}, G_i\right)$.

3.2.5 Training Objective

The training goal of FVD-DPM model is to maximize the log-likelihood of the target distribution. DPMs generally optimize log-likelihood based on their variational lower bound, and employ KL divergence to derive L_{vlb}. However, directly predicting Z_θ can be better than predicting μ_θ, especially when combined with a reweighted loss function [12]:

$$L_{simple} = E_{t,y_i^{(0)},Z}\left[\left\|\bar{Z}_t - Z_\theta\left(y_i^{(t)}, G_i\right)\right\|^2\right]. \quad (14)$$

This goal can be viewed as a reweighted form of L_{vlb}, which does not include the term of affecting Σ_θ. Since L_{simple} does not rely on Σ_θ, we define a new hybrid training objective:

$$L_{hybrid} = L_{simple} + \lambda L_{vlb}. \quad (15)$$

To achieve the identification and localization of vulnerabilities, we employ two distinct schemes. Firstly, we select the node with the highest probability, and its label is used as the prediction for the graph, achieving vulnerability identification. Additionally, by mapping the predicted node labels back to the statements in the source code, we can pinpoint the vulnerable statements, achieving vulnerability localization.

4 Evaluation

4.1 Experimental Setup

4.1.1 Research Questions

We aim to answer the following research questions:

- RQ1: How effective is FVD-DPM when compared to state-of-the-art vulnerability detection approaches?
- RQ2: How effective is CJG in vulnerability detection compared to existing code representations?
- RQ3: Can FVD-DPM perform better in vulnerability detection by incorporating hybrid time encoding into GAT, and simultaneously learning mean and variance of the noisy label distribution?
- RQ4: How effective and precise is FVD-DPM in locating different types of vulnerabilities?

To answer these questions, we implement FVD-DPM in Python using Pytorch.[4] We employ the static analysis tool Joern-0.3.1 to parse the source code and generate CFG, DFG, CG, and PDG. We utilize the database Neo4j-2.1.5 to store and access these graphs. The experiments are conducted on a Linux server equipped with NVIDIA GeForce RTX 4090 GPU and Intel(R) Core(TM) i9-13900K CPU running at 4.60 GHz. We utilize a word embedding vector size of 128 to train the Word2Vec model, from which the embedding representation of node codes can be obtained. The embedding dimension of the nodes in GrVCs is 129. The main hyper-parameters for training FVD-DPM are as follows: the Adam optimizer with a learning rate of 5e-3 is used for training the model up to 15000 epochs; the number of diffusion timesteps T is 40; the batch size is set to 64; the number of GAT layers is 2; the hidden dimensions and the number of heads in GAT are 32 and 2, respectively. We use an optional linear skip connection between each GAT layer and apply a dropout probability of 0.5. The number of nodes in each GrVCs is set to 400.

4.1.2 Datasets

To evaluate the performance of FVD-DPM in detecting vulnerabilities in various scenarios and to compare it with existing state-of-the-art detection methods, we established our dataset using two sources: (1) Two well-known datasets, i.e., NVD and SARD, which have been widely used in previous detection approaches [2,15,17,35]. (2) Three real-world open-source projects, namely OpenSSL, Libav, and Linux Kernel, were manually collected from the GitHub repository.

We followed the methodology in [38] to collect the three open-source projects. Since only a small proportion of commits on GitHub are related to vulnerabilities, we selected vulnerability-related fixing commits by matching a set of predefined vulnerability keywords (e.g., vulnerability, out of bound, use after free, memory leak, null pointer, dereference, buffer overflow) in the commit messages. For each vulnerability-related fixing commit, we first extracted the vulnerable code file, patched code file, and `diff` file. Subsequently, if a function originates from a vulnerable code file and has at least one statement deleted or changed (indicated by "-" in the `diff` file), it is labeled as vulnerable; otherwise, it is labeled as non-vulnerable. Deleted or changed statements are considered vulnerable statements. Each node in GrVCs represents a statement in the source code; nodes corresponding to vulnerable statements are labeled as vulnerable, while the rest are labeled as non-vulnerable. If at least one node in a GrVCs is vulnerable, the entire GrVCs is labeled as vulnerable. More details are in Appendix B.

Real-world data often includes more non-vulnerable examples than vulnerable ones. A model trained on such imbalanced datasets may tend to classify samples into the majority class. Additionally, DPM model treats each GrVCs as an image. If all pixels in an image are identical, having an abundance of such images would not benefit model training. To address these challenges, we employ resampling on datasets

Table 1: Statistics on datasets.

Dataset	#Version	#Vul. Fs	#Fs	#Vul. GrVCs	#Non-Vul. GrVCs	#GrVCs	#Nodes	#Edges
NVD	-	937	2,011	4,355	8,526	12,881	870,855	4,633,355
SARD	-	2,851	5,879	4,742	22,720	27,462	240,202	580,908
OpenSSL	0.9.6-3.0.7	2,009	2,302	6,677	3,362	10,039	221,262	684,357
Libav	0.6-11.5	1,666	1,956	7,710	4,334	12,044	334,964	1,372,749
Linux Kernel	2.6-5.17	1,178	1,528	4,036	2,287	6,323	272,267	1,099,651
Total	-	8,641	13,676	27,520	41,229	68,749	1,939,550	8,371,020

with severely imbalanced samples. Since the positive and negative sample sizes in the NVD are already balanced, we do not perform any resampling on it. For other datasets, we randomly selected approximately 10% of the original non-vulnerable functions to construct our negative samples.

Table 1 displays the statistics of our datasets, indicating a total of 13,676 C/C++ functions collected, with 8,641 being vulnerable. Column 2 provides information on the scope of project versions affected by vulnerabilities in our datasets. Column 5 shows the count of vulnerable GrVCs, and column 6 represents the count of non-vulnerable GrVCs. Columns 8 and 9 present the total numbers of nodes and edges in GrVCs, respectively. For each dataset, we randomly select 80% of the GrVCs for training, with the remaining 20% allocated for validation and testing.

4.1.3 Evaluation Metrics

We employ widely used metrics, including Recall (R), F1 score (F1), Area Under Curve (AUC), and Matthews Correlation Coefficient (MCC), to evaluate vulnerability identification and localization systems. Additionally, Intersection over Union (IoU) is also used to evaluate vulnerability localization results. The metric $IoU = \frac{|U \cap V|}{|U \cup V|}$ is proposed in [15], where U is the set of truly vulnerable statements and V is the set of detected vulnerable statements.

4.1.4 Baseline Methods

To evaluate the effectiveness of FVD-DPM in vulnerability identification, we compare it with seven state-of-the-art detection methods. Cppcheck [4] and Flawfinder [9] are both rule-based detection tools. Devign [39] builds an extended Code Property Graph (CPG) and employs a GNN model to identify vulnerabilities at the functional-level. VulDeePecker [18] and SySeVR [17] are slice-level detection methods that extract sequence-level program slices from PDG and use BGRU to identify vulnerabilities. VulDeeLocator [15] converts source code into intermediate code and employs BGRU to detect vulnerabilities. MVD [2] extracts graph-level program slices from PDG and utilizes a flow-sensitive GNN model to learn code representations and identify vulnerabilities.

Moreover, to assess the effectiveness of FVD-DPM in vulnerability localization, we compare it with four state-of-the-art localization methods. Cppcheck [4] performs semantic checks on nodes in the AST by calling various rule classes. VulDeeLocator [15] applies an attention layer to build a granularity refinement module. It selects the top k statements with the highest attention weight as the vulnerability localization result. DeepLineDP [25] employs a Hierarchical Attention Network (HAN) to calculate the vulnerability risk of the code token and then sums the risks of all tokens in each statement to form statement-level risks, thereby ranking all statements to achieve vulnerability localization. VulChecker [20] is a tool that performs statement-level vulnerability detection, utilizing message-passing graph neural networks to learn code embedding representations. It constructs a new code representation (i.e., ePDG) based on LLVM intermediate representation (IR).

4.2 RQ1: Performance of Proposed Approach

To answer this RQ, we compare FVD-DPM with seven state-of-the-art vulnerability identification approaches and four state-of-the-art vulnerability localization approaches. Specifically, we train and test all approaches except for Devign, VulDeeLocator, and MVD on five datasets. For each approach, we adjust the hyper-parameters through grid search to obtain the optimal model. Due to the unavailability of complete code disclosure by Design, VulDeeLocator, and MVD, we directly cite research results from their articles.

Vulnerability identification (slice-level detection). Table 2 shows the average comparative results of our FVD-DPM with state-of-the-art vulnerability identification methods. Additionally, Figure 5 displays the F1 score of Flawfinder, Cppcheck, VulDeePecker, SySeVR, and FVD-DPM on each dataset. Overall, FVD-DPM achieves better results and outperforms state-of-the-art vulnerability identification methods. On average, FVD-DPM attains an F1 score of 85.73%, a Recall of 82.93%, an AUC of 86.40%, and an MCC of 72.14%. Flawfinder and Cppcheck, as representatives of rule-based detectors, perform the worst among all approaches. The reason is that predefined detection rules or patterns cannot cover the majority of vulnerabilities, limiting the effectiveness of these rule-based detectors. Furthermore, FVD-DPM improves the F1 score over Devign by 12.47%. This indicates that, although GNN's powerful capability in extracting program semantics can make Devign perform outstandingly, the existence of redundant nodes unrelated to vulnerabilities in CPG limits

Devign's ability to detect vulnerabilities.

Table 2: Comparison with state-of-the-art vulnerability identification approaches (metrics unit: %).

Method	F1	R	AUC	MCC
Flawfinder	49.73	52.86	-	10.07
Cppcheck	61.09	71.43	-	-
MVD	65.20	61.50	-	-
VulDeePecker	71.48	77.62	77.65	51.20
Devign	73.26	-	-	-
SySeVR	79.72	81.26	-	60.49
VulDeeLocator	**85.90**	82.07	-	-
FVD-DPM (ours)	85.73	**82.93**	**86.40**	**72.14**

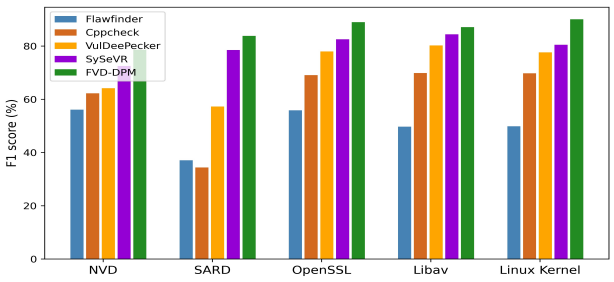

Figure 5: Comparing FVD-DPM with state-of-the-art vulnerability identification approaches on each dataset (F1 score).

VulDeePecker, SySeVR, MVD, and VulDeeLocator are all slice-based detection approaches. As shown in Figure 5, VulDeePecker performs worse than SySeVR on all datasets. The reason for this is that VulDeePecker only considers vulnerability characteristics related to API function calls and ignores control dependencies in the source code. Furthermore, we observe that FVD-DPM improves F1 score and MCC over SySeVR by 6.01% and 11.65%, respectively. One of the main reasons is that our graph-level program slices (i.e., GrVCs) can extract more comprehensive and precise program semantics than the sequence-level slices generated by SySeVR. Notably, compared to the best vulnerability detection approach VulDeeLocator, FVD-DPM achieves competitive result. In addition, MVD is most similar to our approach, both of which are vulnerability detection methods based on graph-level program slices. MVD performs worse than FVD-DPM in terms of each metric. There are two main reasons for this result. On one hand, GrVCs extracted from CJG is more effective than the graph-level slices extracted from PDG by MVD in extracting vulnerability features. On the other hand, our proposed conditional diffusion probabilistic model, which can capture the global contextual information of nodes, is more effective than the GNN-based model in node classification.

Vulnerability localization (statement-level detection). After evaluating the vulnerability identification capability of FVD-DPM, we assess its effectiveness in locating vulnerable statements. Table 3 presents comparative results on the metric IoU between FVD-DPM and three state-of-the-art localization methods. Here, IoU is the average value measured on IoUs between the detected vulnerable code and the ground-truth vulnerable code in the test dataset. We observe that FVD-DPM significantly outperforms the three existing state-of-the-art vulnerability localization methods on all datasets.

Table 3: The performance comparison of different vulnerability localization approaches (metrics unit: %).

Method	NVD	SARD	OpenSSL	Libav	Linux Kernel
Cppcheck	15.27	9.89	48.79	42.82	27.33
DeepLineDP	31.05	14.67	18.53	24.31	30.02
VulDeeLocator	32.60	36.30	-	-	-
FVD-DPM	59.04	72.35	63.13	62.95	72.70

FVD-DPM outperforms Cppcheck in terms of IoU by an average of 37.21%. The fundamental reason for this performance gap is that the predefined detection rules in Cppcheck cannot cover the majority of vulnerabilities, resulting in low localization performance. FVD-DPM, on average, improves IoU by 42.32% over DeepLineDP. One of the main reasons is that DeepLineDP adopts HAN to learn the sequence features of the source code, ignoring the control and data dependencies of the program. FVD-DPM is roughly 31.59% higher than VulDeeLocator. This difference can be attributed to the limitations of the localization module in VulDeeLocator. Specifically, VulDeeLocator applies an attention layer to construct a code granularity refinement module, which selects the most suspicious k statements based on attention weights as the localization result. Due to both the varying lengths of functions and the varying numbers of vulnerable statements they contain, fixing the value of k significantly reduces the localization performance of VulDeeLocator. Instead, FVD-DPM applies a DPM model to predict node labels in graph-level program slices and corresponds each node label to a statement in the source code, thereby achieving more effective localization.

Table 4: Comparative results of VulChecker and FVD-DPM on the Juliet dataset (metrics unit: %).

Method	CWE190	CWE121	CWE122	CWE415	CWE416
VulChecker	97.00	85.40	79.00	100.00	90.90
FVD-DPM	97.87	88.30	90.93	94.83	88.23

Additionally, to achieve a fair comparison with VulChecker, we use the Juliet dataset introduced in [20] to evaluate FVD-DPM. The dataset includes the following five vulnerability types: integer overflow (CWE-190), stack overflow (CWE-121), heap overflow (CWE-122), double free (CWE-415), and use-after-free (CWE-416). As shown in Table 4, FVD-DPM achieves competitive results with VulChecker overall on these

Table 5: Effectiveness of CJG in vulnerability identification and localization (metrics unit: %).

Dataset	Model Structure	Vulnerability Identification				Vulnerability Localization				
		F1	R	AUC	MCC	F1	R	AUC	MCC	IoU
NVD	DPM+CPG	70.87	67.23	79.09	60.25	73.60	63.61	81.73	74.20	47.26
	DPM+PDG	76.56	76.15	82.81	65.80	**78.99**	**78.50**	**89.21**	**78.92**	55.55

	DPM+PDG	83.17	78.66	81.54	62.02	72.36	70.07	84.98	72.05	53.63
	DPM+CJG	**88.99**	**86.80**	**85.15**	**68.80**	**79.09**	**81.27**	**90.56**	**78.97**	**63.13**
Libav	DPM+CPG	80.59	72.80	81.89	64.25	67.19	53.67	76.72	68.64	53.29
	DPM+PDG	84.68	81.42	84.37	**68.55**	77.85	**76.98**	**88.43**	77.74	60.27
	DPM+CJG	**87.11**	**82.70**	**85.10**	68.22	**79.62**	75.40	87.65	**79.64**	**62.95**
Linux Kernel	DPM+CPG	84.63	79.74	86.41	74.10	76.91	68.21	84.01	77.15	62.97
	DPM+PDG	86.82	80.08	87.01	73.14	81.03	78.23	89.08	81.00	67.61
	DPM+CJG	**90.09**	**85.59**	**88.85**	**75.71**	**81.97**	**80.88**	**90.39**	**81.88**	**72.70**

five vulnerability types. This demonstrates that both our CJG built from source code and ePDG built from LLVM IR are effective in capturing fine-grained program semantics. Compared to VulChecker, FVD-DPM achieves an 11.93% higher AUC on CWE-122. This is likely because heap memory allocation and release typically involve many API/library function calls. FVD-DPM generates program slices by analyzing relevant API/library functions, enabling it to extract fine-grained vulnerability characteristics more effectively, thereby better detecting this vulnerability type.

4.3 RQ2: Effectiveness of Code Joint Graph

The two most widely used and effective code representations are PDG and CPG. Many state-of-the-art vulnerability detection approaches [2,8,17,18] extract program slices from PDG or CPG to detect vulnerabilities. Therefore, to evaluate the effective of our CJG in vulnerability detection, we replace CJG with PDG and CPG. We then extract graph-level program slices from these two graph structures using the same program slicing technique. Finally, we apply our designed conditional diffusion probabilistic model to detect vulnerabilities.

We evaluate the effectiveness of CJG in vulnerability detection using the same settings as those for answering RQ1. As shown in Table 5, DPM+PDG, DPM+CPG and DPM+CJG denote that we apply our designed DPM model to train vulnerability detection models based on PDG, CPG, and CJG, respectively. From the table, we observe that, compared with the state-of-the-art baseline approaches in RQ1, the DPM+CPG, DPM+PDG, and DPM+CJG models obtain competitive or better detection performance in most cases. This phenomenon further demonstrates the effectiveness of our DPM model for detecting vulnerabilities. Overall, for each dataset, CJG outperforms CPG and PDG in most metrics. A main reason is that CJG captures more comprehensive and precise code semantics, including control and data flows within and between functions, as well as the natural order of the code. Moreover, the relationships between statements preserved in CJG enable the DPM trained on CJG to better capture the joint dependencies of node labels.

It is worth noting that CPG achieves the worst detection performance in most cases. There are two main reasons for this performance gap. Firstly, CPG may not perform well in the graph model learning process, as information from AST cannot flow across the graph. Another important reason is the issue of node labeling errors. Because there is a one-to-one correspondence between nodes in CJG/PDG and statements in the source code, statement-level vulnerability labels can be directly assigned to nodes in these graphs, with almost no annotation errors. However, AST nodes in CPG are usually composed of partial tokens in a statement, which may not necessarily indicate vulnerabilities, making it difficult to determine the labels of such nodes. Therefore, compared to CPG, we believe that PDG and CJG are more suitable for combining our designed diffusion probabilistic model to train a graph-based fine-grained vulnerability detection model.

Additionally, we provide an evaluation of the impact of different types of edges in CJG on model performance. Overall, the model's performance gradually improved as we added different types of dependency edges to the CFG. Detailed analysis can be found in Appendix C.

4.4 RQ3: Ablation Study

One of the main contributions of our approach FVD-DPM, is the utilization of GAT with hybrid time encoding to predict

Table 6: Comparative experiments on models with and without hybrid time encoding (metrics unit: %).

Time Encoding	Vulnerability Identification				Vulnerability Localization				
	F1	R	AUC	MCC	F1	R	AUC	MCC	IoU
Without	77.20	69.72	80.28	60.64	74.96	72.21	86.04	74.97	58.22
With	86.05	83.34	86.15	71.90	79.72	78.05	88.97	79.65	66.00

Table 7: Experimental results achieved by different objectives (metrics unit: %).

Objective	Vulnerability Identification				Vulnerability Localization				
	F1	R	AUC	MCC	F1	R	AUC	MCC	IoU
L_{simple}	84.98	81.64	85.32	71.05	77.82	74.76	87.32	77.88	63.67
L_{hybrid}	86.41	83.62	86.30	72.61	79.62	77.08	88.48	79.63	66.05

noisy labels at each timestep. By incorporating hybrid time encoding into GAT, FVD-DPM can effectively retain information about the noise level for each timestep. In addition, we estimate the noisy label distribution by simultaneously learning its mean and variance. Correspondingly, we define a new hybrid training objective, which is the weighted sum of the simplified loss L_{simple} and the variational lower bound (VLB). To evaluate the effectiveness of these two improvements, we conduct two groups of comparative experiments: 1) With time encoding vs. without time encoding; 2) Hybrid objective L_{hybrid} vs. simplified objective L_{simple}.

Impact of time encoding. Table 6 illustrates the impact of hybrid time encoding on FVD-DPM's performance. We observe that after removing the time encoding in GAT, FVD-DPM shows a significant decrease in all metrics. In terms of vulnerability localization, F1 score, AUC, MCC, and IoU decrease by an average of 4.76%, 2.93%, 4.68%, and 7.78%, respectively. This can be explained that the time encoding injected to GAT helps the model predict noisy labels, thereby achieving more effective fine-grained vulnerability detection.

Impact of different objectives. As shown in Table 7, overall, the hybrid objective L_{hybrid} significantly achieves better detection results than the simplified objective L_{simple}. Therefore, we usually prefer to employ L_{hybrid} over L_{simple} as it can improve detection performance without reducing likelihood.

Moreover, an evaluation of the performance of FVD-DPM under diverse training epochs is provided in Appendix D.

4.5 RQ4: Results on Different CWE Types

In this experiment, we evaluate the performance of FVD-DPM in locating different types of vulnerabilities. By counting the number of samples of different CWE vulnerability types on the SARD dataset, we select the most common eight types (i.e., CWE-78, CWE-121, CWE-122, CWE-124, CWE-126, CWE-127, CWE-195, CWE-134) for evaluation.

Figure 6 presents the evaluation metrics for each vulnerability type. We observe that FVD-DPM demonstrates good performance in locating vulnerable statements across different vulnerability types. Overall, FVD-DPM excels in vulnerability type CWE-195 and performs less effectively in CWE-121. The primary reason for this performance gap is that CWE-195 (i.e., signed to unsigned conversion error) exhibits a straightforward vulnerability pattern, usually associated with only one code statement. However, the vulnerability pattern of CWE-121 is complex and may involve multiple statements in various functions, making it more challenging to identify. Additionally, CWE-121 vulnerabilities often lead to program crashes, emphasizing the need for increased attention to such vulnerabilities. In future research, exploring methods to further enhance the model's ability for locating CWE-121 vulnerabilities would be valuable.

4.6 Applications to New Versions and Projects

To test the detection capability of FVD-DPM on new versions of the same project and on new projects, we manually collect 18 known vulnerabilities from new versions of OpenSSL, Libav, and Linux Kernel, as well as from new projects like OpenBSD, Asterisk, FreeRDP, and Wireshark.

As shown in Table 8, we identify 7 of the 8 known vulnerabilities in the new versions and 7 of the 10 known vulnerabilities in the new projects. Moreover, we detect 5 unknown vulnerabilities in the new versions, which are similar to some already disclosed vulnerabilities (as confirmed by our manual inspection). Additionally, two vulnerabilities in the FreeRDP project are missed by our model because the CWE types of these examples, CWE-20 and CWE-787, are not included in our training dataset. This implies that if new vulnerability types are encountered in new projects or versions not covered by the original dataset, the model may need to be retrained with these additional datasets.

5 Insights and Findings

We have successfully introduced the DPM model to vulnerability detection, yielding promising performance. This extends the applicability of DPMs to new domains. With

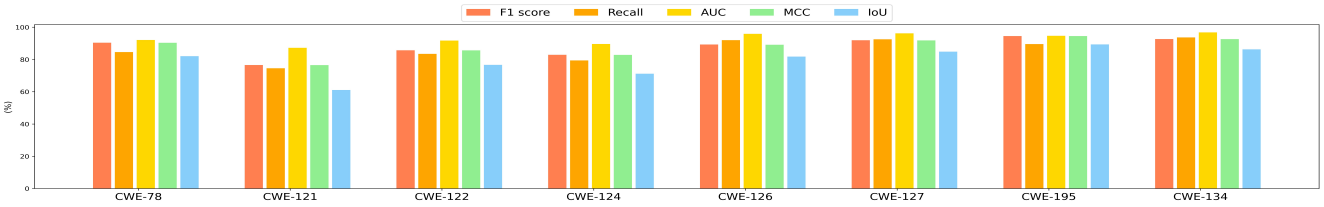

Figure 6: Locating results for the most common eight CWE vulnerability types on the SARD dataset.

Table 8: The 19 vulnerabilities detected and the 4 vulnerabilities missed by FVD-DPM in new versions and new projects.

Project	CVE ID	Vulnerable file	Status
OpenSSL 3.0.8-3.3	CVE-2023-6237	rsa_sp800_56b_check.c	Detected
	CVE-2023-0465	x509_vfy.c	Detected
	-	v3ext.c	Detected

	CVE-2024-26592	transport_tcp.c	Detected
	CVE-2023-40791	scatterlist.c	Detected
	CVE-2023-38430	connection.c	Detected
OpenBSD 5.8	CVE-2022-48437	x509_verify.c	Detected
	CVE-2021-46880	x509_verify.c	Detected
	CVE-2020-16088	ca.c	Detected
Asterisk 18.2.0	CVE-2023-49294	manager.c	Detected
FreeRDP 2.0-3.5	CVE-2023-39354	nsc.c	Detected
	CVE-2022-39318	libusb_udevice.c	Missed
	CVE-2020-13398	crypto.c	Missed
Wireshark 4.2.5	CVE-2024-24476	addr_resolv.c	Detected
	CVE-2016-5358	packet-ppi.c	Detected
	CVE-2016-5353	packet-umts_fp.c	Missed

our training dataset containing numerous real-world vulnerabilities, FVD-DPM can effectively tackle complex projects. Moreover, our collected real-world vulnerability dataset, containing ground-truth labels at function, slice, and statement levels, offers data support for future research in vulnerability detection, localization, and repair.

Table 5 illustrates that the performance enhancement of FVD-DPM is not substantial when transitioning from PDG to CJG. This might be due to the lack of inter-procedural dependencies among many functions in our training datasets. We calculated the proportion of functions with inter-procedural dependencies in each dataset: NVD 2.5%, SARD 34.5%, OpenSSL 35.7%, Libav 27.8% and Linux Kernel 19.6%. We can see that the dataset with the smallest proportion of functions with inter-procedural dependencies corresponds to the worst model performance. This phenomenon indicates that when there are too few functions with inter-procedural dependencies in the training dataset, FVD-DPM struggles to learn useful program information from inter-procedural analysis effectively. Further analysis can be found in Appendix E.

In the training phase of FVD-DPM, we employ a relatively balanced training dataset, ensuring that the DPM model can effectively learn diverse vulnerability patterns. This approach equips FVD-DPM with the ability to identify vulnerabilities comprehensively. Consequently, even in real-world vulnerability scenarios, FVD-DPM effectively leverages learned knowledge of vulnerability patterns to identify potential vulnerabilities. Table 8 shows that FVD-DPM accurately detects the majority of vulnerabilities in new versions and new projects, proving its applicability in real-world situations.

6 Threats to Validity

External validity. External validity of our approach is influenced by two factors. First, we focus on detecting vulnerabilities in C/C++ source code within specific software projects, implying that the detection model might require adjustments when applied to other programming languages or software projects. Nonetheless, our approach is generic and has the potential to be extended to other programming languages and software projects. Second, attackers may employ adversarial machine learning techniques to poison our training datasets, potentially leading to the model missing certain vulnerabilities during deployment. Although this attack is possible, it is challenging because we use code samples collected from large-scale open-source repositories to enhance the coverage and diversity of our datasets. It is unlikely to inject adversarial samples into some large, actively-maintained open-source projects without being noticed by developers and users.

Internal validity. We may encounter label errors during the process of automatically generating ground-truth labels for nodes. These errors can impact the model's ability to identify real vulnerabilities. To avoid the harmful effects of incorrect node labeling on the model's performance, future research should develop more effective and precise node label-

ing methods. While we can partially explain the effectiveness of FVD-DPM, further research is needed in this interpretable direction. Additionally, in the future, we will explore the potential of leveraging popular large language models (LLMs), such as ChatGPT, in fine-grained vulnerability detection.

7 Related Work

7.1 Classical Vulnerability Detection Methods

Existing detection methods can be categorized into dynamic detection methods and static detection methods. Dynamic detection methods, such as symbolic execution [1] and fuzzing [10], are commonly used to identify vulnerabilities in binary code. These methods detect vulnerabilities by monitoring the program's running state, execution paths, and registration status. However, when applied to large-scale software systems, these methods encounter issues related to significant time and space overhead. In contrast, static analysis does not require the program to be running. Consequently, an increasing number of static detection methods have been proposed. Among these, source code-based static vulnerability detection stands out as a prominent technique, encompassing symbolic execution-based methods, rule-based methods, and code similarity-based methods.

Symbolic execution-based methods [29] represent source code using an intermediate language, combining symbolic execution and constraint solving to analyze vulnerabilities. Rule-based detection methods (e.g., ITS4 [31], Flawfinder [9], RATS and Yasca [19]) maintain an internal library of features for various vulnerability types and use lexical analysis algorithms to match these entries for identifying vulnerable code. Due to their reliance on simple parsers and predefined rules, these tools often yield a high false positive rate. The fundamental process of code similarity-based methods [16, 28, 36] involves transforming source code into an easily analyzable intermediate representation, and using a matching algorithm for similarity detection. However, in these methods, the manual extraction process of features is notably time-intensive, and the features often exhibit task-specific tendencies.

7.2 Deep Learning-based Detection

Deep learning-based approaches can automatically capture vulnerability patterns. Considering the scope of detection granularity, existing deep learning-based methods can be roughly divided into function-based methods and slice-based methods. Function-based methods typically focus on a single function to identify vulnerabilities. These methods always extract graph-level representations, such as AST, CFG and PDG, from the function to analyze vulnerable code [21, 32, 33, 39]. Li *et al.* introduced SySeVR [17], and VulDeePecker [18] as slice-based solutions for detection. Thereafter, an increasing number of slice-based methods were proposed [2, 8, 11]. Additionally, VulCNN [35] converts source code into an image and uses CNN to identify vulnerabilities.

Most of the aforementioned detection approaches can determine whether a file, function or code slice is vulnerable. However, these methods generally lack the capability to locate vulnerable statements. To address this issues, Wattanakriengkrai *et al.* [34] employed local interpretable model-agnostic Explanations (LIME) to identify risky code tokens, thus statements containing these tokens are predicted as vulnerable. Both VulDeeLocator [15] and DeepLineDP [25] identify vulnerable statements by designing a granularity refinement module behind the recurrent neural network based on attention mechanisms. Recently, Mirsky *et al.* [20] proposed a tool that achieves instruction-level vulnerability detection.

7.3 Diffusion Probabilistic Models

Taking inspiration from non-equilibrium statistical physics, Sohl-Dickstein *et al.* [27] introduced the concept of DPMs. This idea gained prominence with the development of denoising diffusion probabilistic models (DDPMs) [12], bringing DPMs to the forefront of image generation. DPMs have disrupted the longstanding dominance of generative adversarial networks (GANs) in demanding tasks of image synthesis, showing immense potential across various domains. To achieve more precise predictions and enhance the efficiency of the sampling process, researchers have introduced several improved versions of DDPMs [7, 22]. Recent studies have demonstrated the remarkable achievements of DDPMs across diverse domains, including computer vision [7], natural language processing [37], and multi-modal modeling [23].

The fundamental idea behind all these approaches is to progressively introduce random noise to the data and then remove the noise step by step to generate new data samples. Recently, researchers have uncovered the capability of DPMs to make predictions on complex graph-structured data, such as molecular structure prediction [13]. Inspired by this, we aim to employ DPMs in the field of vulnerability detection.

8 Conclusion

Fine-grained vulnerability detection is a challenging and largely unexplored task. In this paper, we propose an effective fine-grained detection approach, FVD-DPM, by formalizing vulnerability detection as a diffusion-based graph-structured prediction problem. FVD-DPM generates a new fine-grained code representation (GrVCs) by extracting program slices from the Code Joint Graph to capture more precise vulnerability semantics. Based on this, we design a conditional diffusion probabilistic model to predict node labels. Overall, FVD-DPM can simultaneously achieve vulnerability identification and localization.

Appendix

A Improving Model Training Speed

We note that $y_i^{(t)}$ can be sampled from the original data $y_i^{(0)}$. Thus, in the actual training process, we do not need to train the model on all timesteps. By directly sampling to timestep t, we can obtain the $y_i^{(t)}$ at that timestep and use the GAT to predict the injected noise. Specifically, we sample T' timesteps from T diffusion steps. In our experiments, the value of T' is 16. This method can significantly improve the training speed of the model. Its training process is described as: 1) Randomly sample a node label $y_i^{(0)}$ from the initial data distribution $q(y)$. 2) Randomly sample a timestep t from 1 to T, to represent the level of injected Gaussian noise. 3) Randomly sample a t-level Gaussian noise Z_t, and then inject Z_t into $y_i^{(0)}$ using Equation (3). 4) Train the GAT model to predict the noise acting on $y_i^{(0)}$ based on $y_i^{(t)}$.

B Details of Data Collection and Labeling

Our dataset comprises two parts: (1) NVD and SARD. NVD focuses on 19 popular C/C++ open-source software projects (as in [18]), providing corresponding vulnerable code files and patched code files. SARD is essentially a synthetic dataset with a smaller complexity of vulnerable samples compared to those present in real-world scenarios.[5] As vulnerable functions and statements are already labeled in these two datasets, we only need to construct labels for GrVCs and its nodes. (2) Three open-source projects (i.e., OpenSSL, Libav, and Linux Kernel). These projects are popular among developers and offer diverse functionalities. Specifically, we followed the data collection methodology in [38]. The dataset construction and labeling process entails the following steps:

- Commit message filtering. We identify vulnerability-related fixing commits by matching a set of predefined vulnerability keywords.
- Code preprocessing. For each vulnerability-related fixing commit, we extract vulnerable code file, patched code file, and `diff` file. Then we extract functions and statements involving changes from the `diff` file.
- Automatic data labeling. If a function from a vulnerable code file has at least one statement that was deleted or changed (indicated by "-" in the `diff` file), it is labeled as vulnerable; otherwise, it is labeled as non-vulnerable. Deleted or changed statements are considered vulnerable statements.
- Manual verification. We conduct manual verification on a small proportion of samples to ensure the accuracy and reliability of the annotations.

C Analysis of the Various Components of CJG

In this experiment, we progressively added data-flow edges, function-call edges, and code-sequence edges to CFG. Then, we extracted GrVCs based on graph structures at different stages and applied our DPM-based detection model for training and testing. As shown in Table 10, overall, the model's performance gradually improved as we added different types of dependency edges to the CFG. Notably, the model's performance with `CFG+DF` significantly surpassed that of the `CFG`, highlighting the substantial contribution of data flow to extracting vulnerability features. However, the inclusion

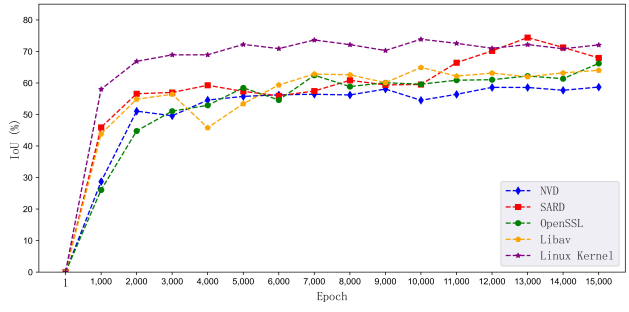
Table 11: Performance comparison of FVD-DPM on original and augmented datasets (metrics unit: %).



Dataset	Vulnerability Identification				Vulnerability Localization				
	F1	R	AUC	MCC	F1	R	AUC	MCC	IoU
Original	78.63	78.54	83.79	67.61	77.21	75.17	87.54	77.14	59.04
Augmented	81.52	79.63	86.54	74.15	84.07	78.82	89.37	84.18	60.14

of inter-procedural analysis in `CFG+DF+CG` did not yield a significant improvement in detection performance. One possible reason for this is the small proportion of functions with inter-procedural dependencies in our dataset (less than 1/4 of the total functions), which may restrict the model's ability to benefit from inter-procedural analysis. We provide further analysis of this phenomenon in Appendix E.

D Results under Diverse Training Epochs

(a) AUC

(b) IoU

Figure 7: localization results of FVD-DPM on the test set under diverse training epochs.

Figure 7 illuminates the dynamic evolution of model metrics across various epochs for each dataset. Notably, the scores for all metrics exhibit a pronounced and swift upsurge during the initial 2000 epochs. Subsequently, within the epoch range of 2000 to 7000, the scores of all metrics show a fluctuating and slow growth trend. Beyond the 7000-epoch mark, a noteworthy observation is the model's gradual convergence. This detailed analysis enhances our understanding of the temporal dynamics governing the model's localization capabilities, offering valuable insights into its evolving behavior throughout the training process.

E Effectiveness of Inter-procedural Analysis

To study the impact of inter-procedural analysis on FVD-DPM in vulnerability detection, we augmented the NVD dataset with new functions featuring inter-procedural dependencies and retrained FVD-DPM on the augmented dataset. Due to the challenge of re-collecting real-world functions with inter-procedural dependencies, we utilized data augmentation techniques to create new functions. Specifically, we employed multiple code refactoring methods to generate transformed code that retained the same labels as the original function. We used a total of 14 types of code refactoring methods, including adding arguments, renaming methods, renaming local variables, and adding print statements. Through this data augmentation, we added 120 new functions with inter-procedural dependencies to the NVD dataset.

We retrained and tested FVD-DPM on the augmented dataset and compared the results with those from the original dataset. As shown in Table 11, FVD-DPM achieves better performance on the augmented dataset. This demonstrates that by adding more functions with inter-procedural dependencies, FVD-DPM can capture more comprehensive vulnerability semantics. Therefore, function-call edges included in CJG are effective for FVD-DPM in detecting vulnerabilities.

A Wolf in Sheep's Clothing: Practical Black-box Adversarial Attacks for Evading Learning-based Windows Malware Detection in the Wild

Abstract

Given the remarkable achievements of existing learning-based malware detection in both academia and industry, this paper presents MalGuise, a practical black-box adversarial attack framework that evaluates the security risks of existing learning-based Windows malware detection systems under the black-box setting. MalGuise first employs a novel semantics-preserving transformation of `call-based redividing` to concurrently manipulate both nodes and edges of malware's control-flow graph, making it less noticeable. By employing a Monte-Carlo-tree-search-based optimization, MalGuise then searches for an optimized sequence of `call-based redividing` transformations to apply to the input Windows malware for evasions. Finally, it reconstructs the adversarial malware file based on the optimized transformation sequence while adhering to Windows executable format constraints, thereby maintaining the same semantics as the original. MalGuise is systematically evaluated against three state-of-the-art learning-based Windows malware detection systems under the black-box setting. Evaluation results demonstrate that MalGuise achieves a remarkably high attack success rate, mostly exceeding 95%, with over 91% of the generated adversarial malware files maintaining the same semantics. Furthermore, MalGuise achieves up to a 74.97% attack success rate against five anti-virus products, highlighting potential tangible security concerns to real-world users.

1 Introduction

With the sustainable development of computer technology, the proliferation of malware, short for **mal**icious soft**ware**, has emerged as a grave security threat that performs malicious activities on computer systems. In particular, the widespread adoption of the Microsoft Windows family of operating systems (*i.e.*, Windows) has rendered it a primary target for malware attacks. According to AV-TEST [8], the first three quarters of 2022 have witnessed approximately 59.58 million new instances of Windows malware, constituting over 95% of all recently identified malware samples during this period [7]. To defend against the ever-increasing Windows malware, considerable research efforts with cutting-edge technologies have been devoted to Windows malware detection [12, 40, 61]. Basically, Windows malware detection can trace its history back to signature-based malware detection in the 1990s, which mainly blacklists suspicious software based on a frequently updated database of previously collected malware signatures. Evidently, signature-based malware detection cannot detect new or previously unknown malware. In the past two decades, a variety of machine learning (ML) and deep learning (DL) models have been explored and employed for Windows malware detection, collectively referred to as *learning-based Windows malware detection* [40, 61] in this paper. Leveraging the high learning capacities of ML/DL models, learning-based Windows malware detection has demonstrated its ability to detect newly emerging and even zero-day malware, establishing itself as a pivotal component of contemporary mainstream anti-virus products in a fiercely competitive market [28, 43].

It is well known that signature-based malware detection can be easily evaded by traditional obfuscation techniques, such as compression, encryption, register reassignment, code virtualization, *etc*. However, with the widespread availability of de-obfuscation tools and the advanced capabilities of learning-based malware detection, traditional obfuscations are largely ineffective in evading learning-based malware detection [2, 30, 48, 63]. On the other hand, recent studies have unveiled that ML/DL models are inherently vulnerable to adversarial attacks [21, 34, 35, 37, 58] in various domains (*e.g.*, computer vision, natural language processing), by which the adversary maliciously creates adversarial examples as the input to trigger the target ML/DL model to make mistakes. Therefore, in addition to traditional obfuscations, this paper explores adversarial attacks with a specific focus on evading present-day learning-based Windows malware detection systems. It should be noted that this paper does not aim to substitute traditional obfuscations, but rather to complement

*Xiang Ling and Zhiyu Wu are the co-first authors. Bin Wang and Jingzheng Wu are the co-corresponding authors.

their limitations in evading advanced learning-based malware detection due to its widespread adoption and escalating prominence in both academia and industry [28, 43, 61].

In particular, this paper attempts to explore an adversarial attack under the realistic black-box setting for effectively and efficiently generating practical adversarial malware files, which are capable of evading learning-based Windows malware detection systems. Towards this, we identify two key challenges (**C#1** & **C#2**) that need to be addressed as follows.

• **C#1**: How to generate practical adversarial malware files that maintain the same semantics as the original ones while remaining less noticeable to possible defenders? Previous adversarial attacks mainly consist of ⓘ adding irrelevant API calls [3, 13, 26, 54], ⓑ manipulating raw bytes of malware partially or globally [5, 19, 31, 33, 41, 51], and ⓜ manipulating the control-flow graph (CFG) of malware by injecting semantic nops [63]. We argue that the first two types of adversarial attacks (ⓘ & ⓑ) are either impractical as they generate adversarial features rather than files, or are strictly limited to specific malware detection like MalConv [48]. While the third type ⓜ exhibits improved scalability against CFG-based malware detection, it only considers coarse-grained transformations that manipulate CFG's nodes, rendering it quite noticeable and easily detectable by defenders. Thus, to tackle **C#1**, we propose a novel fine-grained transformation towards CFG, namely `call-based redividing`, which not only manipulates the nodes (*i.e.*, instruction blocks) but also the edges, *i.e.*, the control-flow relationships between two blocks.

• **C#2**: How to efficiently search in the vast and discrete space of malware under the black-box setting such that the optimized adversarial malware file can evade learning-based Windows malware detection? We investigate existing state-of-the-art black-box adversarial attacks, including gradient estimations with surrogate models [3, 31, 54], evolutionary algorithms [13, 41], and reinforcement learning [5, 63]. It is evident that those attacks based on gradient estimations heavily rely on prior information (*e.g.*, training data, model architecture) about the target system. Likewise, those attacks based on evolutionary algorithms and reinforcement learning are computationally expensive due to the vast and discrete space of malware. Thus, we address **C#2** by employing a Monte Carlo tree search (MCTS)-based optimization to efficiently search for the optimal adversarial malware that can successfully evade the target malware detection system.

To sum up, this paper proposes a practical adversarial attack framework, namely MalGuise, against learning-based Windows malware detection systems under the black-box setting. As depicted in Fig. 2, MalGuise first represents the input Windows malware as the CFG and introduces a novel semantics-preserving transformation of `call-based redividing` that can manipulate both nodes and edges of CFG, making it less noticeable compared to previous attacks. Then, we employ an MCTS optimization that could effectively and efficiently guide MalGuise to search for an optimal sequence of `call-based redividing` transformations within the vast and discrete space of malware under the black-box setting. Finally, based on the optimized transformation sequence, MalGuise reconstructs the adversarial malware file while adhering to the constraints of Windows executables, thereby successfully evading the target Windows malware detection system while preserving the same semantics as the original malware.

We evaluate the attack effectiveness of MalGuise against three representative learning-based Windows malware detection systems (*i.e.*, MalGraph, Magic, and MalConv) compared with two state-of-the-art adversarial attacks on a large wild dataset containing hundreds of thousands of Windows malware and goodware samples. Evaluation results show that MalGuise is agnostic to the target learning-based Windows malware detection systems and consistently achieves a high attack success rate exceeding 95%. Meanwhile, we empirically verify that MalGuise can generate realistic adversarial malware files with a probability of over 91%, a significant improvement over previous adversarial attacks that achieved probabilities of less than 50% or failed completely. Furthermore, to understand the security risks of anti-virus products in the wild, we evaluate and observe that the attack success rate of MalGuise against five commonly used commercial anti-virus products can reach a range of 11.29% to 74.97%. To summarize, we highlight our key contributions as follows:

- To understand and assess the security risks of present-day learning-based Windows malware detection, we propose a practical black-box adversarial attack framework MalGuise that generates realistic adversarial malware files.
- To the best of our knowledge, MalGuise is the first to apply a more fine-grained transformation to the CFG of Windows malware, `call-based redividing`, which not only manipulates its nodes (*i.e.*, instruction blocks) but also its edges, *i.e.*, the control-flow relationship.
- Evaluations demonstrate that MalGuise not only effectively evades state-of-the-art learning-based Windows malware detection with attack success rates exceeding 95%, but also evades five commercial anti-virus products, achieving attack success rates ranging from 11.29% to 74.97%.

2 Preliminaries & Threat Model

2.1 Preliminaries on learning-based malware detection

Fig. 1 provides an overview of learning-based malware detection. First, as ML/DL models only operate on numeric data, the training and testing samples are pre-processed by feature engineering before inputting. Formally, feature engineering can be formulated as $\phi: \mathcal{Z} \to \mathcal{X}$, which produces a feature vector x in the *feature-space* $\mathcal{X}$ (*i.e.*, $x \in \mathcal{X}$) for a given executable z in the *problem-space* $\mathcal{Z}$ (*i.e.*, $z \in \mathcal{Z}$). Then, using training samples, the ML/DL model is employed and trained as the learning-based malware detection $f: \mathcal{Z} \to \mathcal{Y}$.

That is, given an executable $z \in \mathcal{Z}$, f can predict a corresponding label y in the *label-space* $\mathcal{Y}$ (*i.e.*, $y \in \mathcal{Y} = \{0,1\}$), such that $f(z) = y$, in which $y = 0$ denotes goodware while $y = 1$ denotes malware. For ease of notations like [36, 40], we denote the learning-based malware detection that can return the malicious probability as $g : \mathcal{Z} \to \mathbb{R}$, in which $g(z)$ denotes the predicted malicious probability for z and the opposite benign probability is naturally inferred as $1 - g(z)$.

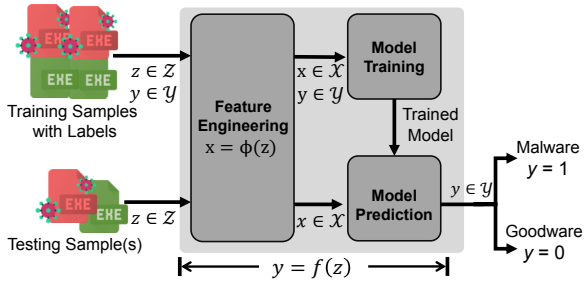

Figure 1: A overview of learning-based malware detection.

2.2 Threat Model

Following the widely used framework of modeling threats in adversarial machine learning [47], we report our threat model in terms of goal, knowledge, and capability as follows.

Adversary's Goal. Aiming at evading learning-based malware detection, it is hugely profitable for the adversary to misclassify malware as goodware, but not vice versa. Therefore, the primary goal of the adversary is to generate an adversarial malware file z_{adv} derived from an input malware $z \in \mathcal{Z}$ (*i.e.*, $f(z) = 1$) with minimal efforts, such that $z_{adv} \in \mathcal{Z}$ can not only evade the target learning-based malware detection f (*i.e.*, $f(z_{adv}) = 0$) but also preserve the same semantics as z [40].

Adversary's Knowledge and Capability. We start with an adversary who intends to perform the classic *zero-knowledge black-box attack* [42, 47] against the learning-based malware detection system. It indicates that the adversary has no prior information on the target system in terms of training data, extracted feature sets, employed learning algorithms with parameters, and model architectures with weights. However, it should be clarified that the zero-knowledge black-box attack retains some minimal information about the target system, including the specific detection task (*e.g.*, static or dynamic analysis), the employed feature type that represents executables (*e.g.*, image, sequence, or graph), and the querying feedback. In this paper, we restrict the adversary's knowledge to only knowing that our target system is based on static analysis that focuses on advanced abstract graph representations like CFG, and knowing the predicted label $f(z)$ along *with* or *without* its probability $g(z)$ after inputting z. Furthermore, to ensure that realistic adversarial malware files can be generated, the adversary has the capability of manipulating Windows executables while adhering to its standard specifications [45].

3 Design of MalGuise

3.1 Problem Formulation

Targeting learning-based Windows malware detection, the primary goal of this paper is to generate a realistic adversarial malware file $z_{adv} \in \mathcal{Z}$ from a given malware z, such that z_{adv} is not only misclassified as goodware but also maintains the same semantics as z. To this end, we explore the problem-space attack [47] that applies *semantics-preserving transformations* within the problem space that can transform z to z_{adv} step-by-step. In particular, as formulated in Eq. (1), we start to define the first black-box attack scenario with the malicious probability $g(\cdot)$ by reducing the probability that z_{adv} is predicted as malicious as much as possible.

$$\arg\max_{\mathbf{T}} \; g(z) - g(z_{adv}) \quad \blacktriangleright \text{ with predicted probabilities} \tag{1}$$

$$\arg\min_{\mathbf{T}} \; f(z_{adv}) \quad \blacktriangleright \text{ without predicted probabilities} \tag{2}$$

$$\text{s. t.:} \quad f(z) = 1,\ f(z_{adv}) = 0,\ z_{adv} = \mathbf{T}(z) \in \mathcal{Z} \tag{3}$$

$$\mathbf{T} = T_1 \circ T_2 \circ \cdots \circ T_n \in \mathbb{T} \tag{4}$$

in which $T \in \mathbb{T}$ denotes one of the atomic transformations that can transform one executable into another semantics-preserving executable; $\mathbf{T} = T_1 \circ \cdots \circ T_n$ denotes a finite and ordered sequence of n transformations that z can step-by-step transform z into an adversarial malware, *i.e.*, $z_{adv} = \mathbf{T}(z)$.

Similarly, Eq. (2) defines another stricter black-box setting where the adversary can only obtain the predicted label $f(\cdot)$ without any predicted probabilities, which simply minimizes the predicted label of z_{adv} to 0 since 0 denotes goodware.

3.2 Overview Framework of MalGuise

As depicted in Fig. 2, the overview framework of MalGuise mainly consists of three backbone phases, *i.e.*, ① adversarial transformation preparation, ② MCTS-guided searching, and ③ adversarial malware reconstruction, which are elaborated in the following parts of §3.2.1, §3.2.2, and §3.2.3, respectively.

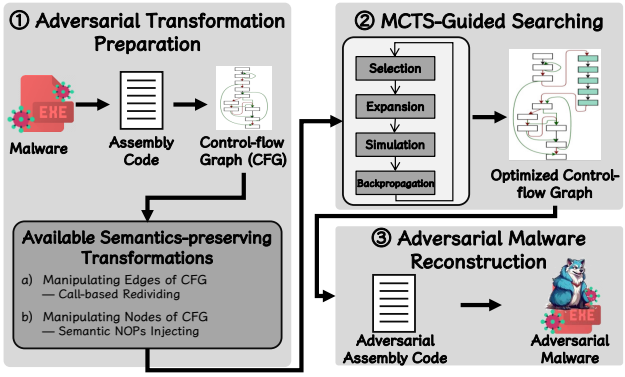

Figure 2: The overview framework of MalGuise.

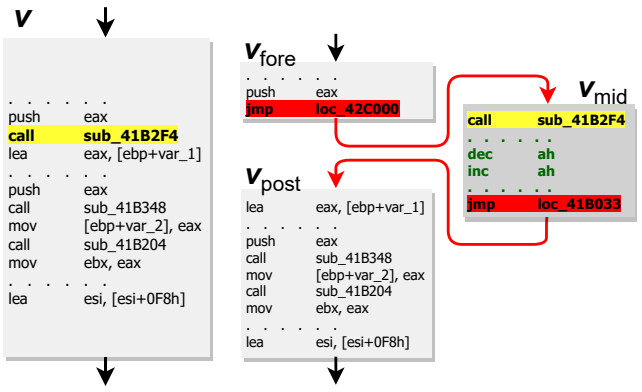

3.2.1 Adversarial Transformation Preparation

To prepare adversarial transformations that manipulate the given malware while preserving its semantics, we initially represent a malware sample as the CFG, in which each node denotes a basic block and each edge denotes a control-flow path between two basic blocks during execution. The main reason to represent malware with CFG is twofold. i) CFG encapsulates the intrinsic control flows during execution, containing rich semantic and structural information of assembly instructions. Therefore, if we can manipulate both CFG's nodes and edges, we can change both the semantics and structures for generating possible adversarial malware files in a more fine-grained fashion, thereby making them less noticeable by possible defenders. ii) CFG has gained widespread adoption in various software analysis tasks [39], and CFG-based malware detection is extensively proven to be technically advanced and highly effective in both industry and academia [23, 38, 59]. Therefore, if we could successfully attack these advanced CFG-based malware detection as representative cases, it would demonstrate the state-of-the-art attack effectiveness of MalGuise.

However, if we transform one executable into another by directly manipulating its CFG, it is extremely easy to cause various unexpected issues like addressing or processing errors, rendering the transformed executable unable to execute properly or even crashing immediately. To circumvent these issues and avoid being noticeable by potential defenders, we propose a novel semantics-preserving transformation for Windows executables, namely `call-based rediviting`. It *redivides* the basic blocks that contain at least one "call" instruction for concurrently manipulating both nodes and edges in the CFG.

To be specific, for a given executable, the `call-based rediviting` first identifies and annotates all available basic blocks with "call" instruction(s). Then, supposing there is a basic block $\mathbf{v}$ containing a "call" instruction, it takes the "call" as the dividing line, and attempts to redivide the original basic block v into a combination of three consecutive basic blocks (*i.e.*, the fore-basic-block $\mathbf{v}_{fore}$, the post-basic-block $\mathbf{v}_{post}$, and the mid-basic-block $\mathbf{v}_{mid}$). Finally, to avoid the basic block of $\mathbf{v}_{mid}$ being easily noticed by defenders due to having only two instructions of "call" and "jmp", `call-based rediviting` enriches the assembly instructions in $\mathbf{v}_{mid}$ by injecting semantic `nops` [14, 41] before the "call" or between the "call" and "jmp", and employs the context-free grammar from [41] to generate the semantic `nops` diversely.

As illustrated in Fig. 3, we first show one basic block of the latest "LockBit 3.0", an active and famous ransom gang, as a representative example in Fig. 3(a). After applying the transformation, Fig. 3(b) shows the transformed composite of three consecutive basic blocks, in which the ends of two basic blocks (*i.e.*, $\mathbf{v}_{fore}$ and $\mathbf{v}_{mid}$) are two newly added "jmp" instructions, and those assembly instructions between "call" and "jmp" in $\mathbf{v}_{mid}$ are newly added semantic `nops`.

(a) Before transformation. (b) After applying a `call-based rediviting`.

Figure 3: The `call-based rediviting` redivides one basic block in the "LockBit 3.0" ransomware (*i.e.*, Fig. 3(a)) into a composite of three consecutive basic blocks (*i.e.*, Fig. 3(b)).

3.2.2 MCTS-Guided Searching

Recalling our adversarial attack formulated in § 3.1 and the `call-based rediviting` transformation towards the CFG representation (*i.e.*, $x = \phi(z)$) of a given malware z in § 3.2.1, we decompose MalGuise into first finding an optimized transformation sequence $\mathbf{T}$ that consecutively transforms the original CFG x into an adversarial CFG of x_{adv} (detailed in this part of § 3.2.2), and then reconstructing the final adversarial malware file (*i.e.*, z_{adv}), which will be detailed in § 3.2.3.

In essence, the optimal solution we are solving here is an optimized sequence of transformations $\mathbf{T} = T_1 \circ \cdots \circ T_N$ of length N, and each $T_k = \{\mathbb{I}_k^{\text{call}}, \mathbb{I}_k^{\text{s-nops}}\}$ involves two decision-making processes: i) Selecting one of all available "call" instructions to be redivided, *i.e.*, $\mathbb{I}_k^{\text{call}}$, and it should be noted that $\mathbb{I}_k^{\text{call}}$ can be *repeatedly* selected in a recursive manner; ii) Determining the proper semantic `nops` to be injected, namely $\mathbb{I}_k^{\text{s-nops}}$, and it can be generated *infinitely* by the employed context-free grammar [41]. In short, determining an optimal $\mathbf{T}$ in MalGuise requires exploring and optimizing in an *infinite* and *discrete* space with a limited computational budget under the *black-box* setting. To this end, our key idea is to employ an MCTS-guided searching algorithm [17] for two major reasons. First, MCTS has been widely and successfully used to solve the long-standing challenging problem of computer Go [17, 49] and other difficult optimization problems that require little or no domain knowledge [10]. Second, our task of optimizing $\mathbf{T}$ under the black-box setting is strictly limited to searching in an infinite and discrete space without prior knowledge. Therefore, we argue that an MCTS-guided searching algorithm aligns well with our task requirements.

Algorithm 1 presents the MCTS-guided searching algorithm, which inputs a given malware z with its CFG x and outputs the transformation sequence $\mathbf{T}$. Firstly, we obtain all available instructions $\mathbb{I}^{\text{call}}$ from x and initialize the MCTS's root node z and $\mathbf{T}$(*line 2–3*). Meanwhile, we limit the max-

Algorithm 1: MCTS-Guided Searching Algorithm.

Input : a given malware z with its CFG x, target system f, max length N, simulation number S, budget C.
Output : the transformation sequence $\mathbf{T}$.

1 **Begin**
2 $\mathbb{I}^{\text{call}} \leftarrow \texttt{GetAllCalls}(x)$;
3 v, $\mathbf{T} \leftarrow \texttt{InitMCTSRootNode}(x, \mathbb{I}^{\text{call}})$, $\emptyset$; //initialize
4 **for** $i \leftarrow 1$ *to* N **do** //loop upto maximum length
5 **for** $j \leftarrow 1$ *to* C **do** //loop upto computation budget
6 **if** $\texttt{random}(0,1) < 0.5$ **then** //avoid unlimited expansion
7 $v_{selected} \leftarrow \texttt{Selection}(v)$;
8 **else**
9 $v_{selected} \leftarrow \texttt{Expansion}(v)$;
10 $reward \leftarrow \texttt{Simulation}(v_{selected}, f, S)$;
11 $\texttt{BackPropagation}(v_{selected}, reward)$;
12 $v_{node} \leftarrow \texttt{ChildWithHighestReward}(v)$;
13 $\mathbf{T} \leftarrow \mathbf{T}.\texttt{append}(v_{node}.T)$;
14 $x_{adv} \leftarrow v_{node}.x$;
15 **if** $\texttt{Evaded}(f, x_{adv}) == True$ **then**
16 **return** $\mathbf{T}$
17 $v \leftarrow v_{node}$

imum length of the optimized transformation sequence to N (*line 4–17*) and limit the maximum number of iterations of MCTS to C, *i.e.*, the computational budget (*line 5–11*). As for the MCTS optimization process, we follow the four standard steps (*i.e.*, `Selection`, `Expansion`, `Simulation`, and `Backpropagation`) (*line 6–11*). It is noted that, as `call-based rediviing` can be performed unlimitedly, the game tree of MCTS can be unlimitedly expanded downwards, *i.e.*, `Expansion`. Therefore, we force to select the most *promising* child node (*i.e.*, `Selection`) in the established game tree via a simple random sampling (*line 6*). After C iterations, we can thus obtain the child node v_{node} with the highest reward value, append its transformation into the transformation sequence $\mathbf{T}$, and update the adversarial CFG x_{adv} (*line 12–14*). Finally, if x_{adv} evades f, return the transformation sequence $\mathbf{T}$, otherwise, continue to use v_{node} as the root node for the next round until reaching the maximum length N. For simplicity, more implementation details can be found in Appendix A.

3.2.3 Adversarial Malware Reconstruction

Finally, we reconstruct the adversarial malware $z_{adv} = \mathbf{T}(z)$ based on the original malware file z and the optimized transformation sequence $\mathbf{T}$, which is briefly outlined in Algorithm 2. It is noted that each transformation $T_k = \{\mathbb{I}_k^{\text{call}}, \mathbb{I}_k^{\text{s-nops}}\}$ and we denote A_k^{call} as the address of $\mathbb{I}_k^{\text{call}}$. We first calculate the space required for all `call-based rediviing` transformations in $\mathbf{T}$ as Δ (*line 2–6*). Meanwhile, let S_{slack} and A_{slack} denote the size and address of the slack space in the ".text" section of z, respectively. Similarly, let A_{last} and S_{last} denote the address and size of the last section. If Δ is less than the size of slack space, we directly take A_{slack} as the

Algorithm 2: Adversarial Malware Reconstruction

Input : original malware z, the transformation sequence $\mathbf{T}$.
Output : the adversarial malware z_{adv}.

1 **Begin**
2 $\Delta \leftarrow 0$;
3 **for** $k \leftarrow 1$ **to** N **do**
4 $\Delta \leftarrow \Delta + \texttt{GetSize}(\mathbb{I}_k^{\text{call}}) + \texttt{GetSize}(\mathbb{I}_k^{\text{s-nops}})$;
5 $\mathbb{I}_k^{\text{jmp}} \iff \text{jmp}\_[A_k^{\text{call}} + \texttt{GetSize}(\mathbb{I}_k^{\text{call}})]$;
6 $\Delta \leftarrow \Delta + \texttt{GetSize}(\mathbb{I}_k^{\text{jmp}})$;
7 **if** $\Delta < S_{slack}$ **then** //inject into the slack space
8 $A^{inj} \leftarrow A_{slack}$
9 **else** //inject into a new section
10 $A^{inj} \leftarrow A_{last} + \texttt{RoundUp}(S_{last}, page\_size)$;
11 take actions to meet the standard specifications;
12 $z_{adv} \leftarrow \texttt{Adv\_Patch}(z, \mathbf{T}, A^{inj})$; //refer to Algorithm 3
13 **return** z_{adv}.

injecting address A^{inj}(*line 7–8*). Otherwise, we will add a new section, whose starting injection address is computed as $A^{inj} = A_{last} + \texttt{RoundUp}(S_{last}, page\_size)$(*line 9–10*). This is because, according to the standard Windows executable specifications [45], its section size must be a multiple of the architecture's page size (*i.e.*, $4KB$ for x86 and MIPS), to prevent unexpected issues (*e.g.*, addressing errors) that may arise during execution. Apart from this, other subsequent actions should be taken to meet the Windows specifications, such as setting the size for the ".text" section or the newly added section and adjusting other fields (*e.g.*, "size of image") in the header of Windows executables.

After obtaining the injecting address A^{inj}, we reconstruct z_{adv} with the procedure of `Adv_Patch`, which is mainly outlined Algorithm 3. In particular, we first replace the selected $\mathbb{I}_k^{call}$ instruction with a new `jmp` instruction (*i.e.*, "$\text{jmp}\_[A_k^{inj}]$"), which transfers the control-flow to the injecting address for the k-th transformation in the new destination, *i.e.*, A_k^{inj} (*line 4*). Secondly, starting from the injecting address A_k^{inj} of either the slack space or the newly added section, we deposit $\mathbb{I}_k^{call}$ and $\mathbb{I}_k^{\text{s-nops}}$ in order (*line 5–7*). Subsequently, we inject a new `jmp` instruction (*i.e.*, $\mathbb{I}_k^{\text{jmp}} \iff \text{jmp}\_[A_k^{\text{call}} + \text{GetSize}(\mathbb{I}_k^{\text{call}})]$), which transfers the control-flow backward to the next instruction of $\mathbb{I}_k^{call}$ in the original section (*line 8–9*). Finally, after all of N transformations are applied, we can reconstruct the final adversarial malware z_{adv} that preserves the same semantics as the original malware z.

Fig. 4 shows the conceptual layout of the generated adversarial "LockBit" after taking one `call-based rediviing` transformation. It is important to note that, just applying two optimized transformations of `call-based rediviing` to "LockBit 3.0", the generated adversarial "LockBit" can successfully evade three state-of-the-art learning-based malware detection (*i.e.*, MalGraph, Magic, and MalConv) and the famous anti-virus product of Kaspersky in our evaluation.

Algorithm 3: Procedure of $\texttt{Adv\_Patch}(z, \mathbf{T}, A^{inj})$

Begin
  $z_{adv}, A_1^{inj} \leftarrow z, A^{inj}$;
  for $k \leftarrow 1$ **to** N **do**
    $z_{adv} \leftarrow \texttt{Patch}(z_{adv}, A_k^{call}, \texttt{jmp}\_[A_k^{inj}])$;
    $z_{adv} \leftarrow \texttt{Patch}(z_{adv}, A_k^{inj}, \mathbb{I}_k^{call})$;
    $A_k^{inj} \leftarrow A_k^{inj} + \texttt{GetSize}(\mathbb{I}_k^{call})$;
    $z_{adv} \leftarrow \texttt{Patch}(z_{adv}, A_k^{inj}, \mathbb{I}_k^{\text{s-nops}})$;
    $A_k^{inj} \leftarrow A_k^{inj} + \texttt{GetSize}(\mathbb{I}_k^{\text{s-nops}})$;
    $z_{adv} \leftarrow \texttt{Patch}(z_{adv}, A_k^{inj}, \mathbb{I}_k^{\text{jmp}})$;
    $A_{k+1}^{inj} \leftarrow A_k^{inj} + \texttt{GetSize}(\mathbb{I}_k^{\text{jmp}})$;
  return z_{adv}

4 Evaluation

This section is dedicated to conducting evaluations aiming at answering the following five research questions:

- **RQ1 (Attack Performance)**: What is the attack performance of MalGuise against the state-of-the-art learning-based Windows malware detection systems?
- **RQ2 (Impacting Factors)**: What impacting factors affect the attack performance of MalGuise?
- **RQ3 (Utility Performance)**: Does the adversarial malware generated by MalGuise maintain the original semantics?
- **RQ4 (Real-world Performance)**: To what extend does MalGuise evade existing commercial anti-virus products?
- **RQ5 (Possible Defenses)**: What is the attack performance of MalGuise against potential defenses?

4.1 Evaluation Setup

4.1.1 Benchmark Dataset

We utilize the same benchmark dataset as employed in prior studies [38]. This dataset is a balanced wild dataset of 210,251 Windows executables with 108,610 goodware and 101,641 malware, consisting of 848 different malware families. As summarized in Table 1, we split it into three disjoint training/validation/testing sets and more details are in Appendix B.

Table 1: Summary statistics of the benchmark dataset.

Dataset	Training	Validation	Testing	Total
Malware	81,641	10,000	10,000	101,641
Goodware	88,610	10,000	10,000	108,610
Total	170,251	20,000	20,000	210,251

4.1.2 Target Systems with Detecting Performance

We evaluate the attack performance of MalGuise against two kinds of target systems (*i.e.*, learning-based malware detection systems and real-world anti-virus products) as follows.

• **Learning-based Windows malware detection systems.** We first employ three SOTA learning-based malware detection (*i.e.*, MalGraph [38], Magic [59], MalConv [48]) from either top-tier academic conferences or highly cited publications. To avoid possible biases, we directly adopt their publicly available implementations with default hyper-parameters and evaluate their detecting performance with three commonly used metrics, *i.e.*, AUC, TPR/FPR, and balanced Accuracy (bACC). Table 2 shows that all of them show similar detecting performance as presented in their original publications, affirming their excellent performance in detecting malware.

Table 2: The detecting performance of three learning-based Windows malware detection systems in our testing dataset.

Target Systems	AUC (%)	FPR = 1%		FPR = 0.1%	
		TPR (%)	bACC (%)	TPR (%)	bACC (%)
MalGraph	99.94	99.34	99.18	92.78	96.36
Magic	99.89	99.02	99.02	89.28	94.59
MalConv	99.91	99.22	99.12	86.54	93.22

• **Anti-virus products.** We additionally employ five anti-virus products, *i.e.*, McAfee, Comodo, Kaspersky, ClamAV, and Microsoft Defender ATP (MS-ATP) [44], due to their widespread recognition in the security community of Windows malware detection. In particular, McAfee, Comodo, and Kaspersky are three award-winning commercial anti-viruses recommended in [52]. ClamAV [16] is the most popular open-sourced anti-virus engine, which has been extensively employed in both academia and industry. MS-ATP [44] is a learning-based security protection tool for Windows and is awarded a perfect 5-star rating by [4]. Notably, we do not employ VirusTotal as it strongly advises against using their anti-viruses for comparative evaluations [55].

4.1.3 Baseline Attacks

We compare MalGuise with two kinds of baseline attacks, *i.e.*, adversarial attacks and obfuscations. In principle, to facilitate

fair comparisons, we follow the same evaluation settings of all baseline attacks as their publications or implementations.

• **Adversarial attacks**: We employ two SOTA adversarial attacks: i) MMO [41] is a white-box adversarial attack that uses gradient-based optimizations to guide binary diversification tools to manipulate the raw bytes of Windows malware. Its maximum iteration number is 200 and the increment rate of adversarial malware size is limited to 5%. ii) SRL [63] is a black-box adversarial attack that employs reinforcement learning to iteratively inject semantic nops into the malware's CFG. Its maximum iteration number, the injection budget, and the modified basic blocks are set to be 30, 5%, and 1250, respectively. Notably, SRL only generates the adversarial CFG features rather than realistic malware files, making it incompatible with MalConv, which requires raw bytes as inputs.

• **Obfuscations**: We employ three obfuscation tools that have been widely employed to obfuscate Windows executables and follow their default settings for evaluations. In particular, UPX [53] is an open-source and universal packing tool for executables by performing compression on the entire file; VMProtect [56] typically uses code virtualization for obfuscations via simulating a virtual machine executing the key part in executables; Enigma [20] employs a combination of multiple obfuscation techniques, *e.g.*, import table elimination, API simulation, code virtualization, *etc*.

4.1.4 Evaluation Metrics

We employ two kinds of evaluation metrics as follows.

• **Attack Success Rate (ASR)**. ASR is the most common evaluation metric for adversarial attacks [37, 41, 63]. Given a candidate malware set $\mathbf{Z}$, ASR is defined as the ratio of generated adversarial malware that successfully evades the target system (*i.e.*, $f(z_{adv})=0$) among all malware (*i.e.*, $f(z)=1$).

$$ASR = \frac{|(f(z)=1) \wedge (f(z_{adv})=0)|}{|f(z)=1|}, \ \forall z \in \mathbf{Z} \qquad (5)$$

where $|\cdot|$ counts the number that meets the condition.

• **Semantics Preservation Rate (SPR)**. As the generated adversarial malware might not preserve the same semantics as the original malware, *i.e.*, it cannot be executed or lose the original malicious behaviors. To this end, we define SPR as the ratio of adversarial malware with the original semantics preserved among all adversarial malware as follows.

$$SPR = \frac{|Sem(z, z_{adv})=1|}{|(f(z)=1) \wedge (f(z_{adv})=0)|}, \ \forall z \in \mathbf{Z} \qquad (6)$$

where $Sem(z, z_{adv})=1$ denotes z_{adv} and z maintain the same semantics. §4.2.3 will detail how to measure SPR empirically.

4.1.5 Implementation Details

MalGuise is primarily implemented with Python and evaluated on a computer equipped with 20 Intel Xeon CPUs, 128 GB memory, and 4 NVIDIA GeForce RTX 3090. Firstly, MalGuise uses IDAPython in IDA Pro 6.4 [24] to disassemble Windows executables and represent them as CFGs. In the MCTS-guided searching algorithm, by default, we set the max length N to 6, set the computational budget C to 40, set the simulation number S to 1, and limit the size of injected semantic nops to no more than 5% of the original size. To reconstruct the adversarial malware file, we mainly employ two Python libraries, pefile[1] and LIEF[2], to parse and patch Windows executables. It is worth noting that, those injected semantic nops can be generally divided into four categories: arithmetic (*e.g.*, "add␣eax, 1; sub␣eax, 1"), logical (*e.g.*, "add␣eax, eax"), comparison (*e.g.*, "cmp␣eax, eax"), and data transfer (*e.g.*, "push␣eax; pop␣eax").

4.2 Evaluation Results & Analysis

4.2.1 Answer to RQ1 (Attack Performance)

To assess the attack performance of MalGuise, we evaluate it by comparing its ASR performance with all baseline attacks on all 10,000 testing malware samples from the benchmark dataset, which is illustrated in Table 3. Recall in §4.1.3, MMO is a white-box adversarial attack, serving as an upper bound to assess the attack performance of its black-box attacks. All three obfuscations only apply to the *w/o prob.* scenario as they do not require any feedback from the target system.

Table 3: The ASR performance (%) comparisons between MalGuise and baseline attacks against three target systems under two black-box scenarios, *i.e.*, *w/ prob.* and *w/o prob.*

Black-box Scenarios	Attacks	MalGraph		Magic		MalConv	
		FPR =1%	FPR =0.1%	FPR =1%	FPR =0.1%	FPR =1%	FPR =0.1%
w/ prob.	MMO	15.55	52.30	12.82	40.13	11.99	39.66
	SRL	2.39	19.59	25.38	86.77	—	—
	MalGuise	**97.47**	**97.77**	**99.29**	**99.42**	**34.36 (97.76)**	**97.38 (99.77)**
w/o prob.	MMO	3.73	27.83	3.41	25.46	2.46	20.72
	SRL	2.59	15.28	3.84	47.48	—	—
	UPX	0.55	4.43	3.30	39.80	0.31	9.32
	VMProtect	0	0	0.23	4.33	0	0
	Enigma	0.81	11.69	0	28.96	0	0.24
	MalGuise	**96.84**	**96.49**	**99.27**	**99.07**	**31.41 (95.18)**	**88.02 (99.77)**

"—" means SRL does not apply to MalConv as it cannot generate real malware files.

For all attacks, Table 3 shows that lower FPR values for the three target systems correspond to higher ASRs achieved by each attack. The reason is evident that a lower value of

[1] pefile: https://github.com/erocarrera/pefile
[2] LIEF: https://lief-project.github.io

FPR allowed by the binary classifier indicates it has a higher threshold. Hence, the adversary can more easily reduce the predicted malicious probability to a level below the threshold. Additionally, it is evident that each attack performs no better in the scenario of *w/o prob.* than in the scenario of *w/ prob.*

Adversarial attacks: MMO achieves low ASR performance against all three target systems in both attack scenarios. Particularly, in the case of FPR=1% for all target systems, the ASRs of MMO are below 16% and 4% in the scenarios of *w/ prob.* and *w/o prob.*, respectively. These imply that, although MMO theoretically can be used against all target systems, it shows inferior attack performance against them. The main reason we conjecture is that, since MMO manipulates the entire raw bytes of malware with binary diversification techniques in general, it does not take into account the discriminative features employed in different target systems.

For SRL, in both scenarios of *w/ prob.* and *w/o prob.*, it shows obviously higher ASRs against Magic than MalGraph in both FPRs. This is mainly because SRL is specifically designed to attack Magic which purely builds on CFG. However, the hierarchical nature of MalGraph that combines both the function call graph and CFG further weakens the attack performance of SRL, as SRL only manipulates nodes of CFG and neglects to manipulate its edges.

Obfuscations: It is observed that all three obfuscations show inferior attack performance, which once again validates that traditional obfuscation tools are largely ineffective against learning-based malware detection [2, 30, 48]. Specifically, VMProtect achieves the worst attack performance against all three target systems, while UPX and Enigma show slightly better attack performance, but remain unsatisfactory with all achieved ASRs not exceeding 40%. This is mainly because, VMProtect typically obfuscates only a small portion of the malware file [56, 57], while both UPX and Enigma can globally obfuscate the entire malware file, which slightly increases the likelihood of altering the discriminative semantic features. However, as UPX and Enigma remain unknown without the security experts' intervention, it is still challenging to purposefully manipulate the discriminative semantic features. More evaluations in terms of size alteration ratio are in Appendix C.

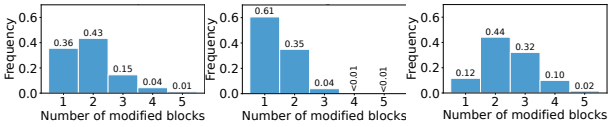
Compare MalGuise with all baseline attacks: Table 3 shows that MalGuise achieves the best attack performance against all three target systems in all scenarios and cases. When attacking MalGraph and Magic in all scenarios and cases, all ASR values achieved by MalGuise exceed 97%. More importantly, even in the strict attack scenario of *w/o prob.*, MalGuise still maintains its ASR performance nearly unchanged, *i.e.*, decrease by no more than 1%, compared to the scenario of *w/ prob.* When attacking MalConv, although the ASR performance of MalGuise is much better than that of all baseline attacks, its ASR is still relatively poor (*i.e.*, below 35%) in the case of FPR=1%. However, when investigating MalGuise in the subsequent §4.2.2, we find that its attack performance against MalConv is highly dependent on the injected semantic `nops`. Thus, by incorporating the 25 most frequently used semantic `nops`, MalGuise is improved to achieve higher ASRs of 97.76% and 95.18% against MalConv in both *w/ prob.* and *w/o prob.* scenarios, respectively.

Answer to RQ1 (Attack Performance): Prior obfuscations and adversarial attacks either cannot provide satisfactory attack effectiveness or fail to scale well to different types of learning-based Windows malware detection. However, even in the strict black-box attack scenario (*w/o prob.*), MalGuise is agnostic to learning-based Windows malware detection with a high attack success rate exceeding 95% in most cases.

4.2.2 Answer to RQ2 (Impacting Factors)

We conduct a series of ablation studies to explore the impacting factors that affect the attack performance of MalGuise.

Impact of key parts in `call-based redividing`. The core of MalGuise is to apply the transformation of `call-based redividing`, which primarily involves two key parts: † injecting semantic `nops` and ‡ redividing `call` instructions, for manipulating the CFG's nodes and edges, respectively. To examine the impact of the above two parts, we compare the ASR performance of MalGuise with its two variants that apply only one of the key parts (*i.e.*, MalGuise† and MalGuise‡) under the attack scenario of *w/ prob.*



From Table 4, both MalGuise† and MalGuise‡ show almost negligible attack performance (with ASRs below 5%) against both MalGraph and Magic in both FPRs. When attacking MalConv, MalGuise‡ still shows inferior attack performance, while MalGuise† shows better attack performance, achieving ASRs of 23.04% and 79.86% in the cases of FPR=1% and FPR=0.1%, respectively. The reason is evident that the essence of MalGuise† is to inject semantic `nops` into malware, which can significantly and directly alter their raw bytes.Thus, MalGuise† can easily affect the detecting performance of MalConv which inputs the raw bytes of malware. Finally, comparing with the above two variants, MalGuise achieves considerably higher attack performance with over 97% ASR in all cases. More evaluations against anti-viruses are in Appendix C. All the above observations indicate that MalGuise with only manipulating either CFG's nodes or edges demonstrates inferior attack performance, and only by combining both can the attack performance of MalGuise be maximized.

Impact of the number of modified basic blocks in CFG. We investigate the impact of the number of modified basic blocks for all generated adversarial malware that successfully evade the three learning-based malware detection when FPR=1%, and show their corresponding frequencies in Fig. 5. It is observed that over 98% of all adversarial malware files that successfully evade the target systems only require modifying no more than four basic blocks in its CFG. In particular, MalGuise only needs to modify one basic block to make 61% of malware samples evade Magic, and only modify two basic blocks to make 79% and 56% of malware samples evade

Table 4: The ASR performance (%) of three MalGuise variants against three target systems under the scenario of *w/ prob.*

MalGuise Variants	MalGraph		Magic		MalConv	
	FPR=1%	FPR=0.1%	FPR=1%	FPR=0.1%	FPR=1%	FPR=0.1%
MalGuise†	0.02	4.35	1.70	3.34	23.04	79.86
MalGuise‡	0.10	4.87	0.10	1.42	0.17	1.86
MalGuise	**97.47**	**97.77**	**99.29**	**99.42**	**34.36** **97.76**	**97.38** **99.77**

MalGraph and MalConv, respectively. These evaluations indicate that, by only modifying a small number of basic blocks in CFG, MalGuise could offer excellent attack performance against all three learning-based malware detection systems.

(a) MalGraph (b) Magic (c) MalConv

Figure 5: Frequency of the number of modified basic blocks of all adversarial malware that evades the three target systems.

Impact of different types of semantic `nops`. When performing MalGuise against MalConv, we examine the impact of different opcodes in the injected semantic `nops` by presenting the occurrence frequency of different opcodes that lead to successful evasions in Fig. 6. It is observed that, some opcodes (*e.g.*, `dec/inc`, `xor`) occur with a relatively high frequency, while some others (*e.g.*, `cmp` and `test`) occur with a lower frequency. Next, we limit MalGuise to use the 25 most frequently used opcodes, it is observed from Table 3 that the ASR performance of MalGuise ASR against MalConv has significantly increased, highlighting the importance of different types of semantic `nops` in MalGuise. To sum up, we can conclude that the attack performance of MalGuise can be significantly improved by fine-tuning the types of semantic `nops` to be injected. More evaluations about the impact of the size of semantic `nops` for MalGuise are discussed in Appendix C.

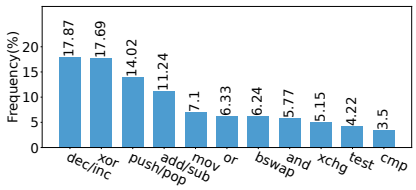


Figure 6: Occurrence frequency of different opcodes in semantic `nops` that lead to successful evasions against MalConv.

Impact of the hyper-parameters in MCTS. We investigate the impact of the hyper-parameters in MCTS (*i.e.*, C and N in Algorithm 1) for MalGuise. First, for the computation budget C, we follow the same implementation settings detailed in §4.1.5 and only vary C to 10, 20, 30, 40, 50, and 60. From Fig. 7, it is observed that, as C increases from 10 to 20, the ASRs of MalGuise rise sharply up to over 97% against all three target systems. When C reaches 20, its ASR performance tends to stabilize at a high value of over 97%.

Similarly, for the max length N, we only vary N (*i.e.*, 2, 4, 6, 8, and 10) to show its impact on MalGuise in Fig. 8. It is observed that when $N=2$, the overall attack performance of MalGuise against all three target systems is pretty well, with ASRs exceeding 97%. With the increase of N, the ASRs of MalGuise remain stable at a high value of over 97% against all target systems. These observations indicate that MalGuise can achieve high attack performance even with no more than two transformations of `call-based redividing` employed.

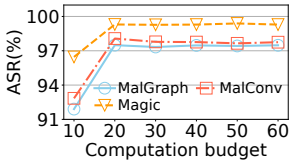

Figure 7: Impact of the computation budget C.

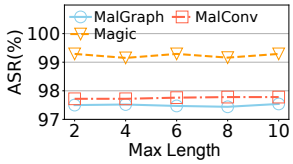

Figure 8: Impact of the max length N.

Answer to RQ2 (Impacting Factors): To sum up, targeting different learning-based malware detection systems, different hyper-parameters in MalGuise have different impacts on the attack performance, and thereby we can fine-tune its hyper-parameters to enhance its attack performance.

4.2.3 Answer to RQ3 (Utility Performance)

As previously defined in Eq. (6), we evaluate the utility performance of MalGuise and two baseline adversarial attacks in terms of semantics preservation rate (SPR), whose core is to judge whether the adversarial malware z_{adv} has the same semantics as the original malware z, *i.e.*, $Sem(z, z_{adv})$. Due to the inherent complexity of executables, there is no exact solution to judge $Sem(z, z_{adv})$ [6] and we resort to an empirical verification to judge it by collecting and comparing the two API sequences (*i.e.*, $\texttt{API}_{z_{adv}}$ and $\texttt{API}_z$) invoked by both z_{adv} and z when they are run on the Cuckoo sandbox [18]. As shown in Eq. (7), to quantify the semantic difference between z_{adv} and z, we thus compute a normalized edit distance $dist_{norm}(z, z_{adv})$ between the two API sequences as follows.

$$dist_{norm}(z, z_{adv}) = \frac{Distance(\texttt{API}_z, \texttt{API}_{z_{adv}})}{max(l(\texttt{API}_z), l(\texttt{API}_{z_{adv}}))} \in [0, 1] \quad (7)$$

in which $Distance(\texttt{API}_z, \texttt{API}_{z_{adv}})$ denotes the edit distance between two sequences and $l(\cdot)$ denotes the sequence length.

However, since malware may perform random actions during execution [27], the API sequences collected by running

the same malware z *twice* in the same sandbox may be different, which means $dist_{norm}(z,z)$ almost can not take the value of 0. Therefore, we calculate the value of $Sem(z,z) \in \{0,1\}$ by comparing the $dist_{norm}(z,z)$ with a general distance threshold $dist_{\Delta}$. To determine $dist_{\Delta}$, we first analyze all original malware samples in the same sandbox twice and then select the value at the 99.5-th percentile among all the corresponding $dist_{norm}(z,z)$ as $dist_{\Delta}$. After that, as shown in Eq. (8), we can finally determine whether z_{adv} and z have the same semantics by comparing their normalized edit distance $dist_{norm}(z,z_{adv})$ with $dist_{\Delta}$, and further evaluate *SPR* according to Eq. (6).

$$Sem(z,z_{adv}) = \begin{cases} 1 & \text{if } dist_{norm}(z,z_{adv}) < dist_{\Delta} \\ 0 & \text{otherwise.} \end{cases} \quad (8)$$

Due to the extreme resource and time consumption of the above evaluation process, we randomly select 10% from all adversarial malware that successfully evades the corresponding target system in §4.2.1 for the subsequent evaluations and present the evaluation results in Table 5. Apparently, evaluating the utility performance of SRL is not applicable as it only generates adversarial features rather than realistic adversarial malware files. As for MMO, it is observed that the achieved SPR values against three target systems are at a low level, *i.e.*, approximately ranging from 40% to 50%. It indicates, only less than 50% of adversarial malware generated by MMO preserve their original semantics. However, MalGuise achieves the best utility performance of over 91% SPR for all three target systems, which demonstrates the best effectiveness of MalGuise in preserving their original semantics.

Table 5: The SPR (%) of MalGuise and two baseline adversarial attacks against three target systems.

Attacks	MalGraph		Maigc		MalConv	
	FPR=1%	FPR=0.1%	FPR=1%	FPR=0.1%	FPR=1%	FPR=0.1%
MMO	41.8	49.4	39.6	39.8	39.2	50.8
SRL	—	—	—	—	—	—
MalGuise	**91.84**	**91.99**	**93.45**	**92.28**	**92.67**	**91.68**

Causes for 9% failures. To investigate the causes behind the approximately 9% of failures in preserving the same semantics in the above evaluations, we conduct manual inspections using IDA Pro [24] and OllyDbg [62] and reveal two primary reasons for these failures. First, there are a few malware samples that contain *overlay*, which is not part of the official Windows executable format but is usually used to perform malicious behaviors in malware. Despite adhering to the standard Windows executable format specifications, the adversarial malware reconstruction phase in MalGuise might affect the overlay of those few malware samples, thereby failing to be executed identically or properly. Second, it is a standard process for Windows executables to push/pop the return address onto/off the stack when handling the "call" instruction. However, there are few malware samples that contain *junk code*, which might not follow the above process, *e.g.*, not popping the return address. These exceptions might render MalGuise ineffective as MalGuise follows the standard Windows specifications to reconstruct the adversarial malware.

Answer to RQ3 (Utility Performance): Prior adversarial attacks either only generate non-executable adversarial "features", or generate a large portion of adversarial malware losing their original semantics. However, MalGuise exhibits the best utility performance with over 91% of generated adversarial malware files preserving their original semantics.

4.2.4 Answer to RQ4 (Real-world Performance)

As discussed in §4.1.2, to further understand the real security threats of MalGuise against anti-virus products, we empirically evaluate MalGuise against five commercial anti-virus products by measuring their ASR performance on 1,000 testing malware samples, which are randomly selected from the testing dataset. It is noted that, the main reason for randomly selecting 1,000 testing malware samples is that all five anti-virus products are deployed remotely on another machine, and their processing and scanning speeds are much slower than the employed learning-based Windows malware detection.

Table 6: The ASR (%) of MalGuise against five anti-viruses.

Attacks	McAfee	Comodo	Kaspersky	ClamAV	MS-ATP
MalGuise	48.81	36.00	11.29	31.94	**70.63**
MalGuise(S)	52.49	36.36	13.36	32.33	**74.97**
Increased ASR	+3.68	+0.36	+2.07	+0.39	+4.34

We observe in Table 6 that, for four (*i.e.*, McAfee, Comodo, ClamAV, and MS-ATP) of the five evaluated anti-viruses, MalGuise achieves ASRs of more than 30%. Especially for MS-ATP, the achieved ASR of MalGuise reaches upto 70.63%. As discussed in §4.2.2, we further limit MalGuise to use the 25 most frequently used opcodes and denote this variant as MalGuise(S) for brevity. Compared with the default MalGuise, MalGuise(S) clearly leads to an overall improvement in the attack performance for all five anti-virus products. In particular, MalGuise(S) increases its ASR against MS-ATP by 4.34%, implying it can be further improved by carefully fine-tuning.

Impact of different types of semantic `nop`s. We further investigate how the different opcodes in the injected semantic `nop`s affect the attack performance of MalGuise against anti-virus products. Similarly, by limiting MalGuise to use the 25 most frequently used opcodes, Fig. 9 illustrates the occurrence frequency of different opcodes of all generated adversarial malware files that lead to successful evasions for five anti-viruses. It is clearly observed that different anti-virus products are sensitive to different semantic `nop`s injected by MalGuise.

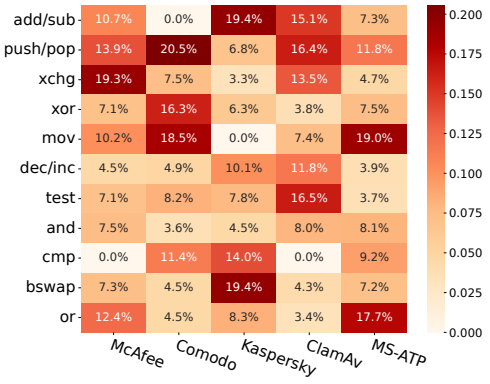

Figure 9: Occurrence frequency of different opcodes in semantic nops that lead to successful evasions for five anti-viruses.

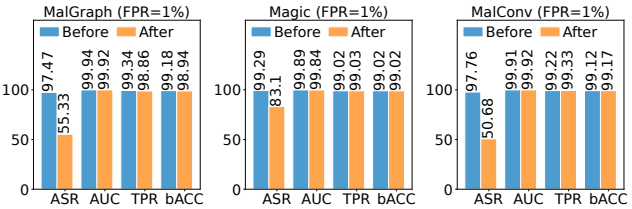
Table 7: Distribution frequency (%) of the number of modified blocks for adversarial malware that evades anti-virus products.

# of blocks	McAfee	Comodo	Kaspersky	ClamAV	MS-ATP
1	96.66	94.28	88.17	97.54	38.21
2	4.58	4.71	9.68	2.05	42.88
3	0.76	1.01	2.15	0.41	17.35
4	0	0	0	0	1.17
5	0	0	0	0	0.39

Impact of the number of modified basic blocks. The distribution of the number of modified blocks in the adversarial malware that successfully evades the target anti-viruses is illustrated in Table 7. For all five anti-viruses, the number of modified blocks in all the adversarial malware is less than 6. Especially for McAfee, Comodo, and ClamAV, more than 90% of adversarial malware only need to modify one block, while the other two anti-virus products (*i.e.*, Kaspersky and MS-ATP) only need to modify two basic blocks. Therefore, we can conclude that MalGuise can be applied against anti-virus products by only modifying very few blocks in CFG.



Answer to RQ4 (Real-world Performance): MalGuise is empirically evaluated to be effective against five anti-virus products in the wild. In particular, MalGuise achieves attack success rates of over 30% against four of them, presenting potential tangible security concerns to real-world users.

4.2.5 Answer to RQ5 (Possible Defenses)

To understand the risks that potential artifacts in MalGuise might be noticed and identified by defenders, we evaluate MalGuise with four categories of possible defenses as follows.

(1) **Adversarial training**: Adversarial training is recognized as one of the most effective defenses against adversarial attacks [9]. Therefore, we evaluate the attack performance of MalGuise against the three target learning-based malware detection systems that have been defended using adversarial training (*i.e.*, the defended systems.) To set up, we re-train them from scratch with nearly unchanged parameter settings, except for integrating corresponding adversarial malware generated by MalGuise during the training process.

Fig. 10 shows, after being defended by adversarial training, the detecting performance (*i.e.*, AUC, TPR, and bACC) of the three target systems remains basically unchanged, while the corresponding ASR values achieved by MalGuise have been decreased to some extent, indicating the defended systems' robustness performance (*i.e.*, the opposite of ASR) has indeed improved. Nonetheless, it is clearly observed that, after being defended by adversarial training, MalGuise remains highly effective, achieving ASRs of 55.33%, 83.10%, and 50.68% against MalGraph, Magic, and MalConv, respectively.

(a) MalGraph (b) Magic (c) MalConv

Figure 10: The overall performance comparisons between the original (before) and the defended (after) target systems.

(2) **Binary code optimizations**: Recalling that our proposed `call-based redividing` transformation involves injecting semantic nops and redividing "call" instructions to manipulate CFG, which might be noticed by potential defenders. Therefore, to evaluate MalGuise's attack performance against possible defenses based on binary code optimizations (*e.g.*, dead code removal or CFG reduction), we employ the off-the-shelf IDA Pro plugin – Optimice[3], which has won the Hex-Rays' IDA Pro plugin contest [25]. To set up, we take Optimice's binary code optimizations as the preliminary step for the three target learning-based malware detection systems and evaluate them under the black-box scenario of *w. prob.*

Table 8: The ASR performance (%) comparisons between the original target systems and the defended systems by Optimice.

Target Systems	Original System	the defended system by Optimice		
		only *w/* dead code removal	only *w/* CFG reduction	*w/* both
MalGraph	97.47	82.25	82.43	80.26 (-17.21)
Magic	99.29	97.94	96.91	93.85 (-5.44)
MalConv	97.76	80.07	75.15	74.63 (-23.13)

Table 8 shows that, with either dead code removal or CFG reduction, or a combination of the above two, the ASR performance achieved by MalGuise has decreased, suggesting the

[3] https://code.google.com/archive/p/optimice/

robustness performance of the defended systems has indeed increased accordingly. However, even when defended with binary code optimizations, MalGuise still achieves relatively high attack performance, with ASRs exceeding 74%.

(3) **Heuristic-based adversarial detection**: To evaluate the impact of possible defenders who are fully aware of the implementation details of MalGuise, we implement an adaptive defense of heuristic-based adversarial detection, which consists of two heuristic rules: $\mathbb{R}_1$ and $\mathbb{R}_2$. In particular, $\mathbb{R}_1$ indicates, other than the ".text" section, there exists another or more sections with executable permission and fixed addresses inside. $\mathbb{R}_2$ indicates, there exists at least one basic block that contains a "call" instruction followed by a "jmp" instruction with semantic nops in between. It is noted that, as MalGuise iteratively generates semantic nops with the context-free grammar [41], determining whether a specific code fragment is semantic nops is well-known as non-trivial and undecidable [15, 50] and we thus employ Optimice [25] to detect the semantic nops as above. To set up, we first randomly select 15000 adversarial malware from all those that have successfully evaded three learning-based Windows malware detection systems and 15000 goodware from the benchmark dataset, and then employ the above adversarial detection to check whether the adversarial malware can be detected, and finally show the detection results in Table 9.

Table 9: The detecting performance (*i.e.*, TPR and FPR) of adversarial detection based on two heuristic rules

Adversarial Detection	TPR	FNR=(100%-TPR)	FPR
$\mathbb{R}_1$-based	70.15	29.85	5.66
$\mathbb{R}_2$-based	96.91	3.09	52.16
$\mathbb{R}_1$ & $\mathbb{R}_2$-based	67.75	33.25	2.95

It is observed that both TPR and FPR of $\mathbb{R}_1$-based adversarial detection are low, suggesting that most goodware indeed has only a ".text" section. However, there is a lot of adversarial malware with only a ".text" section as long as the semantic nops could be injected into the remaining slack space. Moreover, $\mathbb{R}_2$-based adversarial detection shows the best TPR but the worst FPR. It indicates, although $\mathbb{R}_2$ can be used to detect almost all adversarial malware, there exists over 50% of goodware is misclassified as adversarial malware. Similar to $\mathbb{R}_1$, the adversarial detection that combines both $\mathbb{R}_1$ and $\mathbb{R}_2$ shows a TPR of 67.7%, indicating that about 33.2% of adversarial is misclassified as goodware, *i.e.*, evading the corresponding the adversarial detection. Moreover, it also shows an FPR of 2.9%, which is higher than the upper limit of FPR (*e.g.*, 1% or 0.1%) that is tolerated by general malware detection systems.

To sum up, this adaptive defense of heuristic-based adversarial detection can detect adversarial malware generated by MalGuise to a certain extent as it is equipped with all the implementation details of MalGuise. However, it also shows the dilemma that TPR and FPR cannot be balanced simultaneously, *i.e.*, failing to offer satisfactory detecting performance.

(4) **Fuzzy hashing**: As MalGuise is optimized to use as few transformations as possible to preserve the same semantics, it also enables possible defenders to use fuzzy-hashing-based malware analysis (*i.e.*, ssdeep [32], TLSH [46], SpamSum [29], *etc*) for defenses, which has been extensively studied [11, 60]. To implement the fuzzy-hashing-based defenses, we first submit all malware samples in the training set to initialize *the malware database*, and then use the validation set to determine the thresholds satisfying FPR=1% and FPR=0.1% for fair comparisons. After that, we evaluate the detecting performance of fuzzy-hashing-based defenses within the testing set, which is shown in Table 10. By comparing Table 2 with Table 10, we find that all fuzzy-hashing-based defenses show less stable and worse detecting performance.

Table 10: The detecting performance (*i.e.*, AUC, TPR, bACC) and ASR performance of fuzzy-hashing-based defenses

Fuzzy-hashing-based defenses	AUC	FPR=1%			FPR=0.1%		
		TPR	bACC	ASR	TPR	bACC	ASR
ssdeep	83.92	57.61	78.70	52.94	10.16	55.31	100
TLSH	74.23	55.55	77.66	73.70	42.27	71.44	100
SpamSum	83.98	57.72	78.75	50.22	38.91	69.46	98.13

We further reinforce the three fuzzy-hashing-based defenses by submitting all malware samples in the testing set to the *the malware database*, indicating all these defenses have full knowledge of the original malware samples and can use fuzzy hashing for detection. Finally, we evaluate the ASR performance of MalGuise against those reinforced defenses, which is shown in the column named "ASR" in Table 10. It is clearly observed that, in the case of FPR=1%, the ASRs against all three reinforced defenses exceed 50%, and the ASRs are nearly 100% for FPR=0.1%, exhibiting a high attack success rate against fuzzy-hashing-based defenses.

Answer to RQ5 (Possible Defenses): MalGuise remains exceptionally effective against all three categories of possible defenses even though they are adaptively equipped with the knowledge of MalGuise.

5 Discussions

5.1 Related Work

Almost all existing studies on adversarial attacks against malware detection predominantly focus on learning-based malware detection with static features. Owing to the vast diversity of feature representations employed by different kinds of learning-based malware detection, researchers have proposed different adversarial attacks tailored to these detection methods. For instance, to attack those malware detection methods based on API calls, a line of adversarial attacks

has been proposed via adding irrelevant API calls, which are selected by gradient-based optimizations or greedy algorithms [3, 13, 26, 54]. However, these adversarial attacks are impractical because they generate adversarial API calls rather than realistic executable malware files. As for these malware detection based on raw bytes, especially for MalConv [48], researchers have explored either partially modifying specific regions or globally modifying all raw bytes while preserving the same semantics. For instance, all of [5, 19, 31, 33, 51] rely on appending or injecting maliciously generated bytes at specific locations of the input malware, while MMO [41] globally manipulates its raw bytes with binary diversification techniques. However, we argue that those adversarial attacks are strictly limited to raw-bytes-based malware detection, and thus cannot be scalable to other malware detection.

More recently, studies have begun to explore adversarial attacks against more advanced malware detection based on abstract graph representations. In 2022, Zhang *et al.* [63] proposed SRL against CFG-based malware detection, which sequentially injects semantic `nops` into the CFG guided by reinforcement learning. Likewise, our work also aims to evade advanced malware detection based on CFGs, but fundamentally differs from SRL in three key aspects.

- **Fine-grained transformations**. SRL employs a coarse-grained transformation that only manipulates nodes of CFG. However, we propose a finer-grained transformation of `call-based rediviting` that manipulates both nodes and edges, making it less noticeable to potential defenders.
- **Not adversarial "features"**. As discussed in § 4.2.3, SRL is a feature-space adversarial attack that essentially generates adversarial "features", while our MalGuise can successfully generate real adversarial malware files for evasions.
- **Attacking generalizability**. Existing adversarial attacks like SRL are primarily evaluated with limited learning-based malware detection models, while MalGuise additionally targets real-world anti-virus products in practice, thereby demonstrating better attacking generalizability.

5.2 Possible Use Cases

We discuss possible use cases of MalGuise as follows. First, MalGuise, a practical black-box adversarial attack, can complement the blue team's toolkit, addressing the limitations of traditional obfuscations in attempts to evade present-day advanced learning-based malware detection. Second, MalGuise could serve as a means for the R&D team of anti-virus vendors to expose the underlying weaknesses of learning-based malware detection under development, and thus they can proactively and purposefully improve the robustness of anti-virus products. Third, comprehensive and impartial testing for anti-viruses is crucial for ensuring transparency and fostering trust between users and vendors. MalGuise offers a unique opportunity for third-party independent testing organizations like AV-TEST [8] to assess anti-viruses comprehensively, given the exceptional evasion capability of adversarial malware.

5.3 Potential Ethical Concerns

The primary objective of this study is to assess the security risks of learning-based Windows malware detection with adversarial attacks, an approved topic with established precedence in earlier studies [22, 40, 41, 47, 63, 64], which is largely motivated by the concern for potential adversaries to craft Windows malware capable of evading detection, and by highlighting the necessity for more robust learning-based Windows malware detection methods. Even though our intent is strict about assessing the security risks of learning-based Windows malware detection with MalGuise, we recognize the potential ethical concerns associated with our study. Therefore, to strike a balance between avoiding potential ethical concerns and assisting the security community in enhancing the robustness of learning-based Windows detection, we limit our code sharing to *verified academic researchers only*, following the precedent established by previous studies [22, 47, 64].

6 Conclusion, Limitations and Future Work

This paper proposes a novel semantics-preserving transformation of `call-based rediviting`, capable of concurrently manipulating both nodes and edges of the CFG and further presents an adversarial attack framework of MalGuise against learning-based Windows malware detection under the black-box scenario. Extensive evaluations demonstrate that MalGuise can not only effectively evade state-of-the-art learning-based Windows malware detection systems with an attack success rate of mostly exceeding 95%, but also can evade five commercial anti-virus products with an attack success rate of up to 74.97%. We believe our study raises public awareness about the security threats posed by adversarial attacks in the domain of Windows malware detection and calls for further studies to enhance the robustness of existing Windows malware detection. However, we recognize the limitations and outline potential future work as follows.

- **Verification of semantic preservation**. To verify if the generated adversarial malware preserves the original semantics, we have presented an automatic empirical verification in § 4.2.3 and Eq. (7) by comparing their API sequences invoked when running on the same sandbox environment. While practical and reasonable, this empirical verification cannot guarantee the strict semantic equivalence between two malware in all possible environments since some malware may invoke random APIs in different environments.
- **Dynamic-analysis-based malware detection**. MalGuise targets learning-based Windows malware detection, which belongs to static analysis. Particularly, the core of MalGuise is to manipulate the CFG of executables via the `call-based rediviting` transformation, which does not change their execution flow and thereby does not impact dynamic

analysis. Therefore, although dynamic analysis is less ubiquitously deployed due to excessive time and resource consumption, we leave generating adversarial malware against dynamic-analysis-based malware detection as future work.

- **Format-agnostic adversarial malware**. Since there is no malware analysis technique that is universally applicable to all types of malware with different file formats and operating systems, existing malware analysis normally points out the targeted file format and operating systemWhile in this paper, our MalGuise targets the Windows malware in the file format of portable executable, we will explore how to generate format-agnostic adversarial malware against all kinds of malware detection in future work.

Acknowledgments

We sincerely appreciate the shepherd and anonymous reviewers for their valuable comments to improve our work. We would also like to thank Bolin Zhou, Zhiqin Rui, and Yuhao Peng for their valuable contributions during the review process. A More Implementation Detail in MALGUISE

Algorithm 4 outlines the main procedure of `Selection`. As the possible paths in the game tree of MCTS are infinite, exploring all the nodes in the game tree will substantially increase the computational overhead. By employing the Upper Confidence Bounds algorithm [10], `Selection` could select the child of the MCTS node v with the highest score considering the trade-off between the visit times and the reward value (*line 4-6*).

Algorithm 4: Procedure of `Selection`(v).

```
Begin
    max_score ← 0;
    for v_child in children of v do
        exploit ← v_child.reward / v_child.visits;
        explore ← sqrt(2 ln(v.visits) / v_child.visits);
        score ← exploit + λ × explore;
        if max_score < score then
            max_score ← score;
            v_selected ← v_child;
return v_selected ; //the most promising node to be explored
```

Algorithm 5 outlines the main procedure of `Simulation` that returns the reward r. Based on the $v_{selected}$, this procedure iteratively expands the MCTS game tree until the simulation number S is reached (*line 3–6*). In each iteration, the corresponding CFG representation x of the expanded node is input to the target malware detection system f, and the returned reward is calculated as $reward = 1 - f(x)$ (*line 6*).

Algorithm 5: Procedure of `Simulation`($v_{selected}, f, S$)

```
1 Procedure Simulation(v_selected, f, S)
2     v' ← v_selected;
3     for i ← 1 to S do
4         v' ← Expansion(v');
5         x ← v'.x;
6     reward ← 1 − f(x);
7 return reward
```

B More about the Benchmark Dataset

To fairly evaluate the effectiveness of learning-based malware detection systems in detecting previously unseen malware, we employ a time-based training/testing split. In particular, for all malware, we take all malware samples before May 6, 2020, as the training set and equally divide the remaining malware into the validation and testing set. For all goodware, we randomly split them according to the percentages of the training/validation/testing sets of malware. It is reported that there is a total of 848 different malware families, in which its training/validation/testing sets have 780/366/375 different malware families, correspondingly. Fig. 11 illustrates the distribution percentages of the top 30 malware families.

C More Evaluations

The below includes four more evaluations as follows.

(1) More evaluations in terms of size alteration ratio. In Table 11, we measure the "size alteration ratio (%)" of successfully evaded malware samples before and after the obfuscating process to observe the overhead introduced by the obfuscation tools. It is clearly observed that the malware size alteration ratio after being obfuscated by UPX is approximately 3× times that of MalGuise, while the size alteration ratios after being obfuscated by VMProtect and Enigma exceed 980× times and 330× times that of MalGuise, respectively.

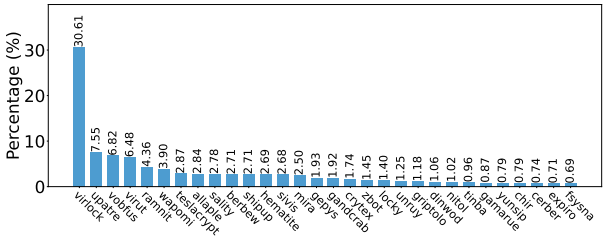

Figure 11: The distribution of top 30 malware families.

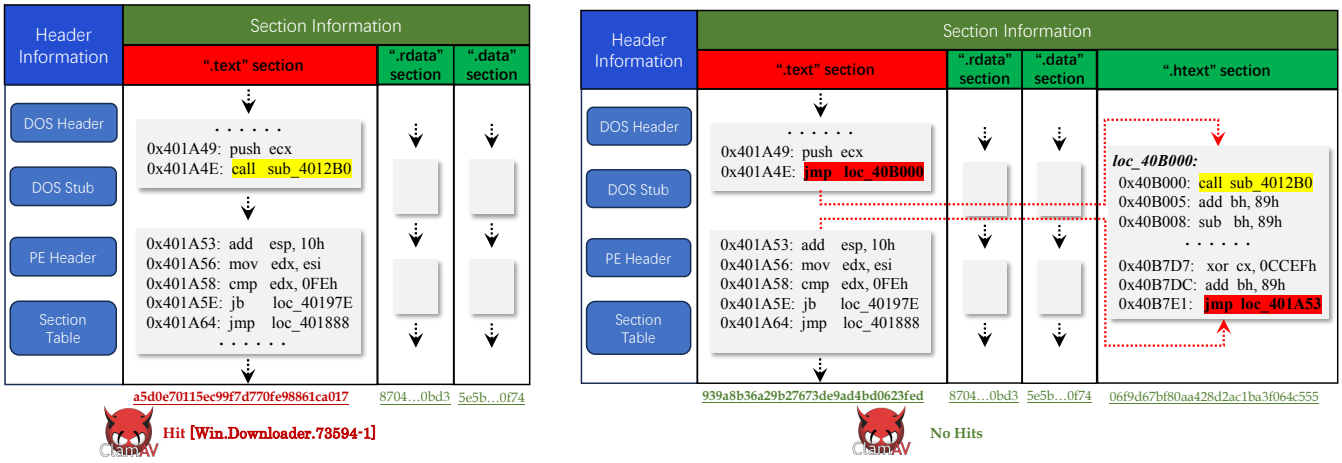
Table 11: The "size alteration ratio (%)" performance comparisons between MalGuise and three baseline obfuscations.

Attacks	MalGraph		Magic		MalConv		Avg.
	FPR =1%	FPR =0.1%	FPR 1=%	FPR =0.1%	FPR =1%	FPR =0.1%	
UPX	-35.8	-28.2	-30.4	-19.6	-11.1	-27.8	23.3
VMProtect	—	—	+822.7	+5343.8	—	—	7767.7
Enigma	+1737.3	+3850.5	—	+2089.7	—	+181.4	2613.1
MalGuise	+7.97	+8.03	+7.89	+7.08	+7.97	+7.72	7.87



(2) More evaluations of MalGuise variants against anti-virus products. Table 12 summarizes the ASR performance of four MalGuise variants against five anti-virus products. In a similar vein, MalGuise and MalGuise(S) achieve the best attack performance than MalGuise† and MalGuise‡ when evaluated by all employed real-world anti-virus products. This observation reconfirms that, only by concurrently applying † injecting semantic `nops` and ‡ redividing `call` instructions, the attack effectiveness of MalGuise can be maximized.

Table 12: The ASR performance (%) of four MalGuise variants against five anti-virus products.

Attacks	McAfee	Comodo	Kaspersky	ClamAV	MS-ATP
MalGuise†	28.82	30.96	4.15	27.22	—
MalGuise‡	44.03	33.41	6.05	29.75	—
MalGuise	48.81	36.00	11.29	31.94	70.63
MalGuise(S)	**52.49**	**36.36**	**13.36**	**32.33**	**74.97**

"—" indicates that we cannot evaluate MalGuise variants against MS-ATP as Microsoft has changed its authorization process since about 2024 and has not officially approved our application until now.

(3) Impact of the size of semantic `nops` for MalGuise. We also investigate the impact of the size of the injected se-

(a) The ransomware is originally detected as malware.

(b) The corresponding adversarial ransomware is mistakenly identified as goodware.

Figure 12: Illustration of a case study of how MalGuise manipulates one ransomware to evade the detection of ClamAV.

mantic nops for MalGuise against three target learning-based malware detection systems in the cases of FPR=1%. Recall from § 3.2.3 that, the size of a newly injected section in Windows executables must be a multiple of the architecture's page size (*e.g.*, 4KB for Intel x86). To this end, we limit the size of semantic nops generated by MalGuise to no more than $m \times 4KB$ (*i.e.*, 1, 2, 3, 4, and 5) and present their attack performance against three target systems in Table 13. It is observed that, for both MalGraph and Magic, MalGuise requires only one time the page size ($m = 1$) to achieve a relatively high and stable ASR performance. Differently, MalGuise requires about three times the page size ($m = 3$) to achieve a high and stable ASR performance against MalConv. The main reason we conjecture is that MalConv purely relies on the raw bytes of malware, and MalGraph and Magic tend to rely on structural information like the function call relationship or control-flow information. Thus, altering the detecting output of MalConv (*i.e.*, evading its detection), requires MalGuise to alter more raw bytes of the given malware, which is mainly accomplished by injecting semantic nops. All the above indicates that MalGuise can effectively evade learning-based malware detection with a small size of injected semantic nops.

Table 13: The ASR performance % of MalGuise against three target learning-based malware detection systems when the size of semantic nops to be injected is limited to $m \times 4KB$.

Target Systems	$m = 1$	$m = 2$	$m = 3$	$m = 4$	$m = 5$
MalGraph	96.31	97.49	97.60	97.54	97.61
Magic	99.16	99.15	99.17	99.17	99.20
MalConv	91.56	96.34	97.33	97.48	97.53

(4) Case study of how MalGuise **evade ClamAV**. To unveil how MalGuise evades real-world anti-virus products, we present a case study of how MalGuise manipulates one wild malware to evade ClamAV. We take ClamAV mainly because four of the five employed anti-virus products are proprietary and closed-source, and only ClamAV is open-sourced by Cisco [16]. Notably, for ClamAV, an executable is reported as malware if any of its signatures match those in the ClamAV Virus Database (CVD), which is continuously updated with the latest malware samples.

To set up our case study, we randomly select one newly emerged malware variant from the WannaCry ransomware attack [1], termed as WANNACRY[4]. Subsequently, as illustrated in Fig. 12(a), WANNACRY is submitted to ClamAV and deterministically detected as malware because the hash signature of the ".text" section (*i.e.*, "a5d0e70115ec99f7d770fe98861ca017") exactly matches the signature in CVD. Finally, as illustrated in Fig. 12(b), after applying only a single `call-based redividing` transformation with MalGuise, the hash signature of the ".text" section has been changed to "939a8b36a29b27673de9ad4bd0623fed", which is no longer matched by any signature in CVD and is therefore mistakenly identified as goodware in the end.

[4]Its SHA245 hash is 043bc5f8da479077084c4ec75e5c1182254366d-135373059906bb6fed0bf5148

Leakage-Abuse Attacks Against Structured Encryption for SQL

Abstract

Structured Encryption (StE) enables a client to securely store and query data stored on an untrusted server. Recent constructions of StE have moved beyond basic queries, and now support large subsets of SQL. However, the security of these constructions is poorly understood, and no systematic analysis has been performed.

We address this by providing the first leakage-abuse attacks against StE for SQL schemes. Our attacks can be run by a passive adversary on a server with access to some information about the distribution of underlying data, a common model in prior work. They achieve partial query recovery against select operations and partial plaintext recovery against join operations. We prove the optimality and near-optimality of two new attacks, in a Bayesian inference framework. We complement our theoretical results with an empirical investigation testing the performance of our attacks against real-world data and show they can successfully recover a substantial proportion of queries and plaintexts.

In addition to our new attacks, we provide proofs showing that the conditional optimality of a previously proposed leakage-abuse attack and that inference against join operations is NP-hard in general.

1 Introduction

Cloud storage is a ubiquitous and convenient solution for clients who want to store their data on remote servers. This service, running without encryption, can provide a client convenience by allowing the server to store large amounts of data and to process queries over the data. However, moving data on to third party servers comes with security and privacy risks to the information stored. Unfortunately, standard encryption techniques are not useful to clients wanting to outsource the storage and computation of a queryable database, because a server cannot perform queries over rows which are encrypted in standard fashion.

Early work on encrypted databases [2, 41] proposed solutions which had unclear security guarantees, using techniques that were not well understood. However, later work [6, 11, 26, 37] proposed a framework for what are now known as *leakage-abuse attacks* (LAAs) against these schemes. In their work, the authors give adversarial models and simulate attacks showing that plausible adversaries could infer or recover data, queries that were performed by the client, or other potentially sensitive information.

Structured Encryption (StE) [17] provides an attractive combination of efficiency and query support, and allows for servers to learn a quantified amount of information called *leakage*. Leakage captures the information (e.g. metadata, patterns) revealed about the StE data and queries within an abstract mathematical model. However, the implications of this leakage for cryptanalysis by a real-world adversary are not immediately clear. For many StE schemes, follow up work [10, 29, 42, 48] has shown sometimes devastating LAAs against the leakage.

A recent line of work has been to design schemes in the StE framework for SQL applications, with a focus on supporting select and join queries [13, 32, 49]. Because SQL is such a wide spread and expressive query language, these StE schemes would be very useful to a client wishing to outsource their database to a server. And, as these and similar schemes become increasingly used, it is important to consider the practical security of the systems in real world settings. For example, work has already shown other practical vulnerabilities in complex non-SQL systems like MongoDB's queryable encryption [27], and many of these vulnerabilities could be avoided with a proper analysis before deployment.

However, the potential for leakage-abuse within StE for SQL schemes has not been studied at all. We seek to address this gap in the security analysis of StE for SQL schemes, by extending the established LAA framework to SQL select and join operations which compose more complex SQL queries. We then design the first LAAs against the above StE schemes,

[*]These authors contributed equally to the project
[†]These authors contributed equally to the project
[‡]These authors contributed equally to the project

and evaluate their effectiveness both theoretically and experimentally.

Our contributions. We evaluate the leakage of modern StE for SQL schemes [13, 32, 49] through leakage-abuse attacks. Our attacks assume a passive, honest-but-curious server with auxiliary data, similar to prior work [6, 26, 37]. Our attacks enable an adversary to infer the plaintext values in SQL select queries and to infer plaintext values within columns after a join operation. For complex or nested SQL queries, our attacks can be applied to any or all of the intermediate select or join operations.

Specifically, our evaluation of modern StE for SQL schemes includes the following contributions:

- We develop the first LAA for query inference against select queries in StE for SQL schemes and provide a proof that it is near-optimal. After selection queries are made, our attack can often recover the plaintext parts of those queries. This attack uses dynamic programming to generalize prior attacks against deterministic encryption, and in Section 3.1, we outline how it applies beyond StE for SQL to many searchable encryption schemes.

- We develop the first LAAs for plaintext inference against performing a many-many join in StE for SQL schemes. Whenever a join is performed, our attacks can exploit the leakage to recover the underlying values of the encrypted rows in the join. Our attacks work well in practice, but we show that optimal inference is NP-hard in general.

- We give an optimal LAA against many-many joins in the (common) case when the join output contains every row from both columns.

- We perform an empirical analysis of our attacks using a real data set, and show they almost always recover a substantial fraction of their targets. For many columns, before even 20% of unique values are selected, our select attack recovers 10-20% of the values and over 40% of the rows that were queried. Our best join attacks are arguably more devastating, recovering 30-40% of the unique values and over 60% of the rows in most experiments.

- In the appendix, we provide an algorithm to partition a set in a way that approximately maximizes a product of sums. This algorithm is useful as a subroutine in our attacks against the leakage of join operations and may be of independent interest.

Our attacks follow from two main technical insights. For our attack against selections, we show how to exploit *partial* frequency information, where prior attacks only worked with full information. For our attacks against joins, we observe that the leakage *between* the columns can give an adversary significantly more information to abuse. Whether it is partial or not, the server observes *correlated* frequency information across the columns, which allows them to make inferences more accurately.

In addition to the above, we identify how the type (i.e. one-one, one-many, many-many) of a join affects the leakage revealed to a passive adversary. Our work illustrates practical impacts of security in SQL systems that can depend both on the distribution of underlying data and the joins which can be performed in the database being queried. Our observations and attacks demonstrate that certain join patterns are more vulnerable to inference attacks than others, and we conclude that some care should be given to the database schema before deploying to a structured encryption scheme.

Attack Evaluation. For our theoretical results, our proofs measure the theoretical success of our attacks in the Bayesian inference framework, following prior work [6]. We consider an attack "optimal" if it returns a maximum likelihood estimator for the information it is trying to infer.

For our experimental results, we use public Chicago data and simulate a scenario where the city moves from public release to using a StE for SQL system. We use the year prior to the hypothetical change as auxiliary information for our adversaries who passively infer information for later years.

Limitations and Mitigations. Despite our use of real-world data, it is important to understand that the leakage that we attack is highly data-dependent in general, making it difficult to make broad conclusions about these scheme's security. In general, we find that columns with few domain values or with highly skewed data is most vulnerable to our attacks. So, one way to mitigate is to study the distribution of data and queries for a particular database and identify potentially vulnerabilities. In such a case, one could modify the schema or implement specific mitigation techniques for the vulnerable information.

To generically mitigate against these new attacks, one could consider using some of the same mitigations proposed in prior work [45, 46], such as volume-hiding [33] or differentially private [1, 40] structurally encrypted primitives.[1] Additionally, one work [13] provides a Modern StE for SQL construction which circumvents the join leakage that we attack at the cost of client computation. While these kinds of solutions would render our attacks ineffective, it is unclear whether new similarly effective attacks could be developed.

To have stronger and more well-understood security, one should instead use more "heavy weight" cryptography such as functional encryption [8], fully homomorphic encryption [21], oblivious RAM [16, 24], or secure multiparty computation [5]. However, these will come at the cost of increased server and/or client computation.

Organization. In Section 2, we include preliminaries, including a high level overview of SQL queries, and review some of the related work. In Section 3, we explain the leak-

[1] However, it is not clear what privacy parameter "ε" would need to be used to effectively mitigate. It may require so much privacy that one would be better off using volume-hiding primitives.

age that provide attacks against in our paper. In Section 4, we present our partial query recovery attack, including a formal attack model, optimality conditions, and experimental results. We differ the proof of the attack's near-optimality to Appendix A of the full version. In Section 5, we present our attacks for plaintext value recovery, including our optimal special case attack, three general case attacks, and our experimental results. Finally, in Section 6, we provide a summary of our findings and present alternatives and new ways forward to improve StE for SQL schemes.

1.1 Adversarial Models

We follow an adversarial model that has been considered in prior leakage-abuse attack work [6, 26, 37]. Throughout the paper, we assume that a server is running one of the modern StE for SQL schemes [13, 32, 49]. Unfortunately, these modern schemes are only provided formally and do not have implementations which can be directly attacked. However, our threat model has been practically considered for servers running other structurally encrypted systems or "smash-and-grab" adversaries that extract equivalent leakage from server logs [19, 27, 37].

We consider persistent passive adversaries on the servers which cannot influence or modify the queries or data. All of our attacks target leakage which is common in this setting for all schemes listed above. Our adversaries additionally have access to some prior knowledge, called *auxiliary information*, about the distribution of data in the database that's being stored on the server. Finally, we assume the adversary knows which column(s) the client queries and, when the exact same query is performed, which is often either leaked directly by the protocol or can be inferred from deterministic tokens or query result sizes. In prior work [37], the adversary has to determine which column was queried through some additional information (i.e. the number of unique values in the column). For simplicity, we assume the adversary has access to this information, since the exact method to determine the targeted column may vary slightly depending on the underlying database and StE scheme chosen.

Query Scope. We narrow our scope to just attacking *select* and *join* operations. Modern StE for SQL schemes support more complicated queries by allowing a client to nest these operations and leave and projection or filtering to be performed client side after decryption. We emphasize that there are no proposed StE for SQL schemes which support the full generality and expressiveness of SQL. Modern StE for SQL schemes [13, 32, 49] only support encrypted query processing for the basic selection and join operations outlined in Section 2.

In these schemes, the client may also issue more complicated queries by nesting the basic operations, running them on intermediate tables. Our adversaries, with distributional information about the targeted columns, can calculate the auxiliary distributions for intermediate SQL tables. Then, using the access pattern of the encrypted query processing, selects and joins on the intermediate table(s) can be attacked. Furthermore, when we attack joins, we consider the (to be defined later) cross-column equality of the encrypted rows between two columns. If multiple joins are composed, then we could run even stronger attacks by considering the cross-column equality between each of the different joins together. So, because complex queries are still vulnerable to our attacks (and maybe to even stronger attacks), we focus on the most elementary operations for simplicity and generality.

Attack Goals. When attacking select operations, the goal of the adversary is to determine the values the user is selecting (i.e. query recovery). The adversary will observe the sizes of the query results for select operations. Then, the adversary uses this and the auxiliary information to infer the most likely queries performed by a client.

For attacks against join operations, the adversary observes the access pattern of the structured encryption algorithm for the duration of the join. The goal of the adversary is to infer the data in the columns that are joined upon (i.e. plaintext recovery) using its auxiliary information and the observed access pattern.

Despite two different attack goals, the leakage of volumes from selections and from access patterns of joins are very similar. For both selects and joins, our attacks take as input some auxiliary information and observed leakage pattern. The output is a guess of which plaintext values correspond to which groups in the observed pattern. This guess has the same output format but will correspond to the predicted set of queries (select) or to the data values in the columns (join).

2 Background

Notation. Given a positive integer n, let $[n] = \{1, \ldots, n\}$. Similarly, for two integers $m < n$, we write $[m, n] = \{m, (m+1), \ldots, n\}$ (with the exception of $[0, 1]$, which represents the real numbers between 0 and 1). We write the image of a function $f : A \to B$ as $\mathrm{Im}(f) = \{b \in B : \exists a \in A, f(a) = b\}$.

We use $\mathrm{Dist}(A)$ to describe the set of distributions over a finite set A (i.e. a function $\rho : A \to [0, 1]$ is in $\mathrm{Dist}(A)$ if and only if $\sum_{a \in A} \rho(a) = 1$).

SQL Queries. We concern ourselves with two main SQL operations in this paper, selections and joins. In particular, we focus on how these operations work on one or two columns in a database, and we will define select and join operations abstractly, ignoring details such as projections, hierarchical joins, and returning columns not involved in the SQL query. This simplified view of joins and selects captures the necessary aspects of the operations to understand the leakage of encrypted SQL databases we attack. Figure 1 shows how these basic elements of SQL queries operate on the tables T_1 and T_2.

Figure 1: Examples of SQL type queries on tables T_1, T_2 and the output of example select and join operations.

We will treat columns as a list of N values $(r_1, \ldots, r_N)$. Each of these values comes from some set of n values $V = \{v_1, \ldots, v_n\}$. We refer to each element of the column as a "row" which takes on a single value (i.e. $r_i \in V$). In a traditional database, this may instead be called a cell or entry while a row refers to the cells across many columns. However, since our attacks use one column from each relevant table, we call these rows.

A *select* is performed with a predicate on a single table. The operation returns a list of rows from the table which return true for the predicate in question. The only predicate that we will consider in this paper is a simple equality predicate, so our selects will return all instances of one value in the column. For simplicity, we introduce a function which takes the equality predicate and the column being selected on and returns a set of indices corresponding to rows in the column which are equal to that value. For example, we write

$$\mathsf{SEL}(\texttt{Bob}, C_2) = \{1, 3, 5\},$$

as the abstracted selection from the example in Figure 1.

An (inner) *join* is performed between two tables on one column from each table. For our purposes, we only care about the result of the join on the two columns being joined upon, and all joins will be (equi)joins that return only matching values. So, a join will return a new column (or table generally) with a row for every matching pair of values between the first and second column. For simplicity, we consider the function to just output a set of matching tuples corresponding to matching rows. For example, we write

$$\mathsf{JOIN}(C_1, C_2) = \{(1,4),(3,4),(5,4),(1,6),(3,6),(5,6),\\ (7,1),(7,3),(7,5),(2,2),(4,2),(6,2)\},$$

for the join shown in Figure 1.

2.1 Related Work

We recall some alternative constructions for processing SQL queries with cryptographic tools. We additionally recall some of the leakage-abuse attacks against those and other related schemes.

Before using the structured encryption framework, some constructions used weaker or property-preserving primitives [41] to support a restricted class of SQL queries on a database. This sparked a line of work attacking these types of constructions [6, 7, 11, 26, 36, 37].

Meanwhile, the structured encryption framework was first introduced in [17]. The framework has since been used to create structurally encrypted databases supporting certain SQL queries [13, 32, 49]. Attacks against these systems, however, have only begun to be analyzed [19, 31], and the practical security of such systems remains an open question. However, other uses of the structured encryption framework are known to be vulnerable to other leakage-abuse attacks [10, 29, 42, 48].

Our select attacks are also applicable to searchable encryption schemes. This line of work focused on reducing leakage while maintaining efficiency. While early works had leakage equivalent to property-preserving schemes (and therefore are vulnerable to the same attacks), more recent work has given efficient schemes that leak only query and access patterns [12, 18]. Most leakage-abuse attacks introduced against such schemes have focused on specific schemes or different adversarial models and/or different leakage than what is considered in this work [4, 11, 22, 38, 42, 44, 46].

There is also a line of work considering generic leakage-abuse against such schemes which only exploit the search pattern, access pattern, or volume pattern without additional information [7, 20, 25, 34].

In addition to the structured encryption framework, there are approaches to encrypted search that make use of tools such as functional encryption [8], fully homomorphic encryption [21], oblivious RAM [24], or secure multiparty computation [5]. These schemes generally have less leakage but come at a significant theoretical and/or practical efficiency cost.

2.2 Comparison to Other Attacks

Before presenting our attacks, we take a closer look at some other approaches to leakage-abuse in prior work. This will identify some of our key differences and where we fit into the body of related literature.

We are the first to consider attacks against Structured Encryption (StE) for SQL; however, we will compare (mostly)

against attacks against Searchable Encryption (SSE), since there is some overlap between those attacks and attacks that apply to StE for SQL. For reference, a recent comparison of attacks against searchable encryption (SSE) is nicely summarized in prior work [45, 46]. We also discuss our own threat model in Section 1.1 in more depth and only focus on the differences between our work and other works.

First, many threat models against SSE or Dynamic SSE (DSSE) assume an active adversary [7, 47, 48], which allows for either data insertion or adversarial queries to be issued. In our work, we consider a weaker *passive* adversary who only tries to infer information about the underlying data or client activity.

Among the work on passive adversaries, there are attacks in which the adversary knows some or all of the underlying data [7, 11, 38, 46]. In our threat model, our adversaries only have access to only *distributional* information about the underlying data, a weaker assumption than partial knowledge. There are also attacks which work for adversaries without even this distributional assumption [7, 20, 25, 34].

The final difference that we consider is related to the type of leakage that is abused, which influences how present the adversary needs to be. For example, some prior work has considered "snapshot" or "smash-and-grab" adversaries [6, 19, 27, 37], who only access a server running an encrypted system once. In contrast, we consider a *persistent* adversary who observes the access pattern and activity of the server as queries are processed. We note, however, for some practical systems recent work has shown persistent adversary attacks may be possible from a single snapshot through the use of server logs [27].

The most similar work to our own are covered in a line of attacks such as [29, 39, 42]. These provide some of the most similar threat models to the ones that we consider. However, these attacks are against (sometimes specific) deployments of SSE rather than StE for SQL, which provides some key differences in the attack setting. For example, SSE deployed for keyword-document lookup will have the same document appear for different keywords, whereas two queries selecting on the same column with different values will never have rows overlap (for the restricted class of queries supported by StE for SQL schemes). This means that our attacks do not actually require access pattern leakage and could be run as a computer-in-the-middle with volume leakage.

Additionally, we are the first paper to consider any attacks against cross-column equality leakage, because this leakage pattern is unique to StE for SQL schemes and not present in previous SSE literature.

3 Leakage of Encrypted Databases

Leakage of select and join operations among current encrypted SQL database solutions broadly fall into a handful of categories. In this section, we will outline the type of leakage that we will provide attacks against. Broadly, we categorize our attacks into attacks against selections and attacks against joins.

3.1 Select Leakage

We begin by focusing on the *column equality* leakage pattern, which our attacks exploit in Section 4.

As prior work has observed, some SQL supporting schemes such as CryptDB [41] or Microsoft's Always Encrypted system [3] employ weakened primitives such as deterministic encryption to perform select operations by the server. These schemes will effectively reveal a deterministically created ciphertext of every row value in the column selected upon. The more formal leakage associated with this pattern is what we call the *complete column equality* (c-eq), because the server can check the equality between any two rows by checking if they are the same ciphertext.

This leakage pattern is well studied in prior work [6, 11, 26, 37]. However, we further this work by proving an optimality result and separation for one of the known attacks in Appendix A of the full version.

More recent work in structured encryption supports simple equality select operations without weakened primitives [13, 32, 49]. However, these encrypted SQL databases still leak the query equality and volume to an honest-but-curious server. Specifically, the server is able to know when a select is repeated (query equality) and which columns and rows are repeated between different queries.

For example, a client querying columns C_1 and C_2 from our example tables in Figure 1, may issues 4 select queries, corresponding to:

$$\mathsf{SEL}(\texttt{Ari}, C_1), \mathsf{SEL}(\texttt{Ari}, C_2), \mathsf{SEL}(\texttt{Bob}, C_1), \mathsf{SEL}(\texttt{Ari}, C_1)$$

and a server could learn that the first and last queries were the same and that the third query was on the same column as the first and last. However, they would not immediately know which specific values were queried. The final relevant aspect of this is that the server would know how many (and which) rows are returned to the client during each of the queries. In this toy example, this would allow a server to learn that there is some value in C_1 which appears 3 times (`Ari`), another that appears 1 time (`Bob`), and a value in C_2 which appears 2 times (`Ari`).

A server, after observing just a few queries, can determine the sizes of these *equality groups*, which are sets of row ciphertexts sharing the same underlying value.

After a client has queried every value in the relevant column, this leakage becomes equivalent to the complete equality leakage. However, before all values are queried, there can still be substantial leakage to the adversary. Especially in instances where a few values dominate most of the rows, this leakage could allow an adversary to infer a lot of the underlying information about the queries being performed.

	Complete	Incomplete
One-One	-	-
One-Many	c-eq	i-eq
Many-Many	c-cross	i-cross

Figure 2: Table showing the leakage available to a server depending on the join type.

Throughout this paper, we refer to this pattern as *incomplete column equality* or *partial equality* (i-eq). We explore this more fully and provide a new near-optimal attack against this leakage in Section 4.

Searchable Encryption. For simplicity, we discuss our attacks against this leakage in the context of encrypted SQL databases, but we observe that our attacks against encrypted SQL select queries can be applied directly to many searchable encryption (SSE) works. The majority of schemes from the SSE and encrypted multimap literature which achieve practical (i.e. linear) efficiency (e.g. [9,12,14,15,17,18,23,43]) and encrypted multimaps supporting simple equality predicates as a select operation will similarly leak the equality pattern of rows returned to an honest-but-curious server. Our attacks are novel in this setting provide a new approach to an existing line of work [29,39,42].

3.2 Join Leakage

There are a few techniques and constructions which provide support for server-computed joins on encrypted SQL databases. This includes the Adjustable Key Join technique used within CryptDB [41], the fully precomputed join indexes (SPX, OPX and FpSj [13,32,49]), and finally some structured encryption schemes with advanced security (Secure-Join and JXT [28,30]).

We identify generic and previously unanalyzed leakage present in every one of these schemes which we call the *cross-column equality* pattern. When issuing a join query, all of these schemes allow the server to observe pairs of rows which have matching values. This allows the server to observe the equality pattern of the rows which are output in the join. This reveals both the equality groups within each column (as with the column equality pattern), but additionally reveals the equality across the columns. For example, the join represented in Figure 1 would reveal to the server that there is some value (`Ari`) which occurs 3 times in C_1 and 2 times in C_2, another value (`Bob`) which occurs 1 time in C_1 and 3 times in C_2, and a third value (`Cal`) which occurs 3 times in C_1 and 1 time in C_2.

However, despite this generic leakage being shared across the proposed schemes, the *join type* of the join being performed informs how the leakage can be exploited, which we summarize in Figure 2. We distinguish join types by whether it is a one-one, one-many, or many-many join and whether the join is complete or incomplete.

The first set of terms inform the uniqueness of values in the columns joined on respectively. A one-one join has no repeated value in either column, a one-many join has no repeated value in one column, and a many-many join may have repeated values in either column. We call a join "complete" if every row has a matching row in the opposite column (i.e. the join outputs every row from both tables at least once), and otherwise the row is said to be incomplete. As an example, our join example in Figure 1, is an incomplete many-many join. It is incomplete because `Eve` does not appear in the join output, and it is many-many because both columns have values which appear multiple times (e.g. `Ari`).

For one-one joins (such as many primary key-foreign key joins), all the server observes is a set of encrypted row pairs, none of which repeat. So, there is no hope for a server, even with auxiliary information, to infer the underlying values.

During one-many joins, the server may observe that multiple rows, in the column allowing repeated values, match with the same value in the other column. This gives a server information about the sizes of equality groups in the column with the repeated values, since rows with the same value in the repeats column will be output with the same encrypted row in the unique column. When a join is complete and one-many, the cross-column equality pattern reduces to the complete column equality (c-eq) of the column with repeated values, and similarly, it reduces to the incomplete column equality (i-eq) when the join is incomplete.

Finally, while performing a many-many join, the server observes encrypted pairs of matching rows across the columns. This is a unique pattern which reveals more than just the equality within the columns. The adversary learns either the *complete cross-column equality* (c-cross) or the *incomplete cross-column equality* (i-cross), if the join is complete or incomplete respectively. This leakage is *strictly more* than the respective equality leakage of the two columns because the server learns both the equality group sizes within as well as across the columns in the join.

In this scenario, the server could run equality pattern attacks on the individual columns, but they may be able to outperform those attacks by knowing the rows which are equal between the two columns. In Section 5, we give new attacks which make use of this cross-column equality pattern and show that this additional leakage *does improve* the performance of inference attacks.

4 Select Query Recovery

In Section 3.1, we sketch how encrypted SQL systems leak the column equality pattern as queries are made. In this section, we consider this leakage more formally and outline a new attack against incomplete column equality and evaluate its performance against real-world data. In Appendix A of the full version, we prove that it is near-optimal as well.

Attack Model. The formalism for our leakage-abuse attacks follows that of prior work [6] but with some differences

in notation. The leakage input to our algorithms is a vector $\vec{c} = (c_1, \ldots, c_m, u)$ which contains the sizes of each of the m leaked "equality groups" (in ascending order without loss of generality) and finally the number of rows without an observed equality group is included as the number u, which can be computed from the leakage discussed in Section 3.1.

For example, if the a client made three queries on the column C_2 from Figure 1 corresponding to the sets:

$$\mathsf{SEL}(\texttt{Bob}, C_2), \mathsf{SEL}(\texttt{Cal}, C_2), \mathsf{SEL}(\texttt{Ari}, C_2),$$

then the server would learn three equality groups sizes 3, 1, and 2 respectively and would know there is 1 row (row 7) which had not been returned on any query. So such an adversary would have the leakage input $\vec{c} = (1, 2, 3, 1)$.

In addition to the leakage input, the adversary receives some auxiliary information in the form of a distribution over values, $\rho : V \to [0,1]$ where $\sum_{v \in V} \rho(v) = 1$. Intuitively, we expect this distribution to describe the plaintext distribution that the column values are each independently drawn from. In such a setting, we design our algorithms to find the most likely mapping between the equality groups and the plaintext values V. So, our attack outputs an injective function $f : [m] \to V$ which represents the guessed value that underlies each equality group. Throughout, we call this kind of function a *plaintext mapping*.

Optimality. We consider an attack optimal if it returns a function that maximizes the likelihood of observing the given equality groups, assuming that the plaintexts are drawn from the distribution ρ and that f is the true mapping. More formally, we want an algorithm which returns

$$\arg\max_{f} \Pr[\vec{c} | \mathbf{f} = f, \rho],$$

where $\mathbf{f}$ is the true plaintext mapping, modeled as a uniformly random injective function. This probability is shorthand, introduced in [6], for the probability that we would observe $\vec{c}$ if f were the true plaintext mapping and rows were independently sampled from ρ.

When analyzing this probability under these assumptions, we can write it in a convenient and simple form. Specifically, for the plaintext mapping f, we want to calculate the probability that we observe the vector $\vec{c} = (c_1, \ldots, c_m, u)$. So, we want the probability that $f(i)$ appears exactly c_i times for each $i \in [m]$.

First, we count the number of ways to arrange m values, $f(1), \ldots, f(m)$, exactly $c_1, \ldots, c_m$ times across the $N = u + \sum_i c_i$ rows in the column respectively. This number is exactly the multinomial coefficient

$$K_{\vec{c}} = \binom{N}{c_1, \ldots, c_m, u},$$

that depends only on $\vec{c}$.

Alg $\mathsf{SelAttack}^{\varepsilon}(\vec{c}, \rho)$

Let $(v_1, \ldots, v_n)$ be the elements of V in a ascending order of likelihood (i.e. $\rho(v_i) \le \rho(v_j)$ for all $i < j$).
Parse $(c_1, \ldots, c_m, u) \leftarrow \vec{c}$
Define $\mathsf{rnd}_{\varepsilon}(x) = \varepsilon \cdot \lceil \frac{x}{\varepsilon} \rfloor$
$(f, p) \leftarrow \mathsf{helper}(n, m, 0)$
Return f

Alg $\mathsf{helper}(i, j, \sigma)$

assert$(i \ge j)$
If $j = 0$ then
  For $k \in [i]$ do $\sigma \leftarrow \sigma + \rho(v_k)$
  Let $f(k) = \perp$ for all $k \in [m]$
  Return $(f, u \log \sigma)$
$(f_1, p_1) \leftarrow \mathsf{helper}(i-1, j-1, \sigma)$
$p_1 \leftarrow p_1 + c_j \log \rho(v_i)$
If $i > j$ then
  $(f_2, p_2) \leftarrow \mathsf{helper}(i-1, j, \mathsf{rnd}_{\varepsilon}(\sigma + \rho(v_i)))$
  If $p_1 < p_2$ then Return (f_2, p_2)
Set $f_1(j) = v_i$
Return (f_1, p_1)

Figure 3: Pseudocode for an attack against column equality leakage.

Next, we consider the probability that of any fixed ordering. Since we assume rows are independent samples, the probability that the rows in the equality groups take on the values f assigned is $\prod_i \rho(f(i))^{c_i}$, given our prior distribution. However, we also need that the u remaining values in the column are *not* in the observed equality groups, which happens with probability

$$\left(\sum_{v \in V \setminus \mathrm{Im}(f)} \rho(v) \right)^{u}$$

Putting this together, we can write the expression

$$\Pr[\vec{c} | \mathbf{f} = f, \rho] = K_{\vec{c}} \prod_{i=1}^{m} \rho(f(i))^{c_i} \cdot \left(\sum_{v \in V \setminus \mathrm{Im}(f)} \rho(v) \right)^{u}.$$

Complete Equality. Notice that when $m = |V|$, the summation drops out. Although this may seem insignificant, it simplifies the structure of the problem. In fact, this case is equivalent to when the complete column equality has been revealed and was directly studied in prior work [6,36,37]. In particular, prior work outlined three different attacks which use frequency analysis, norm-optimization, and bipartite matching respectively. The first and last of which were proven optimal in [36] and [6] respectively. We add to this line of work by proving in the full version that the attack using norm-optimization is optimal when using an ℓ^p-norm with $p > 1$ (Theorem 3) and not optimal when $p = 1$ (Theorem 4) in Appendix A.

4.1 Incomplete Equality

Unfortunately, when a server does not observe every equality group in a column, they cannot run the attacks from prior work, which all rely on the existence of a one-to-one mapping between equality groups and plaintext values. For example, it is unclear how to use frequency analysis in such a setting. One can match the most common plaintexts (based on the distribution ρ) with the largest observed equality groups, but this strategy does not yield an optimal plaintext mapping.

Our attack remedies this issue and works for any $m \leq |V|$. We present the pseudocode for $\mathsf{SelAttack}^{\varepsilon}$ in Figure 3, which details how we recursively compute a plaintext mapping. We sketch some of the intuition of the algorithm and informally why it is optimal.

This algorithm generalizes the frequency analysis attack from prior work [37]. In fact, when $m = |V|$, $\mathsf{SelAttack}^{\varepsilon}$ always outputs the mapping $f(i) = v_i$ where v_i is the ith least frequent element according to ρ. This is the only case that never takes the $i > j$ branch and therefore never rounds nor recurses more than once per call.

However when $m < |V|$, the algorithm sometimes takes the $i > j$ branch. And, each time it is taken, the algorithm is recursing and exploring assignments where v_i is not one of the observed equality groups (and adding this to the probability of the unobserved group). Whereas the normal branch is exploring paths where a c_j sized equality group corresponds to the v_i plaintext.

Without rounding, the end result would output an assignment and the logarithm of its corresponding probability (without the normalization constant),

$$\log\left(\prod_{i=1}^{m}\rho(f(i))^{c_i}\cdot\left(\sum_{v\in V\setminus \mathrm{Im}(f)}\rho(v)\right)^{u}\right)$$
$$= u\log\left(\sum_{v\in V\setminus \mathrm{Im}(f)}\rho(v)\right)+\sum_{i=1}^{m}c_i\log\rho(f(i)).$$

Additionally, we observe that any optimal plaintext mapping will never assign $f(i) = v_1$ and $f(j) = v_2$ when $c_i < c_j$ and $\rho(v_1) > \rho(v_2)$. This is formalized by Definition 2 and Lemma 1 in Appendix A, which says any optimal mapping is *non-crossing*. And this exactly characterizes the mappings that helper recursively considers.

Combining these facts shows that $\mathsf{SelAttack}^{\varepsilon}$ (without rounding) actually explores each of these potential optimal mappings along its recursive branches and only keeps the one with the highest probability (because $\log(\cdot)$ is an increasing function). So, $\mathsf{SelAttack}^{\varepsilon}$ returns an optimal plaintext mapping without rounding.

However when we introduce rounding, it allows us to bound the runtime of $\mathsf{SelAttack}^{\varepsilon}$ very easily. In practice, we supplement our recursive calls with memoization, a well known technique used often in dynamic programming. With memoization and rounding, helper can only receive at most $m\cdot|V|/\varepsilon$ inputs, giving us a runtime of $O(m\cdot|V|/\varepsilon)$. Without rounding, the input σ to helper could vary by just a little bit and still require more recursive calls, and there are many inputs that would run in exponential time (even with memoization). In Appendix A of the full version, we prove that this attack is still near optimal with some rounding (Theorem 5), so we benefit from both a bounded runtime and theoretical guarantees.

4.2 Experimental Evaluation

To supplement our theoretical bound on the performance of the algorithm, we simulate our attack against real-world data to better understand the practical implications of a near-optimal inference.

Setup. We run our experiments on public data from the city of Chicago.[2] Our experiments focus on reconstruction attacks over the taxi, crime, rideshare, and vehicle crash tables in the data from the years 2018 to 2022.[3] We attempt to reconstruct columns containing values for beats, community areas (CA), and speed limits. Further details about the data used in these and other experiments can be found in Appendix D.

We simulate a scenario where Chicago decides, in 2019, to keep their data more private. Specifically, they begin using a Structured Encryption for SQL scheme for their datasets and allow authorized users to make queries. We test the ability of an adversary observing the volumes of selections on the Chicago server to infer the values that a users is querying.

Our attacks use the already published 2018 Chicago tables as the auxiliary distribution ρ in our attacks. For each year 2019-2022, our adversary observes queries over some fraction of the values in the table. They then use $\mathsf{SelAttack}^{\varepsilon}$ to infer the value corresponding to each query. The equality group sizes the adversary observes and selected by either choosing a uniformly random subset of values from the value space or by sampling values randomly weighted according to the number of rows containing that value. For each year, fraction of equality groups revealed, and sampling method, we average over 10 independent trials.

Evaluation. To better understand the practical implications of a near-optimal plaintext mapping, we score our results using the value recovery rate (val-rec) and the row recovery rate (row-rec). These represent the fraction of values or rows inferred correctly in different ways.

More specifically, after m equality groups are revealed in $\vec{c} = (c_1,\ldots,c_m,u)$, we let $f : [m] \to V$ be the true mapping between the equality groups revealed and the underlying plaintext values.

Then, the value recovery rate (val-rec) for a plaintext mapping g is

$$\frac{|\{i\in[m] : f(m) = g(m)\}|}{m},$$

[2] https://data.cityofchicago.org/

[3] Note that there is less (and different) data for the 2020 and 2021 years in some tables, due to the COVID pandemic, which may have an impact on the accuracy of our auxiliary distributions in the attacks.

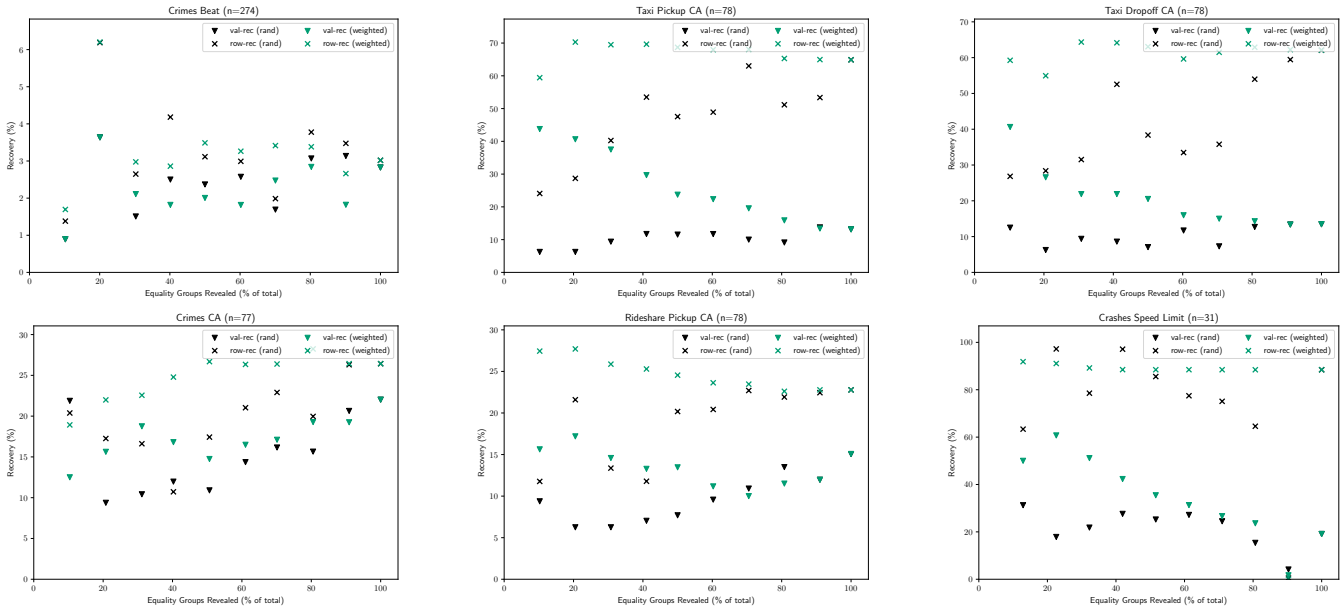

Figure 4: Summary graphs showing the value and row recovery rates for SelAttack$^{\varepsilon}$. We compare sampling values uniformly against sampling weighted by the frequency of the value. Each data point is averaged over the attacks on years 2019-2022 with 10 independently sampled runs for each year.

the number of values inferred correctly to the exact equality group divided by the total number equality groups revealed.

The row recovery rate (row-rec) for a plaintext mapping g and column $(r_1, \ldots, r_N) \in V^N$ is

$$\frac{|\{i \in [N] : r_i \in \mathrm{Im}(f) \wedge f^{-1}(r_i) = g^{-1}(r_i)\}|}{N-u},$$

the number of rows correctly inferred divided by the total number of rows observed.[4] This is similar to the value recovery rate but weighted toward values which appear frequently.

Results. In Figure 4, we present graphs charting how SelAttack$^{\varepsilon}$ performs as more equality groups are revealed. For each column we attack, the corresponding graph shows how our attack perform on average (for uniform and weighted sampling) as more equality groups are revealed. This corresponds to an adversary observing more and more queries from a client. One may expect that attacks would perform much worse when only a small subset of values are queried, but we find that our recovery rates are not heavily influenced by the fraction of values revealed.

Each attack we ran finished in under 40 seconds on an Intel i9 Macbook Pro, without significant optimization. Most would finish in just a few seconds, with the main exception being our Crimes Beat experiments when about 50% of the values were observed, which took 30-40 seconds. This was unsurprising, since this setting of many domain values with half being observed significantly increases the number of branches the algorithm must consider.

[4]For values $v \notin \mathrm{Im}(g)$, we let $g^{-1}(v) = \perp$

Our attack's performance depends on the distribution of the underlying data. Since our attack uses the expected frequencies of certain values, distributions which are very flat and spread across many values (e.g. beats from the crimes table) perform worse, only achieving val-rec of less than 5%. Where as more skewed data on smaller domains typically perform much better, achieving val-rec around 10-40%. Also our attack is very good at recovering the most frequent values, evidenced by our attacks against speed limits, and taxi data, which often get row-rec over 50%, even when values are selected uniformly at random.

Overall, this level of query recovery could be concerning for specific deployments of modern StE for SQL schemes. When a client performs selects on sensitive data, we show that a passive adversary may be able to infer key parts of the client's queries. If a client wants to hide what they do with their data, these attacks indicate that the leakage from these schemes is insufficient, when an adversary might have some prior knowledge over the data distribution.

5 Join Plaintext Recovery

Section 3.2 illustrates how state of the art structured encryption for SQL schemes leak the equality group sizes across the columns during a join. Notice that this leakage is more than just the equality group sizes in both columns. The adversary additionally learns which groups have the same plaintext across the columns.

Attack Model. The formalism for this attack extends the ideas put forward in prior work [6], by using a Bayesian

inference framework. The leakage input to our algorithms attacking cross-column equality are two vectors $\vec{c}_1 = (c_1, \ldots, c_m, u_1)$ and $\vec{c}_2 = (d_1, \ldots, d_m, u_2)$ which contain the sizes of each of the m observed *equality groups* across the two columns. Unlike the vector in Section 4, we cannot assume both of these are in ascending order without loss of generality. Instead, we assume that the equality groups corresponding to c_i and d_i have the same underlying plaintext value and that the observed group sizes of $\vec{c}_1$ are in ascending order. The number of rows without an observed equality group is u_1 and u_2 in the columns respectively, which can be computed from the leakage discussed in Section 3.2.

As an example from Figure 1, if we were to observe the leakage from the join corresponding to $\mathsf{JOIN}(C_1, C_2)$ then we would run our attacks with the observed vectors

$$\vec{c}_1 = (1, 3, 3, 0)$$

and

$$\vec{c}_2 = (3, 1, 2, 1),$$

which correspond to the values `Bob`, `Cal`, and `Ari` (followed by the number of unobserved rows), since we keep $\vec{c}_1$ in ascending order.

In addition to the observed leakage vectors, our algorithms take some auxiliary information as an input. Specifically they take two distributions ρ_1 and ρ_2 over the set of plaintext values V. These distributions describe the plaintext distribution that both columns have their values independently drawn from. In this setting, our algorithms have the goal to find the most likely mapping between the equality groups and the set of plaintext values V.

First Optimality Attempt. Unlike in Section 4, the optimality of our attacks against cross-column equality is not as straightforward. We put forward two possible theoretical objectives of attacks and argue to adopt the latter definition.

First, we parallel Section 4 closely and consider attacks which only output an injective function $f : [m] \to V$, called a *plaintext mapping*, which represents the guessed value that underlies each equality group. This is not the most an adversary could infer, since they additionally know that the rows in the two columns, which were not in the observed equality groups must be unequal from each other. However, this type of attack may capture most of what an adversary would care about and parallels its objective nicely with the attacks from prior work.

An attack of this sort optimal if it returns a plaintext mapping that maximizes the likelihood of observing the given equality groups, assuming that the columns' values are drawn from the distributions ρ_1 and ρ_2 respectively. More formally, an algorithm is optimal if it returns

$$\arg\max_{f} \Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \rho_1, \rho_2],$$

where $\mathbf{f}$ is the true plaintext mapping, modeled as a uniformly random injective function.

Using an analogous probability analysis, as the one made in Section 4, we can somewhat expand the expression for the probability of the observed equality groups for a plaintext mapping f. For vectors $\vec{c}_1 = (c_1, \ldots, c_m, u_1)$ and $\vec{c}_2 = (d_1, \ldots, d_m, u_2)$, we can expand the expression to

$$\Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \rho_1, \rho_2] = K_{\vec{c}_1, \vec{c}_2} T_1^{u_1} T_2^{u_2} P \prod_{i=1}^{m} \rho_1(f(i))^{c_i} \cdot \rho_2(f(i))^{d_i},$$

where $K_{\vec{c}_1, \vec{c}_2}$ is a normalization constant that depends only on the terms in the vectors and the terms

$$T_i = \sum_{v \in V \setminus \mathrm{Im}(f)} \rho_i(v),$$

the total probability of a sample lying outside of the image of f for the distribution ρ_i. Unfortunately, P does not have a clean expression in terms of our input variables, so we leave it in terms of $\mathbf{U}_i$ which is the set values from u_i independent samples of ρ_i conditioned on all u_i samples lying outside of the image of $\mathbf{f}$. With that notation, we can write

$$P = \Pr[\mathbf{U}_1 \cap \mathbf{U}_2 = \emptyset | \mathbf{f} = f, \rho_1, \rho_2],$$

the probability that the two unobserved rows in the two columns are never equal (since otherwise they would've comprised another equality group).

Optimality. We also consider attacks which output f and sets U_1 and U_2 with $U_1 \cap U_2 = \emptyset$ and $U_1 \cup U_2 \subseteq V \setminus \mathrm{Im}(f)$, which represent the guess at the most likely values among rows in the unobserved equality groups in the columns. This definition captures that maximum amount of information an attack could infer about the underlying data from $\vec{c}_1$ and $\vec{c}_2$, by determining the most likely values present in each column respectively. Similar to the other definitions, an attack would be optimal if it returns

$$\arg\max_{f, U_1, U_2} \Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \mathbf{U}_1 = U_1, \mathbf{U}_2 = U_2, \rho_1, \rho_2].$$

For attacks which output these sets, we consider the probability of the triple (f, U_1, U_2) in a more explicit expression. For vectors $\vec{c}_1 = (c_1, \ldots, c_m, u_1)$ and $\vec{c}_2 = (d_1, \ldots, d_m, u_2)$, we can write

$$\Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \mathbf{U}_1 = U_1, \mathbf{U}_2 = U_2, \rho_1, \rho_2] = K_{\vec{c}_1, \vec{c}_2} P(U_1, U_2) \prod_{i=1}^{m} \rho_1(f(i))^{c_i} \cdot \rho_2(f(i))^{d_i},$$

where $K_{\vec{c}_1, \vec{c}_2}$ is a normalization constant that depends only on the terms in the vectors, and

$$P(U_1, U_2) = \left(\sum_{v \in U_1} \rho_1(v) \right)^{u_1} \cdot \left(\sum_{v \in U_2} \rho_2(v) \right)^{u_2}$$

Alg $\mathsf{BM}(\vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$

Parse $(c_1, \ldots, c_n, 0) \leftarrow \vec{c}_1$ and $(d_1, \ldots, d_n, 0) \leftarrow \vec{c}_1$

Let $G = (G_\ell \cup G_r, E)$ be a weighted complete bipartite graph, where $G_\ell = \{\ell_1, \ldots, \ell_n\}$, $G_r = \{r_{v_1}, \ldots, r_{v_n}\}$ and the weight of each edge is

$$w(\{\ell_i, r_{v_j}\}) = c_i \cdot \log(\rho_1(v_j)) + d_i \cdot \log(\rho_2(v_j))$$

Use the Hungarian Algorithm to obtain M, the maximum weight matching for G

Return f where $f(i) = v_j$ if $\{\ell_i, r_{v_j}\} \in M$.

Figure 5: Bipartite matching algorithm BM for attacking complete cross-column equality.

is the probability that all the unobserved rows from the columns fall into U_1 and U_2 respectively.

When $m = |V|$, corresponding to attacking complete cross-column equality, the definitions are equivalent. Since there are no plaintext values outside of the image of f, there is no inference to make about the values outside of the join result. This means attacks only need to output a plaintext mapping f, and in this setting, we give an attack and prove that it is optimal.

When $m < |V|$, the two optimality objectives differ. We find that the latter definition is more useful from both theoretical and practical perspectives. For example, our attacks make use of efficient likelihood estimatation, and in Appendix C, we show that is in fact NP-hard to make an inference which outputs the most likely sets U_1, U_2 of unassigned plaintext values (Theorem 6). Additionally, this definition corresponds to the most an adversary can infer, which is the overarching goal of leakage-abuse attacks. Given these virtues, we stick with this as the standard definition for optimality.

5.1 Complete Cross-Column Equality

Our main attack for attacking complete cross-column equality uses bipartite matching, similar to one of the attacks for complete equality in prior work [6]. The BM algorithm begins by creating a bipartite graph based on the observed equality groups and auxiliary distributional information. A perfect matching in this graph corresponds directly to an assignment of equality groups to plaintext values.

By weighting the edges appropriately, the weight of any matching is just the logarithm of the probability an attack needs to maximize (up to a constant). So, BM just constructs such a graph and uses a subroutine to find a maximum weight bipartite matching, which can be converted into a plaintext mapping maximizing the target probability. We give the pseudocode for BM in Figure 5. Additionally, we prove the Theorem 1 that this attack is optimal, as an almost immediate corollary of the Hungarian Algorithm's correctness.

Theorem 1. *For every n element set V, $\vec{c}_1, \vec{c}_2 \in \mathbb{Z}^n \times \{0\}$ and $\rho_1, \rho_2 \in \mathrm{Dist}(V)$, $\mathsf{BM}(\vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$ (Figure 5) outputs a plaintext mapping g such that $\Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = g, \rho_1, \rho_2] = \max_f \Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \rho_1, \rho_2]$.*

Alg $\mathsf{Greedy}^\varepsilon(\vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$

$S \xleftarrow{s} \binom{V}{m}$; $\delta \leftarrow 1$

$(f, U_1, U_2, p) \leftarrow \mathsf{MapFromSet}^\varepsilon(S, \vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$

While $\delta > 0$ do

  $\delta \leftarrow 0$; $S' \leftarrow S$

  For each $(u, v) \in S' \times V \setminus S'$ do

    $S_{u,v} \leftarrow \{v\} \cup S \setminus \{u\}$

    $(f, U_1, U_2, p_{u,v}) \leftarrow \mathsf{MapFromSet}^\varepsilon(S_{u,v}, \vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$

    If $p_{u,v} - p > \delta$ then $S \leftarrow S_{u,v}$; $\delta \leftarrow p_{u,v} - p$

$(f, U_1, U_2, p) \leftarrow \mathsf{MapFromSet}^\varepsilon(S, \vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$

Return (f, U_1, U_2)

Alg $\mathsf{MapFromSet}^\varepsilon(S, \vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$

Parse $(c_1, \ldots, c_m, u_1) \leftarrow \vec{c}_1$ and $(d_1, \ldots, d_m, u_2) \leftarrow \vec{c}_2$

assert$(|S| = m)$

Let $\rho'_j(v) = \rho_j(v) / \sum_{v \in S} \rho_j(v)$ for $j = 1, 2$ and $v \in S$

$f \leftarrow \mathsf{BM}((c_1, \ldots, c_m, 0), (d_1, \ldots, d_m, 0), \rho'_1, \rho'_2)$

$(U_1, U_2) \leftarrow \mathsf{POAA}^\varepsilon(V \setminus S, \rho_1, \rho_2, u_1, u_2)$

$p \leftarrow \Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \mathbf{U}_1 = U_1, \mathbf{U}_2 = U_2, \rho_1, \rho_2]$

Return (f, U_1, U_2, p)

Figure 6: The algorithm $\mathsf{Greedy}^\varepsilon$ shows one way to optimize over the $\mathsf{MapFromSet}^\varepsilon$ function to find a likely plaintext mapping for incomplete cross-column equality.

Proof. Let $\vec{c}_1 = (c_1, \ldots, c_n, 0)$ and $\vec{c}_2 = (d_1, \ldots, d_n, 0)$. Let f be a function returned by $\mathsf{BM}(\vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$. Then, f is a function which maximizes

$$\sum_{i \in [n]} c_i \log \rho_1(f(i)) + d_i \log \rho_2(f(i)),$$

because the Hungarian Algorithm [35] always returns a maximizing function. But, observing this expression is $\log(\Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \rho_1, \rho_2])$ up to a constant factor (depending only on $\vec{c}_1, \vec{c}_2$) and that $\log(\cdot)$ is an increasing function leads us to conclude that such an f also maximizes $\Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \rho_1, \rho_2]$. □

5.2 Incomplete Cross-Column Equality

The two potential targets for incomplete cross-column equality both have issues when trying to find an effective and optimal leakage abuse attack. For attacks only returning a plaintext mapping, there isn't a very precise general formula for the likelihood of the observed data. And for attacks which maximize the amount they can infer, we show, in Theorem 6 that finding an optimal function is NP-hard in the worst case.

Despite these challenges, we give attacks which output a plaintext mapping f as well as sets U_1 and U_2 to infer the values in the unobserved rows. We do this because they are more general, can just be modified to only output the plaintext

mapping, and having a concrete formula allows us to adapt techniques used in our other leakage-abuse attack settings.

Partitioning Approximation. Throughout our attacks, we use our own Partitioning Optimization Approximation Algorithm (POAA) as a subroutine. The pseudocode for $\mathsf{POAA}^{\varepsilon}$ is in Figure 11 (Appendix B). After a plaintext mapping is chosen, $\mathsf{POAA}^{\varepsilon}$ approximately finds the best way to divide the remaining plaintext values between the two columns. It will then return sets U_1, U_2 which approximately maximize the value $P(U_1, U_2)$.

The algorithm is parameterized by a value $\varepsilon \in (0,1)$, which determines the precision of the approximation. As input, it takes the set of remaining plaintext values R, the distributions ρ_i, and the number of rows which were not in an equality group u_i for both columns ($i = 1, 2$). It returns two sets, which are the respective guesses for the most likely split of the remaining plaintext values across the columns.

Greedy Algorithm. The first approach for solving incomplete cross-column equality is to give a function that can be optimized using generic techniques. In Figure 6, we present $\mathsf{MapFromSet}^{\varepsilon}$ which takes a guess at which m plaintexts are present in the join output and returns a guess at the plaintext mapping, the split between the unassigned values, and the probability estimate for the returned tuple.

It works by first running the BM algorithm on the equality groups, and restricted to the set S to find a candidate plaintext mapping f. From there, it uses the $\mathsf{POAA}^{\varepsilon}$ algorithm on the remaining plaintext values to figure out an approximately good split U_1, U_2. Finally, the algorithm returns the (f, U_1, U_2) along with the approximate output probability of the triple.

We use $\mathsf{MapFromSet}^{\varepsilon}$ as a subroutine for $\mathsf{Greedy}^{\varepsilon}$ in Figure 6. The algorithm $\mathsf{Greedy}^{\varepsilon}$, chooses an initial guess for the set and incrementally chooses a value in the set and a value out of the set to swap. On each iteration, it makes the swap which increases the likelihood of the set the most. Once it can find no more improving swaps, the function returns the mapping for the best set that it iterated to. In our experiments, we run $\mathsf{Greedy}^{\varepsilon}$ with random starting points 5 times and take the most likely mapping returned, and we cap the number of iterations of the outer loop to $1/\varepsilon = 1000$.

Genetic Algorithm. We also use $\mathsf{MapFromSet}^{\varepsilon}$ as a subroutine for $\mathsf{Genetic}^{\varepsilon,k,g,t,\gamma}$ in Figure 7. Our algorithm is inspired by genetic algorithms from machine learning. At a high level, the goal is to treat the probability as a "fitness function," and like genetic selection, we keep "fit" sets and also randomly mutate sets across generations. Over many generations, the goal is to achieve a more fit population and to pick out the best plaintext mapping from the last generation.

In addition to the typical ε, $\mathsf{Genetic}^{\varepsilon,k,g,t,\gamma}$ is parameterized by k, g, t, and γ, which correspond to the population size, generation number, tournament size, and mutation rate respectively. Once these are specified, the algorithm generates k sets of candidate plaintext set guesses and then proceeds to run for g generations, each time testing the likelihood of all

Alg $\mathsf{Genetic}^{\varepsilon,k,g,t,\gamma}(\vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$

$(S_1, \ldots, S_k) \leftarrow\!\$ \binom{V}{m}^p$
For $i = 1, \ldots, g$ do
  For $j = 1, \ldots, k$ do
    $(f, U_1, U_2, p_j) \leftarrow \mathsf{MapFromSet}^{\varepsilon}(S_j, \vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$
  $(p_1, S_1), \ldots, (p_k, S_k) \leftarrow \mathsf{DESC}((p_1, S_1), \ldots, (p_k, S_k))$
  For $j = 1, \ldots, k$ do
    If $j \le \frac{k}{10}$ then $S'_j \leftarrow S_j$
    If $\frac{k}{10} < j \le \frac{9k}{10}$ then
      $\ell \leftarrow\!\$ \mathsf{TournamentSelection}(t, k)$
      $S'_j \leftarrow\!\$ \mathsf{Mutate}(\gamma, S_\ell)$
    If $\frac{9k}{10} < j$ then
      $\ell \leftarrow\!\$ \{1, \ldots, k\}$; $S'_j \leftarrow S_\ell$
  $(S_1, \ldots, S_k) \leftarrow (S'_1, \ldots, S'_k)$
$(f, U_1, U_2, p) \leftarrow \mathsf{MapFromSet}^{\varepsilon}(S_1, \vec{c}_1, \vec{c}_2, \rho_1, \rho_2)$
Return (f, U_1, U_2)

Alg $\mathsf{TournamentSelection}(t, k)$

$T \leftarrow\!\$ [k]^t$; Return $\min(T)$

Alg $\mathsf{Mutate}(\gamma, S)$

$c \leftarrow\!\$ [\gamma]$; $U \leftarrow\!\$ \binom{S}{c}$; $U' \leftarrow\!\$ \binom{(V \setminus S) \cup U)}{c}$; Return $(S \setminus U) \cup U'$

Figure 7: The $\mathsf{Genetic}^{\varepsilon,k,g,t,\gamma}$ attack uses $\mathsf{MapFromSet}^{\varepsilon}$ (Figure 6) as subroutine. Note that min will return the smallest element of the tuple T and DESC returns the tuples in sorted descending order by the first entry (the likelihood).

candidates, keeping the top 10%, a tournament selected 80% (which get mutated), and finally randomly selecting 10%, to keep the population size at k. After g generations, the function turns the most likely set into a solution for the incomplete cross-column problem using $\mathsf{MapFromSet}^{\varepsilon}$ and returns the result.

Split Algorithm. Unlike our incremental optimization, we give a single shot attack in Figure 8 as well as a slightly generalized version, which just takes the best output of a few runs. Our main leakage-abuse attack however, is $\mathsf{Split}^{\varepsilon,\phi_1,\phi_2}$, which is parameterized by a parameter ε used for the $\mathsf{POAA}^{\varepsilon}$ algorithm and distributions ϕ_1, ϕ_2 over the integers $[m+1, n] = \{m, m+1, \ldots, n\}$ (or any superset of this set).

The high level idea is to use the distributions ϕ_1, ϕ_2 as "guesses" of the underlying distribution of the data in the two columns. The algorithm will approximately partition (split) this guessed distribution first, then construct two new observation vectors with terms c'_i and d'_i respectively based on the partitioning returned. These new vectors create an instance of a complete cross-column equality pattern, and so we can run our optimal attack BM with them. Once, we get back a function g, we find the values corresponding to the equality groups f and the plaintext values which correspond to the sets previously split sets.

Because this attack runs in one shot, it is also easy to enumerate over many distribution pair guesses and find one which

Alg $\mathsf{Split}^{\varepsilon,\phi_1,\phi_2}(\vec{c}_1,\vec{c}_2,\rho_1,\rho_2)$

Parse $(c_1,\ldots,c_m,u_1) \leftarrow \vec{c}_1$ and $(d_1,\ldots,d_m,u_2) \leftarrow \vec{c}_2$

$(S_1,S_2) \leftarrow \mathsf{POAA}^{\varepsilon}([m+1,n],\phi_1,\phi_2,u_1,u_2)$

Let $c'_i = \begin{cases} c_i & \text{for } 1 \le i \le m \\ (u_1+u_2)\cdot\phi_1(i) & \text{if } i \in S_1 \\ 0 & \text{if } i \notin S_1 \end{cases}$

Let $d'_i = \begin{cases} d_i & \text{for } 1 \le i \le m \\ (u_1+u_2)\cdot\phi_2(i) & \text{if } i \in S_2 \\ 0 & \text{if } i \notin S_2 \end{cases}$

$g \leftarrow \mathsf{BM}((c'_1,\ldots,c'_n,0),(d'_1,\ldots,d'_n,0),\rho_1,\rho_2)$

Let $f(i) = g(i)$ for $1 \le i \le m$

Let $U_j = \{f(i) : i \in S_j\}$ for $j = 1,2$

Return (f,U_1,U_2)

Alg $\mathsf{Split}^{\varepsilon,\Phi}(\vec{c}_1,\vec{c}_2,\rho_1,\rho_2)$

For each $(\phi_1,\phi_2) \in \Phi$ do

  $(f,U_1,U_2) \leftarrow \mathsf{Split}^{\varepsilon,\phi_1,\phi_2}(\vec{c}_1,\vec{c}_2,\rho_1,\rho_2)$

  $p_{\phi_1,\phi_2} \leftarrow \Pr[\vec{c}_1,\vec{c}_2|\mathbf{f}=f,\mathbf{U}_1=U_1,\mathbf{U}_2=U_2,\rho_1,\rho_2]$

$(\phi'_1,\phi'_2) \leftarrow \arg\max_{(\phi_1,\phi_2)\in\Phi} p_{\phi_1,\phi_2}$

Return $\mathsf{Split}^{\varepsilon,\phi'_1,\phi'_2}(\vec{c}_1,\vec{c}_2,\rho_1,\rho_2)$

Figure 8: The $\mathsf{Split}^{\varepsilon,\phi_1,\phi_2}$ attack against incomplete cross column equality parameterized by distributions ϕ_1,ϕ_2. The second $\mathsf{Split}^{\varepsilon,\Phi}$ attack is parameterized by a set of distribution pairs Φ and returns the best solution from among those pairs.

returns a solution that gives a higher likelihood than the others. This is what we present as $\mathsf{Split}^{\varepsilon,\Phi}$ which is parameterized by a set of distribution pairs. This is more likely to give a better solution, because it can take many guesses at the underlying distributions of plaintext values. The common distributions pairs to try are the uniform distributions and zipfian distributions. We can also change the domain of ρ_1 and ρ_2 from V to $[n]$, where the most likely element to appear is 1, then 2 and so on, and use such a distribution for the $\mathsf{Split}^{\varepsilon,\phi_1,\phi_2}$ function.

5.3 Experimental Evaluation

Setup. We test the practical performance of our leakage-abuse attacks against join leakage from real-world data. We use public data from the city of Chicago[5] which has multiple datasets with columns of common types. We use the taxi, crime, rideshare, and vehicle crash tables from the years 2018-2022 to provide join leakage.[6] Further details about the data used in these and other experiments can be found in Appendix D.

As in Section 4, we simulate a scenario where Chicago decides, in 2019, to keep their data more private. Specifically, they begin using a Structured Encryption for SQL scheme for the tables in question and allow authorized users to query the datasets. We test the ability of an adversary observing the join access pattern on the Chicago server to infer the values in the tables joined on, using the 2018 data as a prior distribution.

Between the taxi and crimes tables, we simulate a join between the pickup community area (CA) and the community area in which a crime occurred as well as the drop-off community area and the community area of a crime. Between the crime and crashes tables, we simulate a join between the beat in which a crime occurred and the beat in which a crash occurred.

For each of these potential joins and every year 2019-2022, we use the 2018 year table as an auxiliary distribution to estimate the column's plaintext distribution for the year we are attacking. We then calculate the cross-column leakage for the year and the columns we are joining. Finally, we take the auxiliary distributions and leakage and run our attacks $\mathsf{Greedy}^{\varepsilon}$, $\mathsf{Genetic}^{\varepsilon,k,g,t,\gamma}$, and $\mathsf{Split}^{\varepsilon,\Phi}$. We compare against a "no-cross" attack which runs $\mathsf{SelAttack}^{\varepsilon}$ on each column's equality group leakage, runs $\mathsf{POAA}^{\varepsilon}$ to partition the remaining plaintext values, and returns the more likely of the two plaintext mappings. We include this to compare between cross-column and column equality more directly, to see how much more devastating an adversary is with the additional leakage between columns.

Evaluation. We evaluate our results using the value and row recovery rates just as in Section 4. For cross-column leakage-abuse attacks, the scoring formulas for the value and row recovery rates in an experiment with m observed values are

$$\frac{|\{i \in [m] : f(m) = g(m)\}|}{m},$$

and

$$\frac{|\{i \in [N_1+N_2] : r_i \in \mathrm{Im}(f) \wedge f^{-1}(r_i) = g^{-1}(r_i)\}|}{N_1+N_2-(u_1+u_2)},$$

respectively, where g is the output plaintext mapping, f is the true plaintext mapping, and the join takes place on columns $(r_1,\ldots,r_{N_1})$ and $(r_{N_1+1},\ldots,r_{N_1+N_2})$. These two formulae capture the fraction of values correctly identified and fraction of rows correctly identified respectively.

Results. We summarize some of our cross-column attacks in Figure 9. For all of our attacks we take $\varepsilon = 0.001$. For our $\mathsf{Genetic}^{\varepsilon,k,g,t,\gamma}$ algorithm, we set $k = 30, g = 15, t = 5$, and $\gamma = 0.2m$, and for $\mathsf{Split}^{\varepsilon,\Phi}$ we try all pairs of the uniform distribution, zipfian distribution, and tail of the auxiliary distribution for each column (for a total of 9 calls to $\mathsf{Split}^{\varepsilon,\phi_1,\phi_2}$). The "no-cross" algorithm is an attack which does not use the the cross-column equality pattern and instead just uses the column equality for each column. Specifically, it runs $\mathsf{SelAttack}^{\varepsilon}$ on each column and uses $\mathsf{POAA}^{\varepsilon}$ to partition any remaining values between the columns. It then returns the more likely triple between the results from the first and second columns.

For every experiment, except Crime vs Crash Beat, each attack we ran finished in under 30 seconds and usually in

[5] https://data.cityofchicago.org/

[6] Note that there is less (and different) data for the 2020 and 2021 years in some tables, due to the COVID pandemic, which may have an impact on the accuracy of our auxiliary distributions in the attacks.

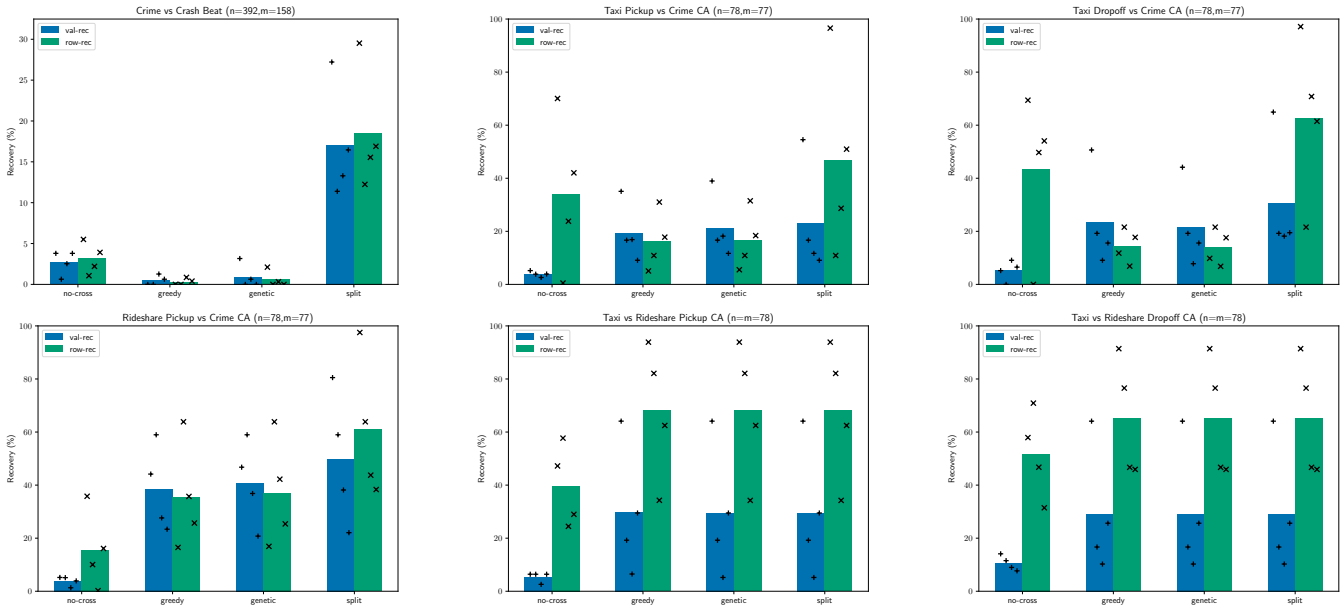

Figure 9: Summary graphs showing performance of our attacks, using cross-column leakage. We indicate the performance of each year using "+" and "x" marks, which represent 2019-2022 from left to right within each bar. Notice that when $n = m$, our attacks reduce to running BM and have the same output.

less than a second on an Intel i9 Macbook Pro, without significant optimization. For Crime vs Crash Beat, our no-cross and Genetic$^{\varepsilon,k,g,t,\gamma}$ algorithms took 3-4 minutes, and Greedy$^{\varepsilon}$ took about an hour. Fortunately, our (overall) best algorithm Split$^{\varepsilon,\Phi}$ is also our most efficient! It only took about 5 seconds to run on Crime vs Crash Beat instances and was less than half a second on all of the other experiments.

Based on our experiments, the cross-column equality pattern allows an adversary to recover substantially more than attacks using only the equality leakage from each column. This is most highlighted by a simulated join between the "beats" column from the crimes table and the one from the crash table. The Split$^{\varepsilon,\Phi}$ algorithm vastly out-performs all other others, recovering over 15% of values and rows on average, versus the others which are all under 5%. This pattern is displayed across our other joins as well, although often to a lesser extent. And, the baseline is generally good at recovering the values which occur in many rows, but additional cross-column information still improves that recovery.

In a deployment of a modern StE for SQL scheme, this cross-column leakage is revealed entirely when a join is performed on the server, which only takes one query. So, when a database is stored with StE for SQL, it is important to understand what a passive adversary could infer, given some prior distributional information. We conclude that if a client wants to keep adversaries from inferring underlying plaintext values, then StE for SQL schemes may give insufficient protection, especially in settings where databases store sensitive information.

6 Conclusion

Based on our theoretical and empirical results, we find that modern Structured Encryption for SQL schemes [13, 32, 49] are often not significantly more secure than older schemes supporting SQL with property-preserving encryption. In some contexts, this level of security carries acceptable risk and can still be used. However, one should take caution using these schemes for databases which contain sensitive information.

In our introduction, we also discuss some of the limitations of these findings and possible mitigations. Specifically, using certain primitives [33, 40] or "heavy weight" cryptography [5, 8, 21, 24] can be used to help with mitigation. However, all the solutions proposed come at some cost to the server or client computation and/or the bandwidth.

Acknowledgments

Support for this work's researchers was provided primarily by DSO National Laboratories. We thank the high-school interns whose exploratory work helped inspired this project: Ming Kee Kang, Ananya Kharbanda, Allison Law, Jemma Lee, Megan Lee, Chelsea Ling Xinyi, Cadence Loh, and Naomi Wang. We thank Eileen Ee and Ryan Seah for their help supporting the interns, and thank David Cash for writing advice.

Availability

Our code can be found at https://github.com/ste4sql/LAA4STE4SQL. Appendix D contains details about data used.

A Column Equality Theory

This section contains theorems and proofs omitted from the main text for brevity. We recall an attack from prior work in Figure 10. The following definition and lemma are useful in proofs below.

Definition 2. *Let V be an n element set, $m \le n$ be an integer, $\vec{c} = (c_1,\ldots,c_m,u) \in \mathbb{Z}^{m+1}$, and $\rho \in \mathrm{Dist}(V)$. We call a function $f : [m] \to V$* non-crossing *if for any $i, j \in [m]$*

$$\rho(f(i)) < \rho(f(j)) \implies c_i \le c_j \text{ and}$$
$$c_i < c_j \implies \rho(f(i)) \le \rho(f(j)).$$

Lemma 1. *Let V be an n element set, $m \le n$ be an integer, $\vec{c} = (c_1,\ldots,c_m,u) \in \mathbb{Z}^{m+1}$, and $\rho \in \mathrm{Dist}(V)$. Then, if f maximizes $\Pr[\vec{c}|\mathbf{f} = f,\rho]$, then f is non-crossing.*

We defer the proof of Lemma 1 to the full version.

Theorem 3. *For every n element set V, $\vec{c} \in \mathbb{Z}^n \times \{0\}$ and $\rho \in \mathrm{Dist}(V)$, and $p > 1$ $\mathsf{L}_p(\vec{c},\rho)$ outputs a plaintext mapping g such that $\Pr[\vec{c}|\mathbf{f} = g,\rho] = \max_f \Pr[\vec{c}|\mathbf{f} = f,\rho]$.*

We defer the proof of Theorem 3 to the full version.

Theorem 4. *There exists a 4 element set V, $\vec{c} \in \mathbb{Z}^5$, and $\rho \in \mathrm{Dist}(V)$, such that $\mathsf{L}_1(\vec{c},\rho)$ may output a plaintext mapping g such that $\Pr[\vec{c}|\mathbf{f} = g,\rho] < \max_f \Pr[\vec{c}|\mathbf{f} = f,\rho]$.*

We defer the proof of Theorem 4 to the full version.

Theorem 5. *Let $\varepsilon > 0$, V be an n element set, $m < n$ be an integer, $\vec{c} = (c_1,\ldots,c_m,u) \in \mathbb{Z}^{m+1}$ (with $u \ge 1$) and $\rho \in \mathrm{Dist}(V)$ with $\rho(v) \ge \varepsilon$ for all $v \in V$. Then, $\mathsf{SelAttack}^{\varepsilon}(\vec{c},\rho)$ outputs a plaintext mapping $g : [m] \to V$ such that*

$$\Pr[\vec{c}|\mathbf{f} = g,\rho] \ge (\max_f \Pr[\vec{c}|\mathbf{f} = f,\rho]) - O(u(n-m)\varepsilon),$$

Alg $\mathsf{POAA}^{\varepsilon}(R, \rho_1, \rho_2, u_1, u_2)$
If $u_1 = 0$ return $(\emptyset, R)$
If $u_2 = 0$ return $(R, \emptyset)$
$\{v_1, \ldots, v_r\} \leftarrow R$
$T_1 \leftarrow \sum_{i \in [r]} \rho_1(v_i)$; $T_2 \leftarrow \sum_{i \in [r]} \rho_2(v_i)$
Define $\mathsf{rnd}_{\varepsilon}(x, y) = (\varepsilon T_1 \cdot \lceil \frac{x}{\varepsilon T_1} \rfloor, \varepsilon T_2 \cdot \lceil \frac{y}{\varepsilon T_2} \rfloor)$
$\mathbf{T}[\mathsf{rnd}_{\varepsilon}(\rho_1(v_1), 0)] \leftarrow (\{v_1\}, 1)$
$\mathbf{T}[\mathsf{rnd}_{\varepsilon}(0, \rho_2(v_1))] \leftarrow (\emptyset, 1)$
For $i = 2, \ldots, r$:
  For $(x, y) \in \mathbf{T}.\mathsf{keys}()$
    $(S, c) \leftarrow \mathbf{T}[(x, y)]$
    If $c = i - 1$ then
      $\mathbf{T}[\mathsf{rnd}_{\varepsilon}(x + \rho_1(v_i), y)] = (S \cup \{v_i\}, i)$
      $\mathbf{T}[\mathsf{rnd}_{\varepsilon}(x, y + \rho_2(v_i))] = (S, i)$
$m \leftarrow 0$; $S' \leftarrow \emptyset$
For $(x, y) \in \mathbf{T}.\mathsf{keys}()$
  $(S, c) \leftarrow \mathbf{T}[(x, y)]$
  $p \leftarrow (\sum_{v \in S} \rho_1(v))^{u_1} (\sum_{v \in R \setminus S} \rho_2(v))^{u_2}$
  If $c = r$ and $p > m$ then
    $m \leftarrow p$; $S' \leftarrow S$
Return $(S', R \setminus S')$

Figure 11: Pseudocode for $\mathsf{POAA}^{\varepsilon}$.

when $\varepsilon > 0$.

We defer the proof of Theorem 5 to the full version.

B Partition Optimization

In this section, we discuss our new Partitioning Optimization Approximation Algorithm (POAA). As written, $\mathsf{POAA}^{\varepsilon}$ uses time an space $O(|R|/\varepsilon^2)$ in a word-RAM model. The same functionality can be performed using only $O(|R|/\varepsilon)$ time and space. The idea is that we do not need to keep track of both dimensions of the sums. Instead, we can just keep track of the largest y available at that point for a given x sum, which is the version used in our experiments.

We further observe that the algorithm could be further optimized to use only $O(|R| + \frac{1}{\varepsilon})$ space at the cost of some time by only tracking the possible sums and recursively reconstructing the sets after the best sum is found. We leave this code out of the paper for brevity and because we didn't need the space improvement in our experiments.

C Hardness of Optimal Inference

In this section, we use the optimality definition from Section 5 which requires an attack to return a triple (f, U_1, U_2) which maximizes $\Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \mathbf{U}_1 = U_1, \mathbf{U}_2 = U_2, \rho_1, \rho_2]$. For concreteness in the proof, we explicitly state the constant implied in Section 5,

$$K_{\vec{c}_1, \vec{c}_2} = \binom{N_1}{c_1, \ldots, c_m, u_1} \binom{N_2}{d_1, \ldots, d_m, u_2},$$

	Crime	Taxi	Rideshare	Crashes
2018	268,820	20,732,089	14,735,872	118,950
2019	261,297	16,477,366	22,783,672	117,763
2020	212,185	3,889,033	53,561	92,092
2021	208,775	3,948,046	11,150	108,764
2022	238,758	6,382,426	21,467,407	108,398

Figure 12: The number of rows for each table by year.

the product of two multinomial coefficients, with $N_1 = u_1 + \sum_i c_i$ and $N_2 = u_2 + \sum_i d_i$.

We go on to define the DICI problem below, which is strictly easier than finding the maximizing triple (f, U_1, U_2).

Name: Decision Incomplete Cross Inference (DICI)
Given: Two integers with $m < n$, a number $t \in [0, 1]$, $\vec{c}_1 \in [n]^{m+1}$ and $\vec{c}_2 \in [n]^{m+1}$ and distributions ρ_1 and ρ_2 over $[n]$ and. [7]
Question: Does there exist a triple (f, U_1, U_2) such that $\Pr[\vec{c}_1, \vec{c}_2 | \mathbf{f} = f, \mathbf{U}_1 = U_1, \mathbf{U}_2 = U_2, \rho_1, \rho_2] \geq t$?

Theorem 6. *Decision Incomplete Cross Inference (DICI) is NP-hard.*

We defer the proof of Theorem 6 to the full version.

D Experimental Data and Results

In our experiments, we use data made public by the city of Chicago.[8] In particular, we using datasets of crimes,[9] taxi rides,[10] rideshare services,[11] and car crashes[12] for years between 2019 and 2022. Information about the number of rows can be found in Figure 12. The lack of data for the 2020 and 2021 years likely negatively impacted our experiments, but we were still able to attack these anomalous years.

[7] Formally, this problem only takes in t and distributions which can be described using $\mathsf{poly}(n)$ bits, rather than all real numbers.

Abstract

The RADIUS protocol is the de facto standard lightweight protocol for authentication, authorization, and accounting (AAA) for networked devices. It is used to support remote access for diverse use cases including network routers, industrial control systems, VPNs, enterprise Wi-Fi including the Eduroam network, Linux Pluggable Authentication Modules, and mobile roaming and Wi-Fi offload.

We have discovered a protocol vulnerability in RADIUS that has been present for decades. Our attack allows a man-in-the-middle attacker to authenticate itself to a device using RADIUS for user authentication, or to assign itself arbitrary network privileges. Our attack exploits an MD5 chosen-prefix collision on the ad hoc RADIUS packet authentication construction to produce Access-Accept and Access-Reject packets with identical Response Authenticators, allowing our attacker to transform a reject into an accept without knowledge of the shared secret between RADIUS client and server.

We optimize the MD5 chosen-prefix attack to produce collisions online in less than five minutes, and show how to fit the collision blocks within RADIUS attributes that will be echoed back from the server. We demonstrate our attack in a variety of settings against popular RADIUS implementations.

It is our hope that this attack will provide the impetus for vendors and the IETF to deprecate RADIUS over UDP, and to require RADIUS to run over secure channels with modern cryptographic privacy and integrity guarantees.

1 Introduction

The RADIUS (Remote Authentication Dial-In User Service) protocol is at the core of today's network infrastructure. Although the protocol was first designed in 1991—during the era of dial-up internet—it remains the de facto standard lightweight authentication protocol used for remote access for users and administrators to networked devices. RADIUS is supported by "essentially every switch, router, access point, and VPN concentrator product sold in the last twenty years" [19].

RADIUS is a critical part of modern telecommunications and enterprise networks. In large enterprises, RADIUS may control access to tens of thousands of switches. Essentially all ISPs offering DSL or FTTH (Fiber to the Home) use RADIUS, as do 802.1X and Wi-Fi authentication [16, 51]. RADIUS is used for 2G and 3G cellular roaming [4, 9] and 5G DNN (Data Network Name) authentication [51]. (3G+ networks may use its successor Diameter.) Mobile Wi-Fi offload with SIM card-based authentication uses RADIUS [16, 51], as does private APN (Access Point Name) authentication, which is used by IoT devices, companies, fire and rescue services, or law enforcement to gain access to non-public networks [37, 45]. SITA uses RADIUS to authenticate passenger aircraft worldwide for telemetry data [44]. Siemens and GE smart grid products use RADIUS [1, 25]. Eduroam shares Wi-Fi to roaming users at educational institutions in 100 countries through a global hierarchy of networked RADIUS servers that saw 7.5 billion authentications in 2023 [32]. The Wireless Broadband Alliance OpenRoaming federation also uses RADIUS.

Much of this RADIUS traffic is sent over UDP. The first hop between a NAS (Network Access Server) and RADIUS server is "almost always" over UDP [16]. While it is possible to send RADIUS traffic over TLS or IPsec, this is typically only done for packets traveling over the open internet; currently only rare security-oriented organizations use RADIUS/TLS internally [16, 51]. Although sending RADIUS/UDP traffic over the internet is discouraged, it still happens. "A majority" of country eduroam networks still send RADIUS/UDP traffic on the internet [38] as do some "cloud" providers [18]. At least one major RADIUS vendor has no TLS support at all [16].

1.1 Our Attack

The core of the RADIUS protocol predates modern secure cryptographic design. Surprisingly, in the two decades since Wang et al. [52] demonstrated an MD5 hash collision in 2004, RADIUS has not been updated to remove MD5. In fact, RADIUS appears to have received notably little security analysis given its ubiquity in modern networks.

In a RADEXT working group Internet-Draft from 2023 entitled "Deprecating Insecure Practices in RADIUS" [18] Alan DeKok, the lead maintainer of FreeRADIUS—the most widely used RADIUS implementation—wrote

> As of the writing of this specification, RADIUS/UDP is still widely used, even though it depends on MD5 and "ad hoc" constructions for security. While MD5 has been broken, it is a testament to the design of RADIUS that there have been (as yet) no attacks on RADIUS Authenticator signatures which are stronger than brute-force.

In this paper, we give an attack against the ad hoc RADIUS Response Authenticator "signature" (actually a MAC) construction. This protocol flaw has been present in RADIUS since the earliest versions [43].[1]

In RADIUS, a NAS acts as a client that verifies an end user's credentials via RADIUS requests to a central server. The server responds with an accept or reject message (or a further challenge). Our attack allows a man in the middle between the RADIUS client and server to forge a valid Access-Accept response to a failed authentication request. This forgery will cause the NAS to grant the adversary access to network devices and services without the adversary guessing or brute forcing passwords or shared secrets.

Our attack combines an MD5 chosen-prefix collision [48] with a protocol exploit that allows us to hide the collision gibberish in an attribute that is guaranteed to be echoed in the server response. The Response Authenticator used to integrity protect server responses is an MD5 hash of several values including a random client nonce, protocol attributes, and a fixed secret shared between client and server. Our man-in-the-middle attacker injects a maliciously constructed attribute into the request that is designed to produce an MD5 collision between the Response Authenticator authenticating the server's legitimate response and the attacker's forged response.

To carry out this attack, the attacker must compute an MD5 chosen-prefix attack online, before the client times out, because the hash collision includes a random session nonce.

We are able to compute this MD5 chosen-prefix attack in about five minutes by making several improvements to Stevens's [46] open-source `hashclash` chosen-prefix attack implementation. We give a novel method to force bytes in collision blocks that allows us to fit the resulting MD5 collisions into the bounded length of a RADIUS protocol attribute.

Although we have stopped our engineering efforts at the five minute mark, our reported running times are a generous upper bound on the capabilities of a well-resourced attacker. Every step of the collision algorithm parallelizes well. An attacker able to implement the attack on GPUs, FPGAs, or hardware would be tens to hundreds of times faster.

We carried out proof of concept attacks against illustrative use cases of RADIUS. These include the default FreeRADIUS client and server implementation, the Okta service's RADIUS integration, a Cisco ASA firewall, and Linux PAM authentication via RADIUS. These targets were chosen due to availability; essentially all implementations are vulnerable by default because the underlying vulnerability is in the protocol.

[1] Although the chosen-prefix MD5 collision attack we use dates from 2007, the first weakness in the MD5 hash function was publicly documented in 1993, SHA-1 was published in 1995, and HMAC dates from 1996 [6]. RFC 5080 [34] noted in 2007 that Access-Request packets not containing a Message-Authenticator attribute may be trivially forged.

1.2 RADIUS/UDP should be deprecated

The `hashclash` software that we build on was also used in 2009 and 2016 to demonstrate attacks against TLS certificates [48] and protocol transcript hash authentication for TLS and SSH [7]. The MD5 hash function has been known not to be collision resistant for two decades, and has had known weaknesses for three. Today, a lack of explicit attacks against the use of MD5 in a protocol is more likely to be a sign of lack of cryptanalytic attention than any robust notion of security.

DeKok's Internet Draft continues

> We recognize that RADIUS/UDP will still be in use for many years, and that new standards may require some modicum of privacy. As a result, it is a difficult choice to forbid the use of these constructs. If an attack is discovered which breaks RADIUS/UDP (e.g. by allowing attackers to forge Request Authenticators or Response Authenticators, or by allowing attackers to de-obfuscate User-Password), the solution would be to simply deprecate the use of RADIUS/UDP entirely. It would not be acceptable to design new cryptographic primitives in an attempt to "secure" RADIUS/UDP.

We give such an attack in this paper. It is time to deprecate RADIUS over UDP and replace it with a transport mechanism that provides modern cryptographic security.

1.3 Contributions

- We develop a novel protocol attack against RADIUS that allows arbitrary forgery of Response Authenticators. While MD5 has been known to not be collision resistant for two decades, it was not known how to exploit this property in the context of the RADIUS protocol.
- We optimize the MD5 chosen-prefix attack computation in order to carry out chosen-prefix attacks in minutes.
- We develop a novel technique for forcing bytes in MD5 collision blocks, which allows us to optimize our collision attack and fit the resulting collisions within the length restriction of RADIUS protocol attributes.
- We have tested our attack against common RADIUS client and server implementations and use cases.

1.4 Summary and Impact

Nearly all RADIUS/UDP implementations are vulnerable to our protocol attack when using non-EAP authentication methods; see Section 7.1. RADIUS Accounting and EAP authentication appear less practically exploitable, although a theoretical protocol vulnerability may exist. Our attack also requires man-in-the-middle network access. Not all of the example RADIUS deployments above in Section 1 are practically exploitable; organizations should independently verify.

1.5 Disclosure

We reported the vulnerability to the IETF and CERT on February 2, 2024. CERT is coordinating the disclosure process among affected vendors; as of this writing 86 potentially affected vendors have been identified and notified. We spoke to Alan DeKok of FreeRADIUS and the IETF RADEXT working group on February 5; he confirmed the vulnerability and we have been in dialog about impact and mitigations. DeKok has authored a white paper detailing practical mitigation considerations for implementers, vendors, and admins [19].

Patches implementing the Message-Authenticator mitigation described in Section 7.1 will be available from major RADIUS implementations in coordinated release with this work; we expect future versions of [18] to update mandated client and server behavior. The IETF RADEXT working group has existing drafts in progress outlining RADIUS/(D)TLS [38]. Ultimately, we hope our work will hasten the formal deprecation of RADIUS/UDP and the standardization of RADIUS/(D)TLS.

1.6 Ethical Considerations

The attack demonstrations we describe in this paper exploit clients that we set up ourselves to test. The server queries we make to remote servers we do not control (e.g., our demonstration against Okta) send only normal protocol messages for registered user accounts and receive legitimate responses; our forgery attack targets the clients processing these responses.

The `hashclash` chosen prefix collision implementation has been public since 2009. Our improvements to the chosen prefix MD5 collision are available at [46]; we do not plan to publish full end-to-end exploit scripts for RADIUS itself.

2 Background

This section provides background on the RADIUS protocol and reviews related work as context for our attack.

2.1 The RADIUS Protocol

The RADIUS protocol provides authentication, authorization, and accounting (AAA) services for end users and administrators on network access servers via a central RADIUS server.

We begin by summarizing the relevant parts of the RADIUS protocol described in RFC 2865 [42], which specifies the Password Authentication Protocol (PAP).

In a typical setting, an end user wishes to authenticate to a networked device by entering a username and password at a login prompt. The networked device is a trusted party in the RADIUS protocol, and is running RADIUS client software. It shares a fixed shared secret with the RADIUS server.

PAP Authentication. The RADIUS client constructs an Access-Request packet that includes a one-byte ID, a 16-byte random nonce called a Request Authenticator, and additional fields (called attributes) that may include the username, user-entered password (encoded with an ad hoc MD5-based obfuscation function), and connection request information such as Network Access Server (NAS) IP address, NAS port, or other request information for the server to process.

The client then sends the request in the clear over UDP to the server. As originally written in RFC 2865 [42], this packet has no encryption outside of the password obfuscation and no integrity check. The server will check whether the source IP address matches a known client; otherwise the request is entirely unauthenticated.

The RADIUS server then processes the Access-Request. This may include looking up the user's password in a database, or querying an authentication server. If the server rejects the request, the server responds with an Access-Reject message. If the server accepts the request, it responds with an Access-Accept message that may contain attributes specifying metadata or configuration options for the connection.

Response Authenticator. Both Access-Reject and Access-Accept packets include a value called a Response Authenticator which is designed to prevent the forgery of responses. The Response Authenticator is computed as $\mathrm{MD5}(\texttt{Code} \,\|\, \texttt{ID} \,\|\, \texttt{Len} \,\|\, \texttt{ReqAuth} \,\|\, \texttt{Attributes} \,\|\, \texttt{Secret})$ where the Code, ID, Length, and Attributes are copied directly from the Access-Accept or Access-Reject packet, the Request Authenticator `ReqAuth` is a 16-byte random nonce included in the corresponding Access-Request packet, and the Shared Secret `Secret` is the fixed shared secret known to client and server.

Message-Authenticator. RFC 2869, "RADIUS Extensions" [54] defines a Message-Authenticator attribute that contains an HMAC-MD5 tag computed over the entire packet using the shared secret as the key. However, this attribute is optional for RADIUS access requests and responses not using EAP and many implementations do not require it by default.

Proxy-State Attribute. Access-Request packets may also contain one or more Proxy-State attributes. RFC 2865 [42]

specifies in numerous locations that any Proxy-State attributes present in an Access-Request "MUST be copied unmodified and in order into the response packet." Each Proxy-State attribute consists of a one-byte code followed by a one-byte length field and a string of at most 253 arbitrary bytes.

EAP Authentication. Extensible Authentication Protocol (EAP) support in RADIUS is defined in RFC 2869 [54] (RADIUS Extensions) and RFC 3579 [8] (EAP & RADIUS) updated in RFC 5080 [34]. A number of EAP authentication methods exist and are commonly used, including EAP-TLS and PEAP. The details of different EAP authentication methods are complex, and are largely orthogonal to our attack.

When EAP is used for authentication, the Access-Request message contains an EAP-Message. For RADIUS/UDP this is sent in the clear via UDP. Some EAP authentication methods may use encryption to protect authentication credentials or user information, but the final EAP Success or Failure message is not encrypted or integrity checked. Once the EAP authentication has terminated, the RADIUS server sends an Access-Accept or Access-Reject packet via UDP which contains an EAP-Message containing EAP-Success or EAP-Failure. RFC 2869 [54] specifies that all packets containing an EAP-Message must also contain a Message-Authenticator attribute, or else they must be silently discarded.

Interestingly, RFC 3579 [8] contains a section on conflicting messages between RADIUS and EAP: "The NAS MUST make its access control decision based solely on the RADIUS Packet Type (Access-Accept/Access-Reject)." Examples include "If the NAS receives an Access-Accept with an encapsulated EAP Failure, it will grant access to the peer."

In a common setup, the EAP Success will be sent by the NAS to the end-user device, while the Access-Accept is interpreted by the NAS. Thus an Access-Accept with EAP Failure could result in the two devices having differing views on whether authentication succeeded or failed. However, in 802.1X, the EAP session also derives a master key that is shared from the RADIUS server to the NAS, and future communication is encrypted with that key. An attacker who bypasses EAP authentication to forge an Access-Accept with an EAP Success would lack this negotiated key and thus be unable to access the network.

RADIUS Accounting RADIUS Accounting, specified in RFC 2866 [39], allows a NAS to use a central server to log network service usage and traffic statistics. This accounting information can be used for billing or auditing.

A RADIUS Accounting client sends an Accounting-Request packet at the start and end of a user's session. Accounting-Request packets are structured similarly to Access-Request packets, except the Request Authenticator is $\mathrm{MD5}(\texttt{Code} \,\|\, \texttt{ID} \,\|\, \texttt{Len} \,\|\, 0^{128} \,\|\, \texttt{Attributes} \,\|\, \texttt{Secret})$ instead of a random nonce. This field is intended to prevent an attacker from forging an Accounting-Request packet with false accounting information: if the Request Authenticator is incorrect, the accounting server ignores the packet.

Response Authenticators from Accounting-Response packets are computed as in Section 2.1. Other types of accounting packets (e.g. CoA and Disconnect) are computed similarly to Accounting-Requests.

2.2 Security analysis of RADIUS

The RADIUS protocol has received surprisingly little academic attention given its widespread use.

Hill analyzed RADIUS in 2001 [26]. He surveyed numerous protocol issues including brute force attacks against the shared secret or password from an attacker who observes the MD5-obfuscated password [36], a precomputation-based brute force attack on Request Authenticators, that repeated Request Authenticators can compromise user passwords, and that short shared secrets are likely to be insecure.

DeKok enumerates these and other vulnerabilities [18]. These include information sent in cleartext, that MD5 is broken, that shared secrets can be brute forced, that Message-Authenticators can be inconsistently used and that Access-Request packets missing Message-Authenticators can be forged or replayed, and that proxies expose MD5-obfuscated user passwords as they de-encode and re-encode them.

We will describe the offline brute-force attack against the shared secret by an adversary who observes a request and corresponding response packet containing a Response Authenticator. Since all of the information used to compute the MD5 hash for the Response Authenticator is present in the request and response except for the shared secret, the attacker can simply brute force shared secret values. The cost to guess an n-character shared secret consisting of printable ASCII characters is $95^n \approx 2^{6.6n}$. For a 7-character secret, this is 2^{46}; for a 10-character secret this is 2^{66}.

Most of the cryptographic security analysis of RADIUS has focused on the MD5-based password obfuscation method. It uses a custom construction using MD5 as a block cipher. Interestingly, we have not seen it observed elsewhere that this obfuscation method is unauthenticated, and thus implementations may be vulnerable to decryption oracle-type attacks.[2]

Implementation vulnerabilities have also been found in RADIUS implementations. For example, a TLS session resumption vulnerability discovered in 2017 could result in an authentication bypass in FreeRADIUS [27].

2.3 The MD5 Hash Function

The MD5 hash function was designed in 1991 by Rivest and described in RFC 1321 [40]. Although it was known to be weak by the mid-1990s, it continued to be widely used for decades, even after full collisions were demonstrated.

[2] In order to protect against password-based timing attacks, FreeRADIUS delays Access-Reject messages by one second by default. [16]

The structure of MD5. The MD5 hash function uses the Merkle-Damgård transform [15,31] to iteratively apply a compression function to blocks of the input message. Messages are processed in blocks of 512 bits, and the final hash output is the output of the final application of the compression function to the final block of message padding.

For the purposes of the attack we describe in this paper, the outcome of this design means that if we have two input messages M_1 and M_2 that result in an MD5 collision $\text{MD5}(M_1) = \text{MD5}(M_2)$, we can append any identical suffix S to these messages and the resulting strings $M_1 \| S$ and $M_2 \| S$ will still have colliding MD5 hashes $\text{MD5}(M_1 \| S) = \text{MD5}(M_2 \| S)$.

2.4 MD5 Collisions

The first pseudo-collisions for the MD5 compression function were found by den Boer and Bosselaers [20] in 1993. Dobbertin exhibited a "free-start" collision in 1996 [21]. Wang, Feng, Lai, and Yu published a full MD5 collision in 2004 [52]. This collision consisted of two fixed strings. Exhibiting such a collision suffices to demonstrate that the MD5 hash function is no longer cryptographically collision-resistant, but attacks on MD5 in real-world contexts generally require collisions on attacker-chosen prefixes.

The structure of this collision was adapted in a straightforward way to an arbitrary common prefix, resulting in a so-called *identical-prefix* collision: given a prefix P, the algorithm computes gibberish blocks G_1 and G_2 such that $\text{MD5}(P \| G_1) = \text{MD5}(P \| G_2)$. This can be used to, for example, produce different PDF documents with identical hashes or to produce so-called "hashquines" [2, 28, 49].

The MD5 collision attack that we exploit in this paper is called a *chosen-prefix* collision and was introduced in 2007 [47]. That is, given distinct prefixes P_1 and P_2, we wish to efficiently compute gibberish blocks G_1 and G_2 such that $\text{MD5}(P_1 \| G_1) = \text{MD5}(P_2 \| G_2)$. Having done so, as noted in Section 2.3, we can then append any fixed suffix S and the resulting messages still have colliding MD5 hashes: $\text{MD5}(P_1 \| G_1 \| S) = \text{MD5}(P_2 \| G_2 \| S)$.

Our attack is based on the improved chosen-prefix collision attack by Stevens et al. [48] that reduced the original cost from [47] for a chosen-prefix collision from 2800 core-days to 39 core-hours. Additionally, this improved attack allows the attacker to reduce the length of collision block gibberish but at a larger computational cost.

Stevens et al. [48] computed a chosen-prefix collision in 2009 that was only 204 bytes long in 28 hours on an array of 200 Sony PlayStation 3s, and used it to create a rogue TLS CA certificate. In the same paper the authors also computed a chosen-prefix collision suffix of only 11+64 bytes long at a cost of about $2^{53.2}$. The `hashclash` code implementing both attacks was made publicly available [46].

The authors appeared to have made their point about the importance of deprecating MD5, and it seems that little further public MD5 cryptanalysis has happened in the intervening 15 years. Nevertheless, despite these MD5 attacks, in 2016 TLS still supported MD5, which Bhargavan and Leurent [7] showed to be vulnerable to transcript collision attacks. They demonstrated an "online" attack in about 1 hour on a 48-core machine using a slightly modified version of `hashclash`.

2.5 Hashclash chosen-prefix attack

At a high level, the chosen-prefix collision attack as implemented in `hashclash` has two stages, called "birthday" and "near-collision". We follow the naming convention of `hashclash`, where the (4×32)-bit *intermediate hash value* (IHV) of some number of message blocks is the internal state of MD5 after processing those message blocks. The difference in the IHVs (called dIHV) between a pair of (partially-constructed) messages will be zero when we have a collision.

Birthday. In the first stage, the algorithm finds bits to append to both prefixes so that the first 32-bit word of dIHV is zero, and the last two 32-bit words of dIHV are equal.

These birthday bits are found using the van Oorschot and Wiener [50] parallel collision search with distinguished endpoints. A large number of *trails* are computed from random starting points. When there are colliding endpoints, birthday bits can be computed from the trail starting points. One stops when a found dIHV only needs B near-collision blocks, where the cost of the birthday stage depends on B, and ranges from 2^{37} for 9 blocks up to 2^{53} for 3 blocks. There are GPU and CPU implementations of this stage in `hashclash`.

Near-collision. The second stage iteratively reduces the number of bit differences in dIHV to zero by appending a sequence of *near-collision blocks*. For each near-collision block, one first constructs *differential paths*: a set of conditions on the bits of the message blocks and of the internal state that will result in the desired change to dIHV. These differential paths are constructed via a *forward* stage that works forward from the previous IHV values, a *backward* stage that works backward from the desired dIHV-change, and a *connect* stage that finds a path connecting a forward path to a backward path. Once a differential path and the corresponding conditions on message bits are known, a *find-collision* algorithm searches for a message block pair satisfying the bit conditions and checks whether they result in the desired changes to dIHV. This find-collision stage is embarrassingly parallel, but the forward, backward, and connect stages are not. These four near-collision stages are only implemented for CPUs.

After enough near-collision blocks, dIHV is reduced to zero, resulting an MD5 collision. Each near-collision cost is comparable to about 2^{35} MD5 compressions.

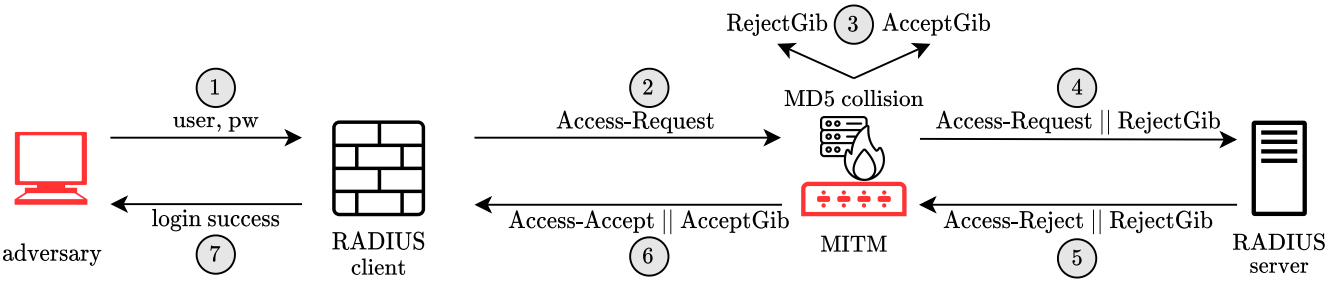

Figure 1: **Our attack flow.** Our adversary triggers an Access-Request with incorrect credentials from a legitimate RADIUS client (1), and then carries out a man-in-the-middle attack (2) and computes an MD5 hash collision (3) to inject a malicious Proxy-State attribute in the request (4). The hash collision allows the attacker to transfer the server-generated Response Authenticator from the legitimate Access-Reject response (5) to the attacker's desired Access-Accept response (6) to get authenticated or authorized by the RADIUS client (7).

3 Forging RADIUS Response Authenticators

In this section, we describe our protocol attack against RADIUS Response Authenticators.

3.1 Attack Model

The adversary in our attack wishes to trick a victim device into accepting a forged response from a RADIUS server.

A successful attack allows various forms of privilege escalation, depending on the access protected by RADIUS. For example, for a network router that uses RADIUS to authenticate administrative access to the device, such an attack would allow an attacker with network privileges to log in as an administrator without a password. For a victim NAS that uses RADIUS to authenticate network users to a protected VLAN or VPN, our attack would allow the adversary to access arbitrary privileged portions of the network without credentials.

We assume that the adversary does not know the shared secret between the RADIUS client and server.

Gaining Man-in-the-Middle Access. Our attack requires the adversary to have network access to act as a man-in-the-middle attacker on the connection between the victim device's RADIUS client and RADIUS server. Our attacker will need to be able to act as a full network man-in-the-middle who can read, intercept, block, and modify inbound and outbound network packets between the RADIUS client and server.

Such access to RADIUS traffic may happen through different mechanisms. Although sending RADIUS/UDP over the open internet is discouraged, this is still known to happen in practice [18, 38]. For internal network traffic, the attacker might initially compromise part of an enterprise network; such compromises appear frequently in news reports and security advisories [10, 12]. Even if RADIUS traffic is confined to a protected part of an internal network, configuration or routing mistakes might unintentionally expose this traffic. An attacker with partial network access may be able to exploit DHCP or other mechanisms to cause victim devices to send traffic outside of a dedicated VPN [33].

3.2 Attack Flow

We describe the steps of our attack as shown in Figure 1.

Step 1 (Login Attempt). We consider the simplest case of PAP authentication. The adversary causes the RADIUS client of a victim's network device to generate an Access-Request by, for example, entering the username and an arbitrary incorrect password at a login prompt for a privileged user.

Step 2 (Access-Request). The RADIUS client generates an Access-Request containing a one-byte ID, a 16-byte randomly generated Request Authenticator, and a collection of attributes including User-Name and User-Password containing the obfuscated incorrect password entered by the adversary. The client sends this Access-Request to the RADIUS server.

Step 3 (Collision). Since the adversary has network access, it is able to observe all of these values in the UDP packet. It will need the ID and Request Authenticator (`ReqAuth`).

If the adversary were to forward this Access-Request packet unmodified to the RADIUS server, it could then observe the format of the Access-Reject response generated by the server. This packet will contain a Response Authenticator that is calculated as $\text{MD5}(\texttt{Code} \,\|\, \texttt{ID} \,\|\, \texttt{Len} \,\|\, \texttt{ReqAuth} \,\|\, \texttt{Attributes} \,\|\, \texttt{Secret})$ as described in Section 2.1.

Once the adversary is ready to carry out the attack, it uses its man-in-the-middle network position to block or mangle the legitimate Access-Request packet so that the server does not receive it or discards it, and begins to generate a maliciously modified request to send to the server instead.[3]

[3] If the server receives both modified and unmodified requests, its behavior is implementation dependent. The modified packet may be treated as a

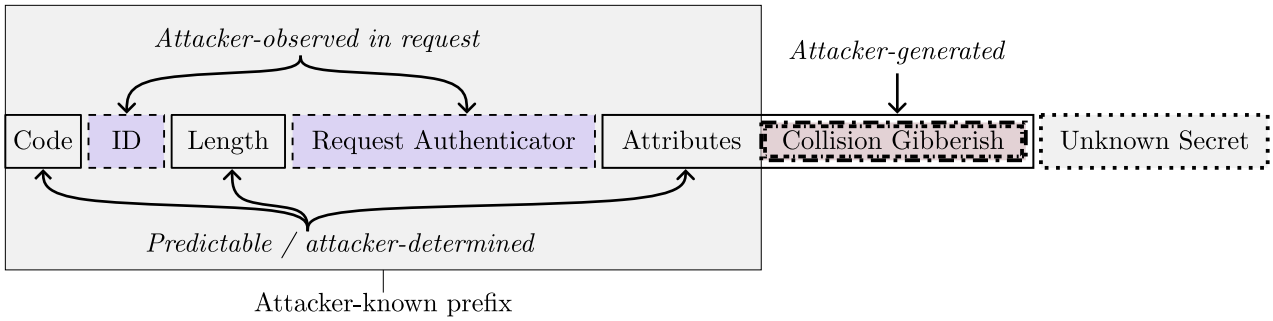

Figure 2: **Constructing Response Authenticator Preimages.** The attacker computes prefixes corresponding to the Response Authenticators from the Access-Reject packet it expects and Access-Accept it desires to forge, and carries out an MD5 collision to ensure the Response Authenticators will collide, without needing to know the shared secret. It hides the collision block gibberish in Proxy-State attributes that are guaranteed to be returned by the server.

Our adversary wishes to modify the Access-Request packet so that the Response Authenticator for the resulting Access-Reject packet is identical to the Response Authenticator for an Access-Accept packet. To do this, our adversary will compute a chosen-prefix MD5 collision. Our adversary does not know the value of the shared secret in the Response Authenticator computation, but this does not matter: it knows or can guess all of the other values that precede the Shared Secret, and as observed in Section 2.3, any identical suffix appended to an MD5 collision will still produce a collision. Our attacker will compute a collision for the Response Authenticator preimage up to the shared secret, and can then transfer the observed Response Authenticator sent from the legitimate server to the maliciously constructed colliding packet.

However, computing an MD5 collision generally involves appending hundreds of bits of unformatted collision block gibberish to the chosen prefixes. Fortunately for the attacker, the Proxy-State attribute of a RADIUS packet is an ideal place to hide this gibberish: any Proxy-State attributes included in an Access-Request must be returned unmodified by the server.

Our network attacker will calculate two prefixes for an MD5 collision with the structure shown in Figure 2. The first prefix is the start of the preimage of the Response Authenticator in the Access-Reject packet that it expects to receive, and ends with the header for a Proxy-State attribute (a code 33 and length `PSLen`): in the simplest case this would be

$\texttt{RejectPrefix} = \texttt{03} \,\|\, \texttt{ID} \,\|\, \texttt{Len} \,\|\, \texttt{ReqAuth} \,\|\, \texttt{33} \,\|\, \texttt{PSLen}.$

Any attributes expected in the reject packet can be included in this prefix. The second prefix is the start of the preimage of the Response Authenticator in the Access-Accept packet that it wishes to forge, and ends with a Proxy-State header:

$\texttt{AcceptPrefix} = \texttt{02} \,\|\, \texttt{ID} \,\|\, \texttt{Len} \,\|\, \texttt{ReqAuth} \,\|\, \texttt{33} \,\|\, \texttt{PSLen}.$

Computing a chosen-prefix collision on these two prefixes results in binary gibberish strings `RejectGib` and `AcceptGib` such that $\text{MD5}(\texttt{RejectPrefix} \,\|\, \texttt{RejectGib})$ equals $\text{MD5}(\texttt{AcceptPrefix} \,\|\, \texttt{AcceptGib})$. We have structured the prefixes so that `AcceptGib` and `RejectGib` will be interpreted as Proxy-State attributes.

retransmission, and receive a cached response. In FreeRADIUS, duplicate detection uses the packet length. If a server receives the original "good" packet, followed by the attacker's "bad" packet, the server may stop processing the "good" packet and process the "bad" packet instead. [16]

Step 4 (Modify Access-Request). After computing the collision, the man-in-the-middle attacker modifies the Access-Request packet to include a Proxy-State attribute containing `RejectGib`. (If necessary, the attacker also strips the request of any Message-Authenticator attributes.) There is no other authentication, so the modification will be unnoticed. The adversary sends the modified Access-Request to the server.

Step 5 (Access-Reject). The server responds with an Access-Reject (or Access-Challenge or Access-Accept) that includes a Response Authenticator computed over the preimage shown in Figure 2 including the Shared Secret. The RADIUS protocol mandates the Proxy-State attributes containing `RejectGib` be included in the server's response, and thus in the Response Authenticator MD5 hash.

Step 6 (Forge Access-Accept). The adversary then verifies that the attributes present in the Access-Reject packet match its anticipated format for the collision. If so, it constructs the desired Access-Accept packet. Conveniently, the Access-Accept packet whose Response Authenticator corresponds to $\texttt{AcceptPrefix} \,\|\, \texttt{AcceptGib}$ is exactly the string $\texttt{AcceptPrefix} \,\|\, \texttt{AcceptGib}$ (see Step 3 above) with the Request Authenticator from the original request replaced with the Response Authenticator from the Access-Reject packet.

Step 7 (Login Success). The adversary then forwards the Access-Accept packet to the victim RADIUS client, who will validate the Response Authenticator against the received packet and shared secret and permit the adversary to log in.

3.3 Adding Additional Attributes

An Access-Accept response may contain attributes specifying network configuration or access to particular resources like a VLAN. An attacker could forge arbitrary attributes in its Access-Accept by including them in the MD5 collision prefix; additional length in the corresponding Access-Reject (or Access-Accept) prefix can be covered by more Proxy-States.

3.4 Practical Challenges

There are several logistical challenges that we need to overcome in order to carry out this attack in practice. First, because the prefixes the attacker is using for the MD5 collision contain the single-byte request ID and random 16-byte Request Authenticator nonce, the attacker must compute the MD5 collision *online* after observing the victim's Access-Request and before the victim client's programmed session timeout. Realistic timeout lengths are generally in the range of 30 to 60 seconds. RFC 5080 suggests a default timeout length of 30 seconds [34]; 60 seconds is a common recommendation when using multi-factor authentication.

Second, the length of the collision must fit within the Proxy-State attribute. The MD5 hash function has a 64-byte block size; to fit within the 253-byte maximum length of a single Proxy-State attribute the collision can be at most three blocks long, plus additional padding and birthday bits. We develop a new technique that allows us to split a longer collision across multiple Proxy-State attributes by placing the two-byte header for additional Proxy-State attributes at desired locations during the collision computation.

3.5 Accounting Request Authenticators

In theory, a similar collision attack affects the construction of RADIUS Accounting Request Authenticators. This construction is also used for CoA-Request and Disconnect-Request [22]. However, the details of exploitation are different, and a practical attack may be more difficult. We did not attempt to implement this attack, but we detail the underlying cryptographic vulnerability.

As described in Section 2.1, RADIUS Accounting-Request packets include a Request Authenticator that is computed similarly to the Response Authenticator we exploit above, except with 16 null bytes in place of the random Request Authenticator from an Access-Request.

An attacker trying to log false accounting information might compute a chosen-prefix MD5 collision to find a colliding pair of Accounting-Request packets: one with the desired false accounting information, and one with true accounting information that the attacker can cause or expect the RADIUS Accounting client to send. As before, the attacker does not know the shared secret, but the packets will still collide when the shared secret is appended, so the correct request authenticator will be the same for both packets.

When the client tries to send the packet with true accounting information, the man-in-the-middle attacker copies the packet's Request Authenticator onto the forged accounting request and sends that instead. If the attacker has correctly predicted the true request, the collision will result in a valid Request Authenticator for the forged request.

Exploiting this would require an attacker to predict the exact content of the Accounting-Request packet. This may be complicated, as attributes include a variable-length Acct-Session-Id attribute that is chosen in an implementation-dependent way, as well as timestamps.

Furthermore, the attacker has much more limited control of the values appearing in the request. In this attack model, the attacker cannot, for example, cause the client to send arbitrary Proxy-State attributes: it needs to cause the client to include its desired collision block gibberish in a legitimate request by including it in an attribute that it can control.

One example of an attacker-controlled attribute might be User-Name. The attribute has a maximum length of 253 bytes; this is room for a three-block MD5 collision plus additional padding. As we note in Section 2.4, it is feasible to compute MD5 chosen-prefix collisions as short as birthday bits plus only a single block: 11+64 bytes in length. A User-Name attribute embedding a null character between a valid username and some collision gibberish could be parsed by a vulnerable implementation using standard C string functions as a normal username, as in the null prefix attacks against SSL/TLS certificates by Marlinspike and Kaminsky [29].[4]

An additional practical complication to this attack is that a chosen-prefix collision would only allow falsifying attributes that appear *before* the collision garbage: all bytes after the collision gibberish would need to be identical.

Since this theoretical attack against RADIUS accounting is likely more difficult to practically exploit than the attack against RADIUS authentication, we leave a practical evaluation to future work.

4 Optimizing MD5 Chosen Prefix Attacks

Our attack requires the adversary to forge the Access-Accept before the victim client times out. This means that our man-in-the-middle adversary must compute an MD5 collision within the timeout window, after seeing the Request Authenticator and ID sent by the victim RADIUS client.

As discussed in Section 6, clients have configurable timeout settings ranging from as little as five seconds to five minutes, with common defaults of 30 and 60 seconds.

When we began this research, running `hashclash` with the default parameters on a machine with an AMD 5950X

[4] A March 1, 1999 email to the IETF RADIUS mailing list documented such a vulnerability affecting Proxy-State: "I had to implement a configurable option to avoid NULs in my Proxy-State attributes in order to interoperate with older Livingston/Merit code (not sure about the latest stuff) since they NUL-terminated all string attributes internally." [3]

CPU and an NVIDIA RTX3080 GPU on two 22-byte prefixes produced a 512-byte collision with 25% probability within 85 minutes. This does not yield a practical attack: 490 bytes of collision gibberish does not fit the 253-byte maximum length of a Proxy-State attribute, and the running time was far longer than a reasonable client timeout range.

In order to mount our attack in practice, we needed to compute MD5 collisions much faster while also remaining compatible with the RADIUS message format. After our optimizations, we could compute a collision formatted as two Proxy-State attributes in under 5 minutes parallelized across our heterogeneous cluster. On the single machine above, our new attack finishes with 25% probability within 30 minutes.

This required large and small changes: we added new capabilities to `hashclash` to fix certain bytes in the collision, shifted some of the computation to precomputation, and optimized the code for speed, scaling, and parallelization latency. We discuss the most important changes below, and detail all of them in Appendix B. The code is available at [46].

4.1 Collisions with Infix Bytes

There is a tradeoff between the length of the collision gibberish and the cost of the birthday search phase: shorter collisions cost more. We wanted to be able to hide longer collision gibberish across multiple consecutive Proxy-State attributes. This requires periodically encoding the two-byte header starting a new attribute in certain near-collision blocks.

One solution achieving this is to choose a 32-bit word m_0 in `MD5Compress` containing the two-byte infix, which fixes the differential path for step $t = 0$, and let the forward stage start at $t = 1$. This unnecessarily reduces the freedom in differential paths and may increase the near-collision search cost.

Instead, our optimal solution is to find all valid differential paths over step $t = 0$ with minimum number of bit conditions that guarantee the two-byte infix. We iterate over all possible m_0 containing the two-byte infix to obtain many valid differential paths for step $t = 0$. Then we simplify each path by attempting to remove each bit condition on the output Q_1 of step $t = 0$ and checking if the result still guarantees the two-byte infix sequence. If so, the bit condition can be safely removed. This approach may generate minimal differential paths multiple times, so we remove any double occurrences.

4.2 Precomputation

Since we are optimizing for the online running time once the prefixes are known, we benefit from shifting some of the computation into a precomputation phase.

For the "backward" phase, we precompute the set of upper paths for all possible message differences $m_{11} = \pm 2^i$ for $i = 0, \ldots, 31$. As the last four steps depend on the actual dIHV in the online attack, the upper paths are only computed over steps $t = 16, \ldots, 34$ that are the same for all possible dIHV.

Due to the partial precomputation of upper paths, Connect will only output differential paths over steps $t = 0, \ldots, 34$. We extended the differential path helper tool to glue any found connected paths to the target upper path over steps $t = 35, \ldots, 63$ to obtain the required full differential paths.

Moreover, we extended the differential path helper tool to negate a set of differential paths. This allows us to convert the precomputed set for $m_{11} = +2^i$ to the desired precomputed set for $m_{11} = -2^i$ for free.

4.3 Cluster Parallelization

We have access to a cluster of 47 CPU machines, with one machine with four GPUs. (We give specifications in Section 4.4.) We developed a number of techniques to parallelize `hashclash` across our existing computing resources. Our machines are clustered together with a shared filesystem using GlusterFS and ZFS, and use Slurm for job management.

File I/O. For communication between processes, `hashclash` uses the file system, which creates a bottleneck when distributing on a cluster. We reduced latency in the code and used in-memory tmpfs filesystems shared via NFS, creating a primitive form of remote direct memory access.

Thread Orchestration and Parallelization. We modified several stages of the algorithm to partition input and output spaces. For example, we extended the "forward" phase to partition the output into N sets and save them concurrently instead of storing all output in one file single-threaded. This might sacrifice some quality for speed: some very good paths might not be found using this approach.

Birthday. The birthday phase has a mode that partitions the trail space over multiple machines. This works best with powerful GPUs. Since we only have one machine with four Tesla T4 GPUs, we instead used our CPU machines as controllers. We introduced a generator mode that uses the four GPUs to generate trails that are processed by the controllers. We use Slurm to start and orchestrate the CPU and GPU nodes.

4.4 Experimental results

We ran our experiments on a heterogeneous cluster with 31 Intel Xeon CPU E5-2699 v4, 14 Intel Xeon CPU E5-2680 v3, one Intel Xeon CPU E7-4860 v2, and one GPU machine with an Intel Xeon CPU E5-2673 processor and four Tesla T4 GPUs. Most machines have 512 GB of memory but none of our operations used significant amounts of RAM. We note that most of these machines date from 2014–2017.

Figure 3 shows the runtime distribution of our MD5 chosen-prefix collision attack. We ran 110 full attacks and aborted 42.7% before they found a collision because they were not

on a good trajectory. Since timings for birthday search and near-collisions are independent, we take their measured times separately and compute the direct sum of all possible combinations. According to Figure 3 we expect 2% of the successful runs to finish before 240s and 16% before 300s.

Our adversary can cope with the failure rate and randomized running time of the attack by triggering multiple requests until one succeeds.

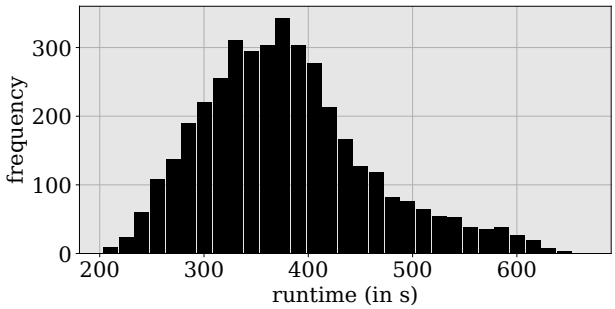

Figure 3: Histogram of the runtime of our attack as direct sum between birthday runtimes and near-collisions runtimes.

4.5 Prospects for further improvement

While we have been able to reduce the online running time for our MD5 chosen-prefix attack from hours down to minutes, this should be interpreted as a generous upper bound for the true cost of such collisions, because of the limits on our computational resources. Newer CPUs than the seven to ten year old machines we have access to would likely provide minutes of improvement, as would optimizing cache locality.

Access to more and faster GPUs would reduce the time for the birthday stage and/or reduce the number of near-collision blocks, reducing time for the near-collision stage.

Reimplementing `hashclash` in hardware, for example on FPGAs (Field Programmable Gate Arrays) or ASICs (Application-Specific Integrated Circuits) would likely improve the running time by a factor of ten to a hundred.

It would be eminently feasible to run this attack on cloud resources. Amazon EC2 lists the on-demand price of a `c7a.48xlarge` instance with 192 vCPUs at $9.85/hour, and the price of a `g6.48xlarge` instance with 192 vCPUs and 8 NVIDIA L4 GPUs at $13.35/hour. It would cost around $50/hour to exceed our computing capacity, and in principle one could scale to many more machines.

We did not pursue this avenue further for two reasons. First, based on previous experience the cost of simply implementing and debugging an attack in the cloud that requires launching hundreds of dollars an hour of computing instances can quickly reach tens of thousands of dollars. Second, achieving further gains would require us to more substantially re-architect `hashclash`. We hope that the reader is already convinced that MD5 is exploitable.

4.6 Comparison to offline brute force

For the six-block collision we chose, the computational cost of our online collision attack is dominated by the birthday phase, with a complexity of around $2^{43.2}$, and is mostly done using GPUs. Comparing this cost to the cost of the offline brute force attack to recover shared secrets discussed in Section 2.2, this is somewhat less than the cost to brute force a 7-character shared secret. Current recommendations prescribe a minimum shared secret length of at least 24 octets in order to protect against offline brute force attacks [18]. Unfortunately, while it is straightforward to mitigate brute force attacks against the shared secret by generating longer shared secrets uniformly at random, this has no effect on the cost of our collision attack.

5 Attack Evaluation

We carried out our attack against several settings of client and server software.

5.1 MITM Implementation

We implemented a man-in-the-middle script in Python using the pyrad library to parse and format RADIUS packets, and our modified version of the `hashclash` software.

Our script implements the attack described in Section 3. It receives an Access-Request from the client, guesses the format of the Access-Reject packet that will be received from the server, then runs our modified version of `hashclash` on the corresponding Response Authenticator prefixes for Access-Reject and Access-Accept packets to compute a six-block MD5 collision formatted into two Proxy-State attributes. Our script appends the two Access-Reject Proxy-State attributes to the Access-Request, strips any Message-Authenticators, and forwards it to the server. After intercepting the Access-Reject response, we construct the Access-Accept packet, copy the Response Authenticator from the Access-Reject received from the server, and forward it to the client.

5.2 FreeRADIUS client and server

The FreeRADIUS website states that "FreeRADIUS is the most widely used RADIUS server in the world. It powers most major Internet Service Providers and Telecommunications companies world-wide and is one of the key technologies behind eduroam, the international Wi-Fi education roaming service. It is the RADIUS server used by all Cloud Identity providers and is embedded in products from network equipment vendors and token card manufacturers." [35]

We installed FreeRADIUS 3.2.3 on a Linux machine running Ubuntu 23.10. We left the default configuration as is, which uses UDP as standard transport protocol. There is an option to require a Message-Authenticator attribute in an access request; this defaults to "no" with a comment that "Old-style

clients do not send a Message-Authenticator in an Access-Request. RFC 5080 suggests that all clients SHOULD include it in an Access-Request."

We then sent a PAP authentication request with the FreeRADIUS client `radclient` for a valid user with an incorrect password via our MITM to the RADIUS server. We set the client timeout to 10 minutes.

Neither `radclient` nor FreeRADIUS include a Message-Authenticator attribute by default. FreeRADIUS will include a Message-Authenticator in proxied Access-Request packets.

FreeRADIUS returned the Proxy-State attributes we included in the request packet. Finally, `radclient` accepted our forged Access-Request without complaining about the Proxy-State attributes.[5]

The `radtest` client does include a Message-Authenticator attribute in its requests, but stripping it has no consequences for the MITM attack with the default settings of FreeRADIUS.

5.3 Okta RADIUS Integration

The Okta authentication service supports RADIUS authentication via a custom agent, allowing customers to offload authentication and MFA support to their service.

We configured a test environment on Ubuntu 22.04 emulating the recommended default setup for such a deployment. In our setup, we ran a TinyRadius server that communicates with the Okta RADIUS Server agent. Within a customer organization's network, the Okta RADIUS Server agent communicates over UDP port 1812. The Okta RADIUS agent then makes requests over TLS to Okta's remote servers, and proxies the responses back to the TinyRadius server, which then communicates the responses to the RADIUS client. In this setup, the TinyRadius server is taking the place of a local authentication server that communicates with Okta.

Okta supports several multi-factor authentication mechanisms. Customers can choose different RADIUS authentication mechanisms depending on their chosen MFA methods: PAP, EAP-TTLS, and EAP-GTC. We used PAP authentication, configured so that the User-Password plaintext contained both the user's static password and MFA passcode (comma-delimited); MFA can also be configured as an Access-Challenge.

We used `radclient` to make a PAP authentication request over UDP to Okta via our man-in-the-middle script using the same `radclient` call as above. Since the User-Password field includes the MFA token value, we entered an arbitrary incorrect password.

The only difference to the setup described above in Section 5.2 is that the Okta servers returned a Reply-Message attribute with a welcome or error message, which we needed to include in our MD5 collision prefixes. No Message-Authenticator attributes were returned with the responses. Our injected Proxy-State attributes were successfully returned by the server as the last attributes in our request. Our MITM attack successfully forged an Response Authenticator for an Access-Accept in under 10 minutes that `radclient` accepted.

5.4 Cisco ASA Firewall

We configured a Cisco ASA 5505 firewall device to use RADIUS as an Authentication-Authorization-Accounting (AAA) server and pointed it to our FreeRADIUS server for authentication. The firewall supports using RADIUS to authenticate users for logging into the device by serial console, giving access to VPN tunnels, and using various services such as Telnet, FTP, and HTTPS. The Cisco ASA has a configurable timeout with a maximum of 300 seconds. We successfully carried out our attack against the Cisco device and forged an Access-Accept message that it accepted within the 300 second timeout.[6] The ASA RADIUS client did not object to our Proxy-State attributes.

5.5 PAM Radius

The pluggable authentication module (PAM) named `pam_radius`[7] "allows any Linux, OSX or Solaris machine to become a RADIUS client for authentication". For example, it can be used to allow programs like `sshd`, `su`, `sudo`, and `login` to query a RADIUS server instead of the local `/etc/passwd` and `/etc/shadow` when authenticating users. It speaks RADIUS over UDP and does not use EAP.

One barrier to demonstrating a practical attack against `pam_radius` is that the maximum configurable timeout is 60 seconds. While it may be possible to exploit retries to lengthen the attack window, for the purpose of expediency we modified the source code to change the maximum timeout from 60 seconds to 600 seconds and rebuilt from source.

We installed our custom build of `pam_radius` on a Linux machine running Ubuntu 22.04, and configured the PAM subsystem to make `su` use RADIUS for authentication.

We pointed the module at the FreeRADIUS server we configured above, via our MITM script. The `pam_radius` module accepted our forged Access-Accept packet (without warnings about the extraneous Proxy-State attributes), allowing us to successfully run `su` with an incorrect password.

5.6 EAP-TLS

The TLS in EAP-TLS protects the EAP traffic but not the RADIUS packets that carry the EAP traffic, which are still

[5] Alan DeKok notes that `radclient` is not intended to complain about anything other than shared secret mismatch, but that he is not aware of any RADIUS client that will take any action when it receives an unexpected Proxy-State attribute. [16]

[6] The most challenging part of the attack was configuring the ASA and configuring our own network to forward UDP packets over TCP to our cluster.

[7] https://github.com/FreeRADIUS/pam_radius

transmitted over UDP in the clear. In theory, depending on implementation decisions made by the RADIUS client and server, our attack could work against RADIUS even when clients use EAP-TLS for authentication. We found that `hostapd` as an EAP / RADIUS client was not vulnerable, but this does not rule out other clients. Similar issues may affect other EAP methods.

Specifically, per RFC 3579 [8], all RADIUS packets with an EAP-Message need a valid Message-Authenticator, and ordinarily an Access-Accept after successful EAP authentication would contain an EAP-Message indicating EAP success. The Message-Authenticator is an HMAC-MD5 of the packet, which we are not able to forge. But the RFC is less clear on how a client should handle an Access-Accept packet at the end of an EAP conversation that has neither an EAP-Message nor a Message-Authenticator; this situation should not happen with a well-behaved server. The RFC states: "If no EAP Message attribute is included within an Access-Accept or Access-Reject, then the peer may not be informed as to the outcome of the authentication, while the NAS will take action to allow or deny access" [8].

In particular, the RFC does not specify whether a client using EAP for authentication should check for a valid Message-Authenticator in an Access-Accept without an EAP-Message. Even when EAP (including EAP-TLS) is expected to be used, a client that does not perform this check would be vulnerable to our attack. Our colliding packets would contain neither EAP-Message nor Message-Authenticator attributes; the Access-Accept should make the client allow access, even without the EAP-Message. This assumes the attacker can cause the server to produce an Access-Reject without a Message-Authenticator, perhaps by trying non-EAP authentication.

While we found that `hostapd` does check for a Message-Authenticator even when no EAP-Message is present, other RFC-conforming clients might not.

A full exploit of such an attack would depend on the broader protocol context. If, as in WiFi discussed in Section 2.1, further communication requires session keys that would have been negotiated via EAP, a forged Access-Success would not be enough for a full attack.

6 Impact

Although alternative transports were proposed a decade ago, RADIUS/UDP remains common in real-world deployments.

Unfortunately, we are not able to use network scanning to provide a representative picture of RADIUS deployments. Many RADIUS servers will be on internal networks. Even for external-facing servers, RADIUS hosts are identified by IP address and servers only accept packets from allowed addresses. The RADIUS RFC specifies that servers should drop requests for hosts that they have not been pre-configured to have a shared secret with. Our scanning host would not be whitelisted by properly configured servers, so an internet-wide scan would thus only turn up misconfigured servers. Additionally, since it is a UDP-based protocol with no handshake before a login request, we cannot do TCP SYN scanning and would need to scan using a well-formed UDP Access-Request, which would appear as an attack to network administrators.

This does not affect the adversary in our attack model, who intercepts traffic between a legitimate client and server.

We examine case studies of real-world deployments instead. There is little documentation about RADIUS deployments in the literature. These case studies are intended to provide concrete instantiations for the factors impacting a practical attack, as well as to illustrate the complex impacts.

6.1 Case Study: A RADIUS Deployment

We give details about RADIUS usage in a large organization whose network administrators were willing to share details of their configuration with us. This organization has around 80,000 affiliated individuals, and uses RADIUS for authentication to the VPN and Wi-Fi network. Their system sees around 90,000 active RADIUS connections at a time, and 300,000 clients over a typical five-day period.

When users connect to the VPN, the end user VPN client connects to the VPN controller, which offloads AAA (Authentication, Authorization, and Accounting) to a Cisco Identity Services Engine (ISE). The Cisco ISE makes RADIUS/UDP requests to a set of load balanced RADIUS servers using PAP mode for authentication. When using multi-factor authentication, the RADIUS requests are proxied to the Duo service. Within the organization, the RADIUS/UDP traffic passes over a VLAN with restricted access. The timeout for the ISE proxy is set to 60 seconds.

Wi-Fi authentication is also done over RADIUS/UDP, using EAP-TLS authentication. The timeout is set to 5s, with 3 retries. Password authentication is done via Active Directory, with passwords sent via NTLMv2.

This organization uses TACACS+ to authenticate network administrators to the routing infrastructure.

Evaluation. In this setting, the VPN authentication setup would be vulnerable to our attack. However, the fact that RADIUS traffic passes over a restricted-access VLAN means that exploitation would likely be an involved process.

6.2 Case Study: Network Infrastructure

RADIUS is essentially universally supported as an access control method for routers, switches and other network infrastructure; RADIUS and TACACS+ are the most commonly used protocols for admin access.

Public security advisories and leaked documents make it clear that compromising routers and switches is a priority for state-sponsored attackers. A 2022 US CISA announcement details a collection of state-sponsored attacks targeting

Cisco and Juniper equipment used by telecommunications and network service providers via credentials obtained from a RADIUS server [11]. Documents leaked by Edward Snowden also highlight the compromise of routers and switches as a priority for the NSA [56].

Evaluation. In this setting, an attacker who is able to access portions of the network that carry RADIUS traffic could exploit our attack to gain privileged access to all of the routers in an organization.

6.3 Case Study: eduroam

The eduroam network is a coalition of educational institutions who share Wi-Fi access via a linked hierarchy of RADIUS servers. In order to participate in eduroam, an institution sets up a RADIUS server. Internet access requests from users who are roaming at participating institutions are proxied via this network of RADIUS servers back to the home institution.

The Internet Draft for RADIUS over (D)TLS [38] documents the RADIUS deployment in eduroam as an example of RADIUS/TLS in "more than a dozen" national branches. The document states as of October 2023, "RADIUS/UDP continued to be used by a majority of country deployments despite its significant security issues." This implies that although RADIUS/TLS "does work, and scales," most eduroam RADIUS traffic is transmitted over the open internet via UDP.

Because eduroam uses 802.1X, it uses EAP within RADIUS for authentication, most commonly EAP-TLS, EAP-TTLS, or PEAP. We spoke to network administrators at an institution participating in eduroam; they told us that the eduroam RADIUS clients are configured with a 15s timeout with three retries.

Evaluation. An attacker may be able to forge an Access-Accept without an EAP-Message as described in Section 5.6. However, as described in Section 2, in the context of 802.1X, further communication relies on a master key that would normally be negotiated during the EAP session, and an attacker who bypasses EAP authentication would not have such a key.

7 Mitigations

Our recommended mitigations were developed in conversation with vendors. Our suggested temporary mitigations comply with the standard and preserve backward compatibility with unpatchable legacy hardware. For hypothetical mitigations that break backward compatibility, it would be better to redesign the entire protocol.

7.1 Short-Term Fix: Message-Authenticator

The optional Message-Authenticator attribute specified in RFC 2869 [54] computes an HMAC-MD5 over the entire packet. Packets that fail this integrity check are specified to be silently discarded. Although the MD5 hash function is no longer collision resistant, this is not known to imply an attack against HMAC-MD5, and HMAC-MD5 has been proven to be secure under the assumption that the compression function is a PRF, removing any reliance on collision resistance [5].

Our attack would be impossible if valid Message-Authenticator attributes were required on all packets, since the HMAC-MD5 would be unforgeable without the shared secret. As specified in RFC 2869 [54], Message-Authenticators are only required for packets containing EAP-Message attributes; RFC 5080 [34] states that clients SHOULD include Message-Authenticators on requests, but does not mandate it.

We learned from vendors that nearly all RADIUS servers are based on one of five implementations: FreeRADIUS, Radiator, Cisco, Microsoft, and Nokia. Before our disclosure, none required Message-Authenticators on non-EAP requests by default. The only RADIUS server we are aware of that did require them by default was OpenBSD's `radiusd`. Among clients, `hostapd` was the only implementation that required Message-Authenticators on non-EAP responses. The client implementations of FreeRADIUS and NPS could be configured to require them but did not do so by default; we are not aware of any other client with such an option.

Requiring Message-Authenticators. Our recommended short-term mitigation for the attack is for clients and servers to always send and require Message-Authenticator attributes for *all* requests and responses. For Access-Accept or Access-Reject responses, the Message-Authenticator should be included as the first attribute. See [19] for specific implementation details. This mitigation has been implemented by all RADIUS implementations that we are aware of.

This measure breaks compatibility with old implementations that may not include Message-Authenticators in requests or responses. However, unlike other options, it is not a fundamental change to the protocol and can be adopted as a fairly simple patch to clients and servers.

Attacks on Partial Enforcement. Unfortunately, it is not enough for senders to always include a Message-Authenticator if the receiving party does not require its presence. We give two example attacks allowing an attacker to circumvent these incomplete mitigations.

For Access-Request packets, the attacker can simply strip a Message-Authenticator sent by a client if it is not required by the server. This is because there is no other authentication of the packet contents. Once the attacker has removed the Message-Authenticator, the request can be modified as desired without being detected.

In the other direction for Access-Accept and Access-Reject responses, a man-in-the-middle attacker cannot simply strip this attribute from the packet as for requests, because the Message-Authenticator attribute is included in

the Response Authenticator. However, we observed that the Message-Authenticator attribute was typically the last attribute in the packet in implementations we examined. If the Message-Authenticator is not the first attribute in the packet then our man-in-the-middle attacker can hide it in a Proxy-State or other attribute by crafting a malicious prefix to end with a Proxy-State header, and simply copy the bytes of the Message-Authenticator into the Proxy-State after the collision. The receiving client will interpret this packet as a valid packet without a Message-Authenticator.

To mitigate this attack, we recommend servers always include a Message-Authenticator as the *first* attribute in any response. This appears to prevent the above attack even if a client does not validate the HMAC-MD5. This is because the value of the Message-Authenticator will be unpredictable, and thus the attacker will not be able to guess its value to include in the collision prefix or abuse other attribute headers to swallow the unpredictable value in the collision.

Practical considerations and interoperability issues for deploying these mitigations are discussed further in [19]. Future versions of [18] are expected to mandate this behavior for clients and servers.

7.2 Long-term fix: RADIUS over (D)TLS

The long-term solution to the vulnerabilities we describe in this paper is to use RADIUS inside of an encrypted and authenticated channel that offers modern cryptographic security guarantees. We expect future work in the IETF to formally deprecate RADIUS/UDP and standardize RADIUS over (D)TLS.

Transport security for RADIUS has been defined in the experimental RFC 6614 [53], specifying RADIUS over TLS, and RFC 7360 [17], specifying RADIUS over DTLS.

The IETF RADIUS EXTensions working group has a current Internet Draft to update and modernize the security recommendations for (D)TLS Encryption for RADIUS [38]. It is not yet on the standards track.

Unfortunately, although the proposals for RADIUS over TLS have existed for a decade, many systems continue to use RADIUS/UDP. Deploying TLS and maintaining a public-key infrastructure continues to be a much more involved process for system administrators than simply using UDP; many of the challenges are documented in the (D)TLS Internet Draft [38].

7.3 Partial Mitigation: Management VLAN

A current best practice for RADIUS/UDP traffic is to expose it only to a restricted-access management VLAN within an organization. While this reduces the attack surface and is certainly preferable to exposing UDP traffic to a broader network or the open internet, there may still be vulnerabilities in case of a network misconfiguration or attacker compromise of this portion of the network.

This approach is also at odds with the US Executive Branch Office of Management and Budget's 2022 memo, which envisions moving to systems that do not rely on network separation for security: "A key tenet of a zero trust architecture is that no network is implicitly considered trusted" [55].

7.4 Non-Mitigation: Decreasing timeouts

It is tempting to hope that simply setting a client timeout below our reported MD5 collision running times would defend against our attack. We believe this should not be done: it decreases usability and does not protect against our attack.

Our MD5 collisions were computed after applying some optimizations to a 15-year-old proof-of-concept codebase, which we are running on CPUs mostly dating from seven to ten years ago, because these are the resources we have access to. An adversary with a budget for professional engineering would be able to decrease the computational cost of the collision by a factor of tens to hundreds (cf. Section 4.5).

The most common timeout in practice is 30 seconds [16], and 60 seconds is commonly recommended when multifactor authentication is involved (for example, [23]) as shorter timeouts could be problematic for real users.

7.5 Non-Mitigation: TACACS+ or Diameter

RADIUS is not the only protocol to suffer from the types of security issues that we outline. TACACS+ is a popular (TCP-based) administrator login protocol for switches that also does not meet modern cryptographic security standards. RFC 8907 [14] was published in September 2020, and explicitly mandates that TACACS+ be used with a secure transport:

> With respect to the observations about the security issues described above, a network administrator MUST NOT rely on the obfuscation of the TACACS+ protocol. TACACS+ MUST be used within a secure deployment; TACACS+ MUST be deployed over networks that ensure privacy and integrity of the communication and MUST be deployed over a network that is separated from other traffic.

There is a current draft for TACACS+ over TLS 1.3 [13]. Much like RADIUS, however, TACACS+ is still most commonly used over insecure transports [16].

A suitable countermeasure would be to mandate transport security for RADIUS in an analogous fashion.

Diameter [24] was initially designed as a successor to RADIUS, although it never replaced RADIUS for many common use cases. It is used in 3G+ networks, and is generally only supported in large NAS equipment used by bigger ISPs and telecommunications providers; consumer or enterprise-grade equipment typically only supports RADIUS [16].

Although Diameter was intended to replace RADIUS, the protocol itself offers no security when used over TCP. As a result, RFC 6733 suggests that Diameter messages should be secured using TLS or DTLS; 5G has replaced Diameter with signaling over HTTP/2 [30]. The US government has described exploits against Diameter targeting mobile users [10].

7.6 Non-Mitigation: Random shared secrets

Organizations can protect against dictionary attacks on the shared secret by picking random shared secrets of sufficient length, as the runtime of such an attack grows exponentially with the entropy of the secret. For example, [18] recommends shared secrets with at least 96 bits of entropy, so an offline dictionary attack would involve on the order of 2^{96} MD5 compressions. However, as our attack does not try to brute-force the shared secret, choosing a strong shared secret does not affect the runtime of our attack.

7.7 Non-Mitigation: MFA

Multi-factor authentication (MFA) is not a mitigation either. Our attack largely bypasses the user authentication mechanism, and forges the accept response from the server's reject. MFA may be supported through multiple mechanisms within the RADIUS protocol, including authentication protocols like PAP that are vulnerable by default to our attack.

For example, when using Okta, a user's password and passcode can be entered together (as a single comma-delimited string) as the User-Password attribute in an Access-Request using the RADIUS PAP protocol. We carried out a successful proof of concept attack against Okta with MFA enabled in this setting, detailed in Section 5.3.

7.8 Non-Mitigation: Rejecting Proxy-States

Our forged Access-Accept packets contain Proxy-State attributes that the client is not expecting. However, having the client discard packets with unexpected Proxy-States does not mitigate the vulnerability. First, such a mitigation would only apply to a NAS; the Proxy-State attribute is actually used by RADIUS server proxies and thus difficult to remove without breaking functionality [16].

Even if NAS clients rejected unexpected Proxy-State attributes, it would be possible to craft colliding packets where the Access-Accept has the collision gibberish in a different attribute such as Vendor-Specific or Reply-Message that is likely to be accepted; the client does not need to support or attempt to interpret the garbage attribute to be vulnerable.

The colliding Access-Reject packet would still use Proxy-State attributes, as the server is guaranteed to include Proxy-State attributes unchanged in an Access-Reject. For simplicity our implementation uses Proxy-States in both colliding packets, as no RADIUS client we tested complained about the unexpected Proxy-State.

7.9 Non-Mitigation: Replacing MD5

It is tempting to think that simply replacing MD5 in the Response Authenticator with a secure hash function like SHA-2 or SHA-3 might be a short-term mitigation against our attacks. However, since the RADIUS protocol does not provide for any cryptographic agility, such a change would be incompatible with all existing implementations, and thus be equivalent to requiring a new protocol. Given the other security and privacy concerns with the rest of RADIUS, it would be better at that point to redesign the entire protocol or transport.

8 Conclusion

Beyond the RADIUS protocol itself, our work raises some broader issues in cryptographic security.

Over the past couple of decades, there has been a concerted effort in both academia and industry to deploy secure encrypted protocols on the internet.

However, the world of standardization bodies, and the relationship between standards and real-world deployment can be extremely complex and require large investments of time and money. This process relies on the economic interest of companies to fund employees to participate; long-term maintenance of protocols, working groups, and open-source software is subject to the shifting tides of employment and interests. This contributes to the current situation where vital portions of our network infrastructure are essentially maintained as a labor of love by a small number of dedicated individuals. Academic researchers may in some cases even have negative incentives from their university employers to do practical work that does not immediately result in academic publications.

That said, joint efforts in recent years between cryptography researchers and industry to develop and standardize provably secure versions of protocols like TLS and secure messaging have been successful. Given the enormous amount of effort put into securing these protocols it is surprising that a protocol as ubiquitous as RADIUS has received so little cryptanalytic attention over the years. TLS may be the charismatic megafauna of cryptographic protocol research, but in order to actually secure our infrastructure we need to analyze and secure the entire universe of enterprise security that academic cryptographers have little to no visibility into or insight in.

A On the origin of Proxy-State

The Proxy-State attribute was proposed for addition in an email to the IETF RADIUS working group on May 24, 1995 [3]. The justification provided in the email is to allow stateless proxying between clients and a pool of authentication servers. This attribute was included in the May 1995 protocol draft [41]. The only way that this attribute appears to be used in modern implementations is for catching proxy loops [16]. RFC 2865 mentions in at least seven different places that Proxy-State attributes must be returned in order and unmodified in responses. The presence of this attribute makes the protocol vulnerability much simpler to exploit than it would have been otherwise.

B Changes to hashclash

The code is available at [46]. We do not plan to publish our cluster scripts; they are uninformatively tailored to our setup. The following is an exhaustive summary of changes to `hashclash` that we made, categorized by program and goal.

`md5_birthdaysearch`:
- (Scaling) Add parameter to control how frequently trails are distributed/saved to and loaded by controllers.
- (Scaling) Add generatormode that only generates trails and distributes them to controllers.
- (Latency) Immediately save birthday collision when found, instead of waiting until all threads finish.
- (Fix) AVX256 allocation: Older GCC might not properly do large alignment as required for AVX256.

`md5_diffpathhelper`:
- (Section 4.1) Fix a few bytes at the start of a near-collision block.
- (Section 4.2) Add support to combine diffpaths, in order to use precomputed set of upper differential paths and overwrite the full differential paths with the correct ending differences for the near-collision block at hand.
- (Section 4.2) Add support to negate a set of diffpaths, in order to negate each 'positive delta m11'-based precomputed set of upper differential paths instead also computing the 'negate delta m11'-based set.
- (Fix) Add support to join files consisting of just a differential path (not a set of one).

`md5_diffpathforward`:
- Speed up differential path fast solvability checking: only check change, assume input paths were solvable.
- (Speed) Progressively increase output set size for the first few steps (t=1,2,3) of forward.
- (Speed) When full decrease maxcond to stop processing paths that will be pruned later on.
- (Speed) Use C++ move instead of copy.
- (Scaling) Use threadlocal buffers to global container to reduce contention.
- (Scaling, Latency) Add splitsave parameter to save output over multiple files in parallel.

`md5_diffpathconnect`:
- (Speed) New mintunnel parameter to prune search from start to avoid bad full paths with too few tunnels.
- (Latency) Parallel read of both inputfiles, new option to wait for file to exist before trying to load it.

All:
- (Scaling) Improve input distribution over threads.
- (Latency) Diffpath archives: gzip with `best_speed`.
- (Fix) Clean up comparison operators.
- (Fix) Make `dostep_index` volatile, read at start, write after critical section.

Key Recovery Attacks on Approximate Homomorphic Encryption with Non-Worst-Case Noise Flooding Countermeasures

Qian Guo

ENS Lyon

Thomas Johansson
Lund University

Abstract

In this paper, we present novel key-recovery attacks on Approximate Homomorphic Encryption schemes, such as CKKS, when employing noise-flooding countermeasures based on non-worst-case noise estimation. Our attacks build upon and enhance the seminal work by Li and Micciancio at EUROCRYPT 2021. We demonstrate that relying on average-case noise estimation undermines noise-flooding countermeasures, even if the secure noise bounds derived from differential privacy as published by Li et al. at CRYPTO 2022 are implemented. This study emphasizes the necessity of adopting worst-case noise estimation in Approximate Homomorphic Encryption when sharing decryption results.

We perform the proposed attacks on OpenFHE, an emerging open-source FHE library garnering increased attention. We experimentally demonstrate the ability to recover the secret key using just one shared decryption output. Furthermore, we investigate the implications of our findings for other libraries, such as IBM's HElib library, which allows experimental estimation of the noise bounds. Finally, we reveal that deterministic noise generation utilizing a pseudorandom generator fails to provide supplementary protection.

1 Introduction

Fully homomorphic encryption (FHE) is a cryptographic primitive that supports arbitrary computations on encrypted data without using the decryption key and without revealing information about plaintexts. This problem appeared already in the 70s [29] but a solution did not appear until 2009, when Gentry [18] constructed the first such schemes. Many homomorphic encryption schemes [6, 12, 15, 17, 19] have now appeared and most of them are based on the security of the Learning with Errors (LWE) problem or some of its variants. In 2022, Brakerski, Gentry, and Vaikuntanathan received the prestigious Gödel prize for their transformative contributions to cryptography by constructing efficient FHE schemes.

FHE is a very powerful cryptographic tool and can be a solution to many security problems, particularly for distributed or outsourced computation. A future application area is also in AI and privacy-preserving machine learning.

A very popular FHE branch is *approximate* homomorphic encryption such as CKKS [10] and its variants [7, 8]. FHE on approximate numbers, as proposed by Cheon, Kim, Kim and Song [10], has attracted much attention from the fact that it improves the efficiency of computing on encrypted data in many applications where approximate results are acceptable, like privacy-preserving machine learning. FHE based on LWE builds ciphertexts that contain noise and as operations on ciphertexts are performed, the noise is increasing. One has to control the noise and make sure it does not grow to be too large, in order to ensure correct decryption. The main contribution in CKKS was the observation that it can be tolerable for decryption to be approximate so that the plaintext from the decrypted ciphertext is only approximately the correct one. Typically, this is the case in applications where small errors can occur. The CKKS scheme then supports real-valued plaintexts, making it efficient and attractive for certain applications, allowing for some small errors in the least significant bits. CKKS has since been implemented in many well-known open-source libraries for homomorphic encryption and also been extensively examined and optimized.

The CKKS scheme as most other lattice-based FHE schemes meets the basic security notion of indistinguishability under chosen plaintext attack (IND-CPA), assuming the hardness of some well-studied problems, like the average-case hardness of the Learning With Errors (LWE) problem which in turn relates to the worst-case complexity of some computational problems on lattices. Achieving a stronger security notion – indistinguishability under chosen ciphertext attack (IND-CCA), which presumes an active adversary capable of tampering with (or injecting) arbitrary ciphertexts – is challenging, due to the inherent nature of FHE operations.

Li and Micciancio [23] have recently shown that the traditional formulation of IND-CPA security does not adequately capture the security of approximate encryption against passive attacks. Specifically, in the context of a homomorphic encryption scheme, a passive adversary has the capability to

select or know the homomorphic function that is being executed. Such an adversary can also observe the outcome of the decryption process. Despite being able to eavesdrop, this adversary remains categorized as passive, as it is not permitted to manipulate, inject, or modify ciphertexts, nor alter the final computational result. Li and Micciancio have shown that the CKKS scheme is vulnerable to an efficient key recovery attack under these conditions.

They also proposed a new, enhanced formulation of IND-CPA security that they called IND-CPA with decryption oracles (IND-CPA$^{\mathsf{D}}$). This notion captures better the threats of a passive attacker. It is proven to be identical to IND-CPA security for encryption schemes with exact decryption, but the situation is different when allowing approximate decryption. The primary distinction lies in the utility of observing decryption outcomes. In encryption schemes with exact decryption, an adversary gains no additional information from observing the decryption result. This is because the adversary, who already knows the original message and evaluation function, can calculate the final outcome on its own. Conversely, for approximate encryption schemes, observing the decryption output could yield invaluable information not readily computable by the adversary. Such information may be exploited by a passive adversary for effective key recovery.

A relevant security notion is KR$^{\mathsf{D}}$ security against key recovery attacks, a notion that, while implied by IND-CPA$^{\mathsf{D}}$ security, is significantly weaker. This weakness arises because key recovery attacks constitute a more potent form of attack compared to distinguishing attacks.

Li and Micciancio also suggested some ideas of countermeasures to avoid the proposed attack, and the open-source libraries implementing CKKS include different but similar countermeasures to thwart the attack in [23]. Subsequently, Li, Micciancio, Schultz, and Sorrell further examined the use of differential privacy to assure IND-CPA$^{\mathsf{D}}$ security in [24]. Their method necessitates the inclusion of a considerable amount of additional noise.

FHE schemes, and CKKS-like schemes in particular, involve different parameters and a major task for the designer of the scheme is the choice of parameters that should give the best trade-off between efficiency and security. Both these aspects relate to the connected noise growth in the scheme. For approximate FHE, encoding noise and encryption noise should be considered together. Also, we have to keep track of the level of ciphertexts as in traditional FHE schemes as well as a so-called scaling factor. CKKS-like schemes consider the precision of the scheme and one has to track how it changes through homomorphic operations and its influence on the encrypted data. The scale parameter is typically a way for the user to control the desired precision.

The CKKS paper provided an open-source implementation in the "Homomorphic Encryption for Arithmetic on Approximate Numbers", Heaan [1], other implementations of the scheme have been included in essentially all mainstream libraries for secure computation on encrypted data, like Microsoft's "Simple Encrypted Arithmetic Library" SEAL [26], IBM's "Homomorphic Encryption" library HElib [21], the lattice cryptography libraries PALISADE [2] and Lattigo [16]. Recently, the PALISADE authors along with a subset of authors from the other libraries released a new library in July 2022, under the name OpenFHE [4]. OpenFHE provides implementations of all main FHE schemes.

These libraries are also used as a part of other implemented tools and applications. A well-known example is Intel's nGraph-HE compiler [5] for secure machine learning applications. Other implemented applications include the encrypted computation of logistic regression [20], security-preserving support vector machine [27], homomorphic evaluation of neural networks and tensor programs [14], and clustering over encrypted data [11].

A recent trend in the implementation of CKKS-like schemes involves using a non-worst-case noise estimation, such as an empirical or average-case noise estimation, as seen in sources like [4, 13, 21]. In this context, a worst-case noise bound refers to a bound that tracks the maximum possible noise throughout each step of homomorphic evaluation. Conversely, empirical noise estimation involves setting the noise limit based on empirical tests, while average-case noise estimation models the noise as a Gaussian distribution, keeping tracks of the variance during each homomorphic encryption operation. Opting for a non-worst-case approach can enhance performance, since the non-worst-case noise bound can be significantly smaller than the worst-case noise bound, thus substantially improving the scheme's efficiency. This is particularly appealing when considering the efficiency loss incurred while protecting against the Li-Micciancio attack.

To our knowledge, OpenFHE is the first major open-source library to claim the implementation of the differential privacy countermeasure as proposed in [24], yet they suggest the use of a non-worst-case noise estimation. In this paper, we explore the potential impact of such noise estimations on security, when the decryption results need to be shared.

1.1 Contributions

The main contributions of this work can be summarized as follows. Firstly, using non-worst-case estimation methods, such as relying on the central limit theorem (CLT) for average-case noise estimation [13] or experimentally determining the noise bound, can introduce significant security vulnerabilities. For instance, even when adopting the secure noise bounds suggested in [24] to achieve IND-CPA$^{\mathsf{D}}$ security through differential privacy, KR$^{\mathsf{D}}$ security may not be ensured if the noise size is estimated in a non-worst-case manner. The novel observation is that such non-worst-case estimation assumes that the message distribution or the computation gate should follow some average-case or predefined behaviour; however, in the IND-CPA$^{\mathsf{D}}$ attacker model, the adversary has the power

to control the message distribution, causing it to deviate significantly from the average case. The adversary also has the power to select the functions and gates among the possible valid options.

We implement a key-recovery attack on the recent OpenFHE implementation, requiring only a single shared decryption output. The OpenFHE library, a successor to PALISADE, is chosen as the primary target implementation since it incorporates the noise-flooding countermeasure with the new secure noise bounds [24] derived from differential privacy[1]. In contrast, Microsoft SEAL disallows the sharing of decryption results, while open-source HElib and HEAAN have not implemented countermeasures based on the latest CRYPTO 2022 research [24]. We are capable of attacking OpenFHE as its noise estimation method aligns with the average-case noise estimation proposed in [13].

The experimental noise estimation employed in HElib necessitates that the server performing homomorphic evaluation adheres to the message/ciphertext distribution and the evaluation gates assumed by the user. However, these requirements contradict the adversary model of IND-CPA$^{\mathsf{D}}$ security. Our analysis indicates that the flooding countermeasure with such noise estimation is also insecure.

Finally, as an additional finding, we show that the protection of utilizing a pseudorandom generator to produce deterministic noise with the ciphertext serving as an input seed does not improve security. Such a countermeasure has been suggested in [9,23] and implemented in HElib. We have carefully designed a mechanism to bypass this security measure. The code for all of our experiments is public[2].

1.2 Organizations

The remainder of this paper adheres to the following organization. Section 2 introduces the background on Approximate Homomorphic Encryption schemes. Section 3 presents the attack targeting implementations using non-worst-case noise estimation. Section 4 describes the attack method for deterministic noise estimation for "fresh ciphertexts". Lastly, Section 5 offers concluding insights and additional discussions.

2 Preliminaries

In this section, we provide essential background information on Approximate Homomorphic Encryption schemes and describe their security notions.

Notation. Let $\mathbb{Z},\mathbb{Q},\mathbb{R},\mathbb{C}$ represent the sets of integers, rationals, reals, and complex numbers, respectively. Bold characters, such as $\mathbf{a}=(a_1,\ldots,a_n)$, denote vectors. The dot product of two vectors is written as $\langle \mathbf{a},\mathbf{b}\rangle$. For a probability distribution $\mathcal{D}$, we use $x \leftarrow \mathcal{D}$ to indicate that x is sampled according to the distribution $\mathcal{D}$. We denote the additional noise of countermeasures with ε, which, though not necessarily small, can be considered as random computational noise. Let $\lfloor\cdot\rceil$ denote the operation of rounding to the nearest integer. The security parameter is represented by κ. A function f is deemed negligible in κ if $f(\kappa)=\kappa^{-\omega(1)}$.

2.1 Lattices and the Ring-LWE problem

A lattice is a discrete subgroup of $\mathbb{R}^n$. Let n,d be two positive integers, and let $\mathbf{b}_1,\ldots,\mathbf{b}_d$ be linearly independent vectors in $\mathbb{R}^n$. The lattice they generate is $\mathcal{L}(\mathbf{b}_1,\ldots,\mathbf{b}_d)=\sum_{i=1}^{d}\mathbb{Z}\mathbf{b}_i$. If $d=n$, the lattice is considered full-rank.

Let $N=2^k$ be a power of 2. Let $\psi(N)=X^N+1$ be a power-of-2 cyclotomic polynomial. Let $R=\mathbb{Z}[X]/\psi(N)$. For $b\in R$, we denote $\|b\|_2$ the Euclidean norm of the vector of its coefficients. Let $R_q=\mathbb{Z}_q[X]/\psi(N)=R/qR$.

We define $\mathcal{N}(\mu,\sigma)$ as the discrete Gaussian distribution with mean μ and standard deviation σ – that is, a probability distribution supported on $\mathbb{Z}$ with a probability mass function $p(x)\propto\exp\left(-(x-\mu)^2/(2\sigma^2)\right)$. Such a distribution can be approximated by its continuous counterpart. Specifically, if $x\leftarrow\mathcal{N}(\mu_1,\sigma_1)$ and $y\leftarrow\mathcal{N}(\mu_2,\sigma_2)$, respectively, the sum $x+y$ is regarded as a draw from $\mathcal{N}(\mu_1+\mu_2,\sqrt{\sigma_1^2+\sigma_2^2})$. We can make the distribution over $\mathbb{Z}_q$ by reducing the output mod q.

The best-known FHE schemes are built upon the Learning with Errors (LWE) problem [28]. In the CKKS scenario, we focus more on its ring version, known as the Ring-LWE problem [25]. The Ring-LWE distribution is obtained as follows.

Definition 1 *Let $k\geq 1, q\geq 2, \alpha\in\mathbb{R}, s\in R_q$. The Ring-LWE distribution is obtained as follows:*

$$a \leftarrow \mathcal{U}(R_q);$$

$$e \leftarrow R \quad \textit{with coefficients} \leftarrow \mathcal{N}(0,\frac{\alpha q}{\sqrt{2\pi}});$$

The oracle subsequently returns $(a, a\cdot s+e)\in R_q\times R_q$.

2.2 Approximate Homomorphic Encryption

In their work [10], Cheon et al. introduced the first approximate homomorphic encryption scheme, commonly referred to as CKKS, named after its creators. Here, we first present the definition of Homomorphic Encryption. Gentry's bootstrapping blueprint [18] allows for the construction of a Fully Homomorphic Encryption (FHE) scheme from an HE scheme.

Definition 2 (Homomorphic Encryption (HE)) *A (public-key) HE scheme comprises four polynomial time algorithms:*

[1] https://github.com/openfheorg/openfhe-development/blob/main/src/pke/examples/CKKS_NOISE_FLOODING.md.

[2] https://github.com/d-nabokov/KRAonCKKS

- *A (randomized) key generation algorithm* $\mathsf{KeyGen} : 1^\kappa \to \mathcal{PK}^2 \times \mathcal{SK}$ *that generates the public key, evaluation key, and secret key.*
- *A (randomized) encryption algorithm*
  $\mathsf{Enc} : \mathcal{PK} \times \mathcal{M} \to \mathcal{C}$.
- *A (deterministic) decryption algorithm*
  $\mathsf{Dec} : \mathcal{SK} \times \mathcal{C} \to \mathcal{M}$.
- *A (deterministic) homomorphic evaluation function*
  $\mathsf{Eval}\ \forall k, \mathcal{PK} \times (\mathcal{M}^k \to \mathcal{M}) \times \mathcal{C}^k \to \mathcal{C}$.

In the given definition, $\mathcal{PK}$ signifies the collection of public keys, inclusive of the evaluation keys, while $\mathcal{SK}$ denotes the set of secret keys. Additionally, $\mathcal{M}$ represents the message space, and $\mathcal{C}$ stands for the ciphertext space. The function provided to the evaluation method is a circuit comprising multiple gates.

In standard HE schemes, the correctness of the scheme is defined as

Definition 3 (HE Correctness) *For an arbitrary circuit* $\mathfrak{C}$ *the following holds*

$$\mathsf{Dec}_{\mathsf{sk}}(\mathsf{Eval}_{\mathsf{ek}}(\mathfrak{C}, (c_1, \ldots, c_k))) = \mathfrak{C}(m_1, \ldots, m_k),$$

where $(\mathsf{pk}, \mathsf{ek}, \mathsf{sk}) = \mathsf{KeyGen}(1^\kappa)$ *and* $c_i = \mathsf{Enc}_{\mathsf{pk}}(m_i)$ *for all* $i \leq k$.

Approximate HE schemes Approximate HE schemes are a special type of HE schemes where the notion of correctness does not hold. They allow approximate arithmetic on encrypted data, considering errors of homomorphic operations as part of the computational errors in the approximate computation. As the first approximate HE proposal, CKKS supports two approximate homomorphic operations:

- $\mathsf{Dec}_{\mathsf{sk}}(\mathsf{Add}(\mathsf{Enc}_{\mathsf{pk}}(m_1), \mathsf{Enc}_{\mathsf{pk}}(m_2))) \simeq m_1 + m_2$,
- $\mathsf{Dec}_{\mathsf{sk}}(\mathsf{Mult}(\mathsf{Enc}_{\mathsf{pk}}(m_1), \mathsf{Enc}_{\mathsf{pk}}(m_2))) \simeq m_1 * m_2$,

with a tracker on the size of the noise. Next, we will delve into the specifics of the CKKS scheme, beginning with its method for message encoding.

The CKKS message encoding. In order to perform pointwise addition and multiplication of vectors in the SIMD manner, the CKKS scheme designs the following encoding method. Let ω be the $2N$-th root of unity. Let $\phi : R \to \mathbb{C}$ be the mapping from $a(X) \in R$ to $\phi(a) = \hat{\mathbf{a}} = (a(\omega^{4j+1}))_{j=0}^{N/2-1} \in \mathbb{C}^{N/2}$. The CKKS scheme chooses a positive real Δ called scaling factor and defines the encoding and decoding functions as

- $\mathsf{Encode}(\mathbf{z} \in \mathbb{C}^{N/2}; \Delta) = \lfloor \Delta \cdot \phi^{-1}(\mathbf{z}) \rceil$,
- $\mathsf{Decode}(a \in R; \Delta) = \phi(\Delta^{-1} \cdot a) \in \mathbb{C}^{N/2}$,

where ϕ^{-1} is the inverse function of ϕ.

The CKKS scheme [10]. The CKKS scheme supports the encryption and decryption of floating-point inputs using the message encoding interface. We now consider the plaintext space as R_q and the ciphertext space as R_q^2. We have a ciphertext module q and a discrete Gaussian error distribution χ, where $\chi = \mathcal{N}(0, \sigma)$. We bypass many intricate details, focusing on the primary procedures and attributes pertinent to this study. The following description is from [24]. For a more comprehensive understanding, we refer the reader to [10].

- $\mathsf{CKKS.KeyGen}(1^\kappa)$: Let $w = w(\kappa)$ and $p = p(\kappa, q)$. We sample s from the set $s \in \{-1, 0, 1\}^N$ with w non-zero entries in s and designate sk as $(1, -s)$. Alternatively, s can be sampled from a uniform distribution over $\{-1, 0, 1\}^N$. We sample $a \leftarrow R_q$, $e \leftarrow \chi$ and take $\mathsf{pk} = (a, b)$ with $b = a \cdot s + e$. We sample $a' \leftarrow R_{pq}$, $e' \leftarrow \chi$ and take $\mathsf{ek} = (a', b')$ with $b' = a' \cdot s + e + p \cdot s^2 \mod pq$. Return $(\mathsf{sk}, \mathsf{pk}, \mathsf{ek})$.
- $\mathsf{CKKS.Enc}_{\mathsf{pk}}(m)$: Let ξ represent the distribution over $\{-1, 0, 1\}^N$, where each coefficient is independently sampled as 1 or -1 with a probability of $1/4$, and 0 with a probability of $1/2$. Then, we sample $r \leftarrow \xi$, $e_0, e_1 \leftarrow \chi$, and return $r \cdot \mathsf{pk} + (m + e_0, e_1) \mod q$.
- $\mathsf{CKKS.Add}(c_0, c_1)$: Return $c_0 + c_1 \mod q$.
- $\mathsf{CKKS.Mult}_{\mathsf{ek}}(c_0, c_1)$: Assume $c_0 = (a_0, b_0)$ and $c_1 = (a_1, b_1)$. Return (a_2, b_2), where $(a_2, b_2) = (a_0 b_1 + a_1 b_0, b_0 b_1) + \lfloor p^{-1} \cdot a_0 a_1 \cdot \mathsf{ek} \rceil \mod q$.
- $\mathsf{CKKS.Dec}_{\mathsf{sk}}(c)$: For $c = (a, b) \in R_q^2$, return $b - a \cdot s \mod q$.

Analyzing the addition operation in the worst-case scenario can be done straightforwardly. Suppose c_0 and c_1 are two ciphertexts with positive error bounds $errb_0$ and $errb_1$, respectively. The ciphertext resulting from the Add operation on c_0 and c_1 would have an error bounded to $errb_0 + errb_1$.

2.3 Security notions

The standard notion of security for FHE is IND-CPA (Indistinguishability - Chosen Plaintext Attack) security defined as follows.

Definition 4 (IND-CPA **security**) *We say that a FHE scheme* $(\mathsf{KeyGen}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Eval})$ *is* IND-CPA ***secure*** *if each efficient adversary* $\mathcal{A}$ *has negligible advantage* $\mathsf{Adv}_{\mathcal{A}}(\kappa)$*, where the advantage is defined as*

$$\mathsf{Adv}_{\mathcal{A}}(\kappa) = \left| \Pr\left[\mathcal{A} \xrightarrow{\mathsf{Expr}_0} 1\right] - \Pr\left[\mathcal{A} \xrightarrow{\mathsf{Expr}_1} 1\right] \right|.$$

The experiments are as follows :

Expr_b :

$\mathcal{C}$		$\mathcal{A}$
$(\mathsf{sk},\mathsf{pk},\mathsf{ek}) \leftarrow \mathsf{KeyGen}$	$\xrightarrow{\mathsf{pk}}$	
$c \leftarrow \mathsf{Enc}(\mathsf{pk}, m_b)$	$\xleftarrow{m_0,m_1}$	
	$\xrightarrow{c}$	*Outputs a bit b*

An additional security notion, IND-CPA^D, proves vital when the decryption outputs require sharing, as pointed out in [23]. For non-approximate HE, the IND-CPA^D notion is proven to be equivalent to the IND-CPA notion in [23]. However, for approximate HE, it represents a much stronger security notion. We present a formal definition as follows.

Definition 5 (IND-CPA$^{\mathsf{D}}$ **security [23])** *Given a public-key homomorphic (possibly approximate) encryption scheme $\mathcal{E}$, where $\mathcal{E} = (\mathsf{KeyGen}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Eval})$, with plaintext space $\mathcal{M}$ and ciphertext space $\mathcal{C}$, we define an experiment $\mathsf{Expr}_b^{\mathsf{indcpa}^D}[\mathcal{A}]$, parameterized by a bit $b \in \{0,1\}$ and involving an efficient adversary $\mathcal{A}$ that is given access to the following oracles, sharing a common state $S \in (\mathcal{M} \times \mathcal{M} \times \mathcal{C})^*$ consisting of a sequence of message-message-ciphertext triples:*

- *An encryption oracle $\mathsf{E}_{\mathsf{pk}}(m_0, m_1)$ that, given a pair of plaintext messages m_0, m_1, computes $c \leftarrow \mathsf{Enc}_{\mathsf{pk}}(m_b)$, extends the state*

$$S := [S; (m_0, m_1, c)],$$

  with one more triplet, and returns the ciphertext c to the adversary.

- *An evaluation oracle $\mathsf{H}_{\mathsf{ek}}(g, J)$ that, given a function $g : \mathcal{M}^k \to \mathcal{M}$ and a sequence of indices $J = (j_1, \ldots, j_k) \in \{1, \ldots, |S|\}^k$, computes the ciphertext $c \leftarrow \mathsf{Eval}_{\mathsf{ek}}(g, S[j_1].c, \ldots, S[j_k].c)$, extends the state*

$$S := [S; (g(S[j_1].m_0, \ldots, S[j_k].m_0), \\ g(S[j_1].m_1, \ldots, S[j_k].m_1), c)]$$

  with one more triplet, and returns the ciphertext c to the adversary. Here and below $|S|$ denotes the number of triplets in the sequence S, and $S[j].m_0, S[j].m_1, S[j].c$ denote the three components of the j-th element of S.

- *A decryption oracle $\mathsf{D}_{\mathsf{sk}}(j)$ that, given an index $j \leq |S|$, checks whether $S[j].m_0 = S[j].m_1$, and, if so, returns $\mathsf{Dec}_{\mathsf{sk}}(S[j].c)$ to the adversary. (If the check fails, a special error symbol $\perp$ is returned.)*

The experiment is defined as

$$\begin{aligned}&\mathsf{Expr}_b^{\mathsf{indcpa}^D}[\mathcal{A}](1^\kappa) : (\mathsf{sk},\mathsf{pk},\mathsf{ek}) \leftarrow \mathsf{KeyGen}(1^\kappa)\\ &\qquad S := []\\ &\qquad b' \leftarrow \mathcal{A}^{\mathsf{E}_{\mathsf{pk}},\mathsf{H}_{\mathsf{ek}},\mathsf{D}_{\mathsf{sk}}}(1^\kappa, \mathsf{pk}, \mathsf{ek})\\ &\qquad \mathsf{return}(\mathsf{b}')\end{aligned}$$

The advantage of adversary $\mathcal{A}$ against the IND-CPA^D *security of the scheme is $\mathsf{Adv}_{\mathsf{indcpa}^D}[\mathcal{A}](\kappa)$ defined as*

$$\left|\mathbf{Pr}\left[\mathsf{Expr}_0^{\mathsf{indcpa}^D}[\mathcal{A}(1^\kappa)] = 1\right] - \mathbf{Pr}\left[\mathsf{Expr}_1^{\mathsf{indcpa}^D}[\mathcal{A}(1^\kappa)] = 1\right]\right|,$$

where the probability is over the randomness of $\mathcal{A}$ and the experiment. The scheme $\mathcal{E}$ is IND-CPA^D*-secure if for any efficient (probabilistic polynomial time) $\mathcal{A}$, the advantage $\mathsf{Adv}_{\mathsf{indcpa}^D}[\mathcal{A}](\kappa)$ is negligible in κ.*

Another relevant security notion is the KR$^{\mathsf{D}}$ security, implied by the IND-CPA$^{\mathsf{D}}$ security. Although KR$^{\mathsf{D}}$ security is considered much weaker than the IND-CPA$^{\mathsf{D}}$ security, a key-recovery attack is predominantly employed to demonstrate the vulnerability of the analyzed schemes. This methodology aligns with the research presented in this paper. We present the formal definition of KR$^{\mathsf{D}}$ security in Definition 6.

Definition 6 (KR$^{\mathsf{D}}$ **security [24])** *Let $\mathcal{E} = (\mathsf{KeyGen}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Eval})$ be a public-key homomorphic (possibly approximate) encryption scheme with plaintext space $\mathcal{M}$ and ciphertext space $\mathcal{C}$. We define a game $\mathsf{Expr}^{\mathsf{KR}^{\mathsf{D}}}[\mathcal{A}]$, parameterized by an adversary $\mathcal{A}$ that is given access to the (stateful) oracles $\mathsf{E}'_{\mathsf{pk}}$, H_{ek}, D_{sk}, where $\mathsf{E}'_{\mathsf{pk}}(m) := \mathsf{E}_{\mathsf{pk}}(m, m)$ with oracles E_{pk}, H_{ek}, D_{sk} defined as in Definition 5.*

The game is defined as

$$\begin{aligned}&\mathsf{Expr}^{\mathsf{KR}^{\mathsf{D}}}[\mathcal{A}](1^\kappa) :\\ &\qquad (\mathsf{sk},\mathsf{pk},\mathsf{ek}) \leftarrow \mathsf{KeyGen}(1^\kappa)\\ &\qquad S := []\\ &\qquad \mathsf{sk}' \leftarrow \mathcal{A}^{\mathsf{E}'_{\mathsf{pk}},\mathsf{H}_{\mathsf{ek}},\mathsf{D}_{\mathsf{sk}}}(1^\kappa, \mathsf{pk}, \mathsf{ek})\\ &\qquad \mathsf{return}(\mathsf{sk} == \mathsf{sk}')\end{aligned}$$

The scheme $\mathcal{E}$ is said to have k bits of KR$^{\mathsf{D}}$*-security if, for any adversary $\mathcal{A}$,*

$$k \leq \log_2 \frac{T(\mathcal{A})}{\mathsf{Adv}_{\mathcal{A}}},$$

where $T(\mathcal{A})$ is the running time of $\mathcal{A}$.

In [24], the application of differential privacy technique results in a finer-grained definition of bit-security, parameterized by both a computational parameter c and a statistical parameter ν. We define this security notion as follows.

Definition 7 (**(c,ν)-bits of security [24])** *Let Π be a cryptographic primitive, and $\mathcal{G}$ be an indistinguishability game. Let $\mathsf{Adv}_{\mathcal{A}}$ be the advantage of an adversary $\mathcal{A}$ in breaking the security of Π in the $\mathcal{G}$ game. The scheme Π has (c,ν)-bits of $\mathcal{G}$-security if, for any adversary $\mathcal{A}$, either*

$$\log_2 \frac{T(\mathcal{A})}{\mathsf{Adv}_{\mathcal{A}}} \geq c, \quad \text{or,} \quad \log_2 \frac{1}{\mathsf{Adv}_{\mathcal{A}}} \geq \nu. \tag{1}$$

3 New key-recovery attacks

In this section, we improve upon key-recovery attacks initially presented by Li and Micciancio [23], when non-worst-case noise estimation is employed. We begin with the theoretical framework, then transition to the security implications for the OpenFHE and HElib homomorphic encryption libraries.

3.1 Theoretical framework

Attack model. We adopt the adversary model defined in [23], as also illustrated in Definition 6 and Figure 1. In this model, the adversary gains access to three stateful oracles $\mathsf{E}'_{\mathsf{pk}}$, H_{ek}, and D_{sk}, with $\mathsf{E}'_{\mathsf{pk}}(m) := \mathsf{E}_{\mathsf{pk}}(m,m)$. These oracles are defined in Definition 5. The adversary aims to recover the secret key sk and is capable of querying the three oracles, selecting messages and evaluation functions as inputs. Notably, this adversary remains passive; unlike an active adversary who can manipulate arbitrary ciphertexts, this model restricts the adversary to decryption queries on valid ciphertexts produced through legitimate operations, such as encryption and homomorphic computation via public interfaces or APIs provided by HE libraries.

Real-world scenarios. In practical applications, it is highly likely that decrypted data will be shared among parties who lack access to the secret key, making IND-CPA$^{\mathsf{D}}$ security indispensable. This sharing could facilitate significant applications like two-party computation for Privacy-Preserving Machine Learning as a Service (MLaaS), wherein the server owns a model it wishes to provision as a service, while the client seeks to obtain a homomorphically computed inference on its confidential data. The ecosystem might comprise a user holding the secret key and other participants lacking it, who function as passive adversaries. Service providers contribute by supplying APIs and computational resources.

An interesting case study involves a commercial application that collects encrypted data from the user and leverages a cloud service's API for homomorphic computations. We posit that the application can only invoke the API using ciphertexts authenticated by the user, thereby precluding the tampering or injection of fraudulent ciphertexts. The API invocation resembles the usage of the evaluation oracle H_{ek} as outlined in Definition 5. Should the user disclose the decrypted outcome, our novel attack strategy remains viable, even if non-worst-case noise-flooding countermeasures have been deployed.

The Li-Micciancio attack. Similar to [23], we use a simplified CKKS scheme without the encoding and decoding procedures as an example to explain the attack idea. The secret key is $\mathsf{sk}=(1,-s)$, where s is a power-of-two cyclotomic ring element in R_q. The only unknown part of the secret key is s, so the recovery of sk is equivalent to recovering s. The

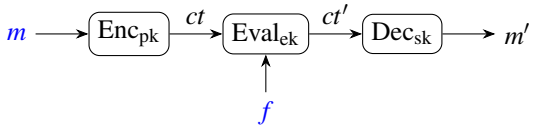

Figure 1: Figure illustrates a passive attacker scenario based on Li and Micciancio's model [23]. In this context, the attacker may choose/know the plaintext m and the homomorphic function f. The attacker can eavesdrop on the ciphertexts ct, ct' and decryption result m', but is not allowed to tamper with (or inject) ciphertexts or alter the computation's final outcome.

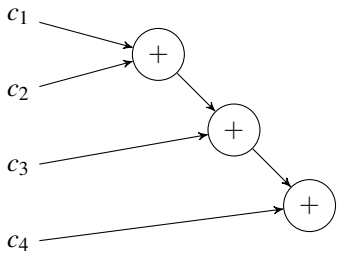
adversary encrypts m as $\mathsf{Enc}(m) = (a,b) \in R_q^2$, where $a \in R_q$ is selected at random and $b = a \cdot s + e + m$ for a polynomial $e \in R_q$ where the coefficients of e are a small perturbation from the distribution $\mathcal{N}(0,\sigma_1)$. The decryption function computes $\mathsf{Dec}_s((a,b)) = b - a \cdot s = m + e$. In the Li-Micciancio attack, the adversary $\mathcal{A}$ selects the message $m = 0$ and requests the computation of the identity function, effectively equivalent to performing no operation. The adversary then proceeds to request an approximate decryption and carries out subsequent computations of

$$b' = b - \mathsf{Dec}_s((a,b)) = a \cdot s.$$

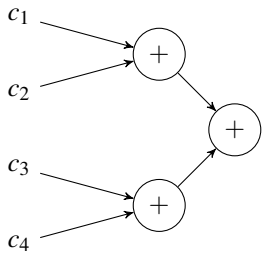
The secret key s can then be recovered by computing

$$s = a^{-1} \cdot b',$$



if a is an invertible element in R_q. Otherwise, the adversary requires for more decryption queries.

Noise-flooding countermeasures. Li and Micciancio have proposed a countermeasure from the noise-flooding technique, for protecting against their attack in [23]. The main idea is to introduce an additional noise in the decryption function. Thus, the decryption function of CKKS, named decryption for share, can be defined as



$$\mathsf{Dec}^{\mathsf{D}}_s((a,b)) = \mathsf{Dec}_s((a,b)) + e_{\mathsf{new}},$$

where $e_{\mathsf{new},i} \leftarrow \mathcal{N}(0,\sigma_2)$ and $e_{\mathsf{new},i}$ is the coefficient of e_{new}. When the adversary $\mathcal{A}$ computes $b' = b - \mathsf{Dec}^{\mathsf{D}}_s((a,b))$, the output is $a \cdot s + e_{\mathsf{new}}$; if the noise is sufficiently large, then the new ring-LWE instance $(a, a \cdot s + e_{\mathsf{new}})$ is hard to solve.

Achieving IND-CPA$^{\mathsf{D}}$ through differential privacy [24]. The general idea is to add a noise with sufficiently large variance. The newly proposed schemes, referred to as S-CKKS$_\sigma$, are detailed in [24]. Initially, they establish a noise bound, $\mathsf{ct.t}$, designed to accommodate the worst-case noise growth, following which they add a component-wise noise, $\mathcal{N}(0, \sigma \cdot \mathsf{ct.t})$, in the noise-flooding countermeasure. In [24], the following lemma is proved.

(a) Iterative addition

(b) Tree-based addition

Figure 2: Iterative and tree-based addition for $g_t(\mathbf{c})$ with $t = 4$

Lemma 1 ([24]) *Assume the number of decryption oracle calls is bounded to q and $\sigma = \sqrt{24qn}2^{\nu/2}$. If* CKKS *is $(c + \log_2 24)$-bit* IND-CPA*-secure, then* S-CKKS$_\sigma$ *is (c,ν)-bit* IND-CPA$^{\mathsf{D}}$*-secure.*

On the other hand, for recent open-source implementations (e.g., in [4]), non-worst-case noise estimation approaches are preferred to enhance efficiency.

New attack scenario. We describe an attack scenario when the standard deviation σ_2 of the added Gaussian noise in the noise-flooding countermeasure is a function that grows much slower than the estimated noise in the worst-case noise analysis.

In alignment with the IND-CPA$^{\mathsf{D}}$ model outlined in Definition 5, the adversary has the capability to execute computations on valid ciphertexts using a chosen function. Specifically, the adversary employs the evaluation oracle H_{ek} for homomorphic calculations. Our primary focus is on the evaluation function $g_t(\mathbf{c})$, which performs homomorphic addition of t ciphertexts $\mathbf{c} = (c_1, c_2, \ldots, c_t)$. This function, illustrated in Figure 2, can be executed through either an iterative addition over $t-1$ layers or a tree-based addition spanning $\lceil \log_2(t) \rceil$ layers. Depending on the approach, the gate latency stands at either $t-1$ or $\lceil \log_2(t) \rceil$.

In this new attack scenario, we stick with the case where $m = 0$, first generate a ciphertext $c_0 = (a,b)$, and then homomorphically evaluate the addition $g_t(\mathbf{c})$, where $\mathbf{c}$ is a vector repeating the ciphertext c_0 for t times. The noise, therefore, is grown from e to $t \cdot e$. The new decryption function $\mathsf{Dec}_s^{\mathsf{D}}(\cdot)$ gives us the value of

$$e_{\mathsf{total}} = t \cdot e + e_{\mathsf{new}}.$$

We need the following lemma to characterize the distribution of conditional probability $(e_i | e_{\mathsf{total},i} = l)$, where e_i and $e_{\mathsf{total},i}$ are the i-th coefficient of e and e_{total}, respectively.

Lemma 2 ([22]) *For two positive numbers σ_a and σ_b, let X and Y be variables of distributions $\mathcal{N}(0,\sigma_a)$ and $\mathcal{N}(0,\sigma_b)$, respectively. Let $\sigma = \sqrt{\sigma_a^2 + \sigma_b^2}$, then $(X|X+Y=l)$ follows the distribution $\mathcal{N}(l \cdot \frac{\sigma_a^2}{\sigma^2}, \frac{\sigma_a \sigma_b}{\sigma})$.*

In the attack, we can obtain the value of e_{total} from the new decryption function. Conditioned on this observation, the distribution of the noise e needs to be updated. Since $t \cdot e_i$ is sampled from $\mathcal{N}(0, t \cdot \sigma_1)$ and $e_{\mathsf{new},i}$ is sampled from $\mathcal{N}(0,\sigma_2)$, from Lemma 2, we know $(t \cdot e_i | e_{\mathsf{total},i} = l)$ follows the distribution $\mathcal{N}(l \cdot \frac{t^2\sigma_1^2}{\sigma_2^2 + t^2\sigma_1^2}, \frac{t \cdot \sigma_1 \cdot \sigma_2}{\sqrt{t^2 \cdot \sigma_1^2 + \sigma_2^2}})$[3] and, hence, $(e_i | e_{\mathsf{total},i} = l)$ follows the distribution $\mathcal{N}(l \cdot \frac{t\sigma_1^2}{\sigma_2^2 + t^2\sigma_1^2}, \frac{\sigma_1 \cdot \sigma_2}{\sqrt{t^2 \cdot \sigma_1^2 + \sigma_2^2}})$. Thus, for each value of $e_{\mathsf{total},i}$, we compute

$$b_i' = b_i - e_{\mathsf{total},i} \cdot \frac{t \cdot \sigma_1^2}{\sigma_2^2 + t^2\sigma_1^2}. \tag{2}$$

The new polynomial b' with the i-th coefficient b_i' satisfies

$$b' = a \cdot s + e', \tag{3}$$

where the coefficients of e' follow the distribution of $\mathcal{N}(0, \frac{\sigma_1 \cdot \sigma_2}{\sqrt{t^2 \cdot \sigma_1^2 + \sigma_2^2}})$, we use σ_{attack} to denote the standard deviation of it.

Intuition. We next show applications where the standard deviation of the new noise variable can be very small, making the new Ring-LWE problem easy to solve. To simplify the analysis, we let t be arbitrarily large. This assumption permits us to focus on the leading terms and consider the asymptotic behavior. In the first scenario, where $\sigma_2 = \sqrt{t}\sigma_1$, the standard deviation is of the order $\Theta(t^{-1/2})$. Conversely, in the second scenario with σ_2 as a constant, the standard deviation is $\Theta(t^{-1})$. In either case, it is feasible to choose a sufficiently large t to minimize the noise to negligible levels.

It is important to note that this assumption serves merely as a simplifying element for illustrative purposes. We are constrained by a noise budget and a target level of precision. In the attack scenarios explored throughout the paper, we begin

[3] In [22], the authors assume a continuous Gaussian distribution. In contrast, our approach in Lemma 2 utilizes discrete Gaussians as approximations for their continuous counterparts. Empirical tests conducted with OpenFHE's discrete Gaussian distributions, as depicted in Figure 3, affirm the precision of our approximation methodology. For an in-depth discussion, refer to Section 3.2.1.

operations using a fresh ciphertext with a small noise level. Consequently, the t values required to initiate the attack do not exceed the permissible noise thresholds in the associated libraries.

Efficient implementation of $g_t(\mathbf{c})$ for the adversary using c as a t-fold repetition of c_0. Let $t_{\lambda_0-1}\dots t_1 t_0$ be the binary representation of t, where t_0 is the least significant bit. In the tree-based addition variant of $g_t(\mathbf{c})$, where $\mathbf{c}$ is a vector composed of t repetitions of the ciphertext c_0, each addition operation within the same layer receives and produces identical input and output. This condition leads to the transformation of $g_t(\mathbf{c})$ into an alternate function, denoted as $g'_t(\mathbf{c})$, which effectively performs the following operations (which is similar to exponentiation by squaring[4]):

- Initialize: we assume that the most significant bit is set, i.e. $t_{\lambda_0-1}=1$, let $c_1 \leftarrow c_0$.
- For i in the range $\{1,\dots,\lambda_0-1\}$ iteratively compute $c_{i+1} \leftarrow \begin{cases} c_i + c_i & \text{if } t_{\lambda_0-1-i}=0 \\ c_i + c_i + c_0 & \text{otherwise} \end{cases}$
- Eventually output c_{λ_0}.

This implementation requires at most $2\lambda_0$ homomorphic additions and exhibits a latency of λ_0. When querying the evaluation oracle using either the evaluation function $g_t(\mathbf{c})$ or $g'_t(\mathbf{c})$ with $\mathbf{c}$ as a t-fold repetition of c_0, the resulting ciphertexts are identical, while the amount of computation needed to evaluate g'_t is greatly reduced.

3.2 Average-case and empirical noise estimations are not KR^{D} secure

In the threat model, the adversary may select messages and operations for evaluation. If this did not match with the computation or message distribution used to heuristically determine the error bound, then the security guarantee wrt. the Li-Micciancio attack can be destroyed.

The error bound should carefully record the real worst-case bound that can be achieved in the computation; otherwise, the adversary could fool the user. For instance, the in-trusted user may pick a different message and different evaluation circuit to lead to a much larger real error than the estimated error in the decryption client.

In [13], Costache et al. presented an average-case noise analysis for the CKKS scheme using the central limit theorem (CLT). The authors discussed that their approach is suitable for the noise-flooding countermeasure. For example, they wrote in [13] that

> "Not only does our work provide tighter bounds for B_{ctxt} (resolving an open problem in [13]), but also our analysis enables us to directly characterise the distribution of e and its variance."

In this subsection, we present a simple key-recovery attack showing that the average-case approach can be problematic when being applied in the mode releasing the decryption results.

The CLT noise estimation. In such a scenario, the precision tracker needs to make some heuristic assumptions such that the added or multiplied random variables are independent. Then, the tracker can get tighter noise bound using the central limit theorem. For instance, the addition of two ciphertexts will lead to a new ciphertext with noise variance the sum of the noise variances of the two input ciphertexts. In the worst-case analysis, we add the standard deviation instead.

The average-case precision tracker can be more accurate in the average case; the adversary, however, may be able to pick inputs to falsify the assumed independence assumption and make the average-case estimation inaccurate.

We consider the circuit of adding t ciphertexts. In the average case, adding t independent ciphertexts with noise $\varepsilon_i \sim \mathcal{N}(0,\sigma I_n)$ will lead to new ciphertexts with noise $\varepsilon \sim \mathcal{N}(0,\sqrt{t}\sigma I_n)$. If the adversary picks t identical ciphertexts, then the noise distribution follows $\varepsilon \sim \mathcal{N}(0,t\sigma I_n)$.

Importantly, the adversary can efficiently execute $g_t(\mathbf{c})$ by employing $g'_t(\mathbf{c})$, where $\mathbf{c}$ represents a t-fold repetition of a ciphertext c_0. When using a CLT noise tracker that assumes the independence of the two inputs in a homomorphic addition gate, one can still approximate the output ciphertext's estimated noise as $\varepsilon \sim \mathcal{N}(0,\sqrt{t}\sigma I_n)$. The actual noise distribution similarly adheres to $\varepsilon \sim \mathcal{N}(0,t\sigma I_n)$.

The empirical noise estimation. Both the worst-case noise estimation and the CLT noise estimation can be designed so that a ciphertext inherently carries a noise bound, which homomorphic evaluations then automatically update. An alternative approach is what we term 'empirical noise estimation', where the user holding the secret key, or other involved parties, conduct preliminary experiments to set a noise bound for decryption with sharing. However, this empirical method generally presupposes that an adversary must perform certain computations, thereby contradicting the IND-CPA$^{\mathsf{D}}$ adversary model, which allows the choice of the evaluation function. Additionally, the user in possession of the secret key may lack prior knowledge of the function to be evaluated, as could occur in cases involving private circuits. This lack of information renders the assumptions underlying empirical noise estimation invalid.

Estimating empirical noise can compromise noise-flooding protection due to the formal adversary model in IND-CPA$^{\mathsf{D}}$

[4] Here, we present the case for arbitrary t to provide a more general perspective on the attack. However, it's worth noting that in practical applications, one would likely choose t to be a power of 2. As a result, the function g'_t becomes considerably simpler, as it merely calculates $c_{i+1} \leftarrow c_i + c_i$.

or KR^{D} security, which allows the attacker to select valid ciphertexts and perform computations on them. Furthermore, the distribution of ciphertexts and computation gates significantly influences empirical noise estimation. The attacker can inflate the actual noise beyond the estimated noise by choosing identical ciphertexts as inputs to the simple $g_t()$ function and selecting a much larger value of t than what was used in the empirical noise estimation.

To be specific, the noise bound predetermined by the user possessing the secret key for decryption essentially acts as a constant noise level for the adversary who selects the t value in the $g_t()$ function. Utilizing the attack strategy outlined in Section 3.1, a passive adversary may choose a sufficiently large t value, thereby rendering the noise negligible.

3.2.1 Experiments on average-case noise estimation

In this section, we present the experimental results on the OpenFHE library, focusing on average-case noise estimation.

The noise estimation in OpenFHE. OpenFHE suggests performing the computation in two steps. First, the noise is estimated on a freshly generated key pair with messages chosen from a suitable set of messages. The noise estimation is done by measuring the noise/precision-loss in the imaginary slots of the decrypted plaintext [13]. In this step, the value σ_{est} is computed. During the actual computation, the decrypted message is subjected to noise flooding with discrete Gaussian noise with a standard deviation of $\sigma_2 = \sqrt{12q}2^{\nu/2}\sigma_{\mathsf{est}}$. Here, q represents the number of decryption queries ($q = 1$ in our attack), and $\nu \geq 30$ is the statistical security parameter.

The split of computation in two steps signifies OpenFHE's use of an empirical noise estimation technique. Concurrently, OpenFHE intends to introduce a feature akin to HElib's noise estimator, which associates a noise bound with each ciphertext and adjusts it dynamically during homomorphic operations (refer to [4]). This embedded noise bound in individual ciphertexts serves as an effective mechanism to reconcile disparities between predicted and actual noise levels that could arise due to a different adversary-chosen evaluation function.

OpenFHE recommends for the use of its own empirical noise evaluation strategy, initially suggesting a method akin to average-case noise estimation. The results from this method are, in specific cases under scrutiny, the same as those acquired through the CLT noise estimation method. Specifically, this involves gauging the noise or precision-loss in the imaginary slots of the decrypted plaintext [13]. In the discussion that follows, we deliberately apply identical computations in both phases, to negate the impact of function variations chosen by an adversary. Our attention is specifically geared towards OpenFHE's average-case noise estimation, highlighting the disparities arising from the input message distributions for simple gates that an adversary could select.

	n	$\log q$	ν	precision	plaintext slots
OpenFHE	2^{14}	$155-181$	30	25	16

Table 1: Parameters used in the attack on OpenFHE. The modulus q is chosen by OpenFHE dynamically, it increases for higher values of t; range for q is presented for the values $46 \leq \log t \leq 57$ from the Fig. 3. The value q is allowed to grow up to around 2^{410} for the scheme to provide 128 bits of (quantum) security [3].

In Section 3.2.2, we demonstrate that OpenFHE's primary recommendation of empirical noise estimation is more vulnerable to attacks. Specifically, this vulnerability arises because the adversary has the freedom to select a different evaluation function.

Key recovery attack on OpenFHE. The attack scenario follows Section 3.1. The user sets up the parameters for the scheme that are provided in Table 1 and generates public and private keys. Then he estimates the noise of g_t for another freshly generated key pair for the adversary's choice of t and initializes the oracles. The adversary then uses encryption and evaluation oracles to compute a ciphertext from $g_t(\mathbf{c})$ and calls decryption oracle on it. The function $g_t(\cdot)$ is implemented as $g'_t(\cdot)$ by both the user and the adversary.

For the $g_t()$ function, the estimated noise σ_{est} is very close to $\sqrt{t}\sigma_{1,\mathsf{est}}$, where $\sigma_{1,\mathsf{est}}$ is the noise estimation for a freshly generated ciphertext. We notice a possible bug in OpenFHE, $\sigma_{1,\mathsf{est}}$ is close to $3.19\sqrt{2/3 \cdot n}$ for the secret with uniform ternary coefficients, whereas the actual noise σ_1 of a fresh ciphertext is close to $3.19\sqrt{4/3 \cdot n}$. This implies that the injected noise is somewhat less than expected. Though this has a minor impact on the scheme's security, making the attack slightly more effective, the attack can still proceed without this difference.

Treating ν as a constant, from the formula for the standard deviation of the noise flooding $\sigma_2 = \sqrt{12q}2^{\nu/2}\sigma_{\mathsf{est}}$, we obtain $\sigma_2 = \Theta(\sqrt{t}\sigma_1)$. As mentioned earlier, by choosing a sufficiently large t, we can make σ_{attack} negligible. In order to obtain the same value of σ_{attack} for scenarios when $\nu = 0$ and $\nu > 0$, one need to increase $\log t$ by ν. To evaluate $g'_t(\cdot)$, one needs no more than $2\lceil \log t \rceil$ ciphertext additions which translates to $2\lceil \log t \rceil n$ additions over modulo q. In other words, the attack complexity linearly depends on ν, which means that by simply increasing ν the attack could not be prevented.

Let us emphasize once again that the attack relies on a single decryption call. The adversary decrypts $t \cdot c_0$, obtains e_{total}, and computes b'. In the real attack scenario, the adversary can utilize b', a, and an estimate of e' to extract information about s. However, in our experiments, we employ s to derive e' from b' and validate the theoretical estimates.

Figures 3 and 4 demonstrate σ_{attack} and the weight of e', re-

spectively. These figures clearly illustrate that the parameter ν delays the attack, while the value of σ_{attack} remains the same. The parameters for $\nu = 0$ are the same as in Table 1 except that $\log q$ is lower. When $\log t - \nu \geq 27$, the trivial attack of computing $s = a^{-1}b'$ becomes possible, as e' becomes 0 with a high probability. However, the retrieval of s is not limited to this trivial attack. Even with smaller values of t, we can still obtain an RLWE sample with noise smaller than that used in the public key and retrieve the secret key with additional post-processing.

Note that since e' is sampled from a discrete Gaussian distribution, it is natural for the empirical standard deviation to be smaller than the theoretical one for small σ_{attack}. This effect can be observed in Fig. 3 when $\log t - \nu \geq 24$. A slight deviation from the theoretical prediction in the preceding part of the graph could be attributed to the fact that Lemma 2 was originally formulated for the continuous Gaussian distribution, whereas we employ the discrete Gaussian distribution, which is approximated by the continuous one.

OpenFHE supports both 64-bit and 128-bit precision computations and uses 64-bit computation by default. Since for the attack to work we need, say, $t = 2^{57}$, the noise grows significantly and to support that we need to compile the library with NATIVE_SIZE = 128 option to support 128-bit precision computations.

Experiments were run on a computer with an Intel i7-11700K processor running at 3.60GHz using 64 GB of RAM. For the trivial attack with $\log t = 57$ the running time of all oracles called by the adversary is 2.7 seconds.

After oracle calls the adversary need to compute b' as in Eq. (2), then he can obtain $s = a^{-1}b'$. For simplicity this step was implemented in SageMath, but the computation is not optimized. The total time is over one minute, where most of the time is spent on computing a^{-1}.

With values of σ_{attack} approaching 0, the coefficients of e' are usually zeroes with a few coordinates being -1 or 1. Outside of lattice reduction techniques, there is a simple post-processing idea, when one assumes that e' has i non-zero coefficients and brute-forces all possible $\binom{n}{i}2^i$ errors e'' with i non-zero coefficients from $\{-1,1\}$ for $i = 0,1,\ldots$ Then the adversary can compute $s' = a^{-1}(b' - e'')$ and check if the result is small (i.e. ternary for OpenFHE) and, if necessary, try to decrypt a ciphertext with a known message to avoid the false-positive result. Fig. 5 demonstrates the success probability of the attack with and without simple post-processing, the data is the same as for Figs. 3 and 4, i.e. we take empirical probability from 100 runs. The number of guesses for e'' is $\sum_{i=0}^{2}\binom{n}{i}2^i \approx 2^{29}$, making the computation time reasonable. Guessing more positions can significantly increase the post-processing time.

Summary. When we focus on the parameter set outlined in Table 1 and choose $t = 2^{57}$, we observe an empirical success rate of 100% (100 successes in 100 trials) without the need for any post-processing. On our desktop system, the average time needed to produce the desired ciphertext to query to the decryption oracle is approximately 2.7 seconds, while the key recovery process takes up to one minute after receiving the decryption results. While it's possible to lower t to $2^{56.5}$ if reasonable post-processing is employed, this modification has a minimal impact on the complexity and latency involved in creating the designed ciphertext. However, it considerably increases the complexity of key recovery. As a result, we recommend adhering to the straightforward version of the attack that excludes post-processing.

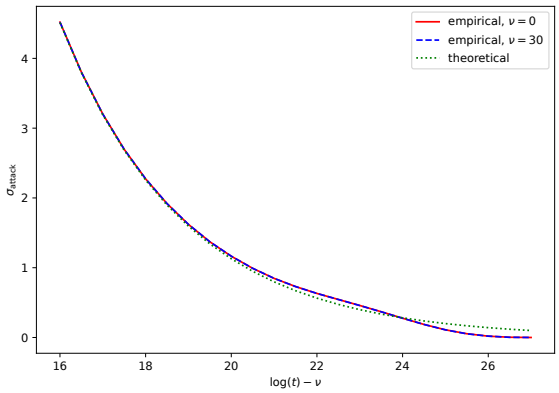


Figure 3: Standard deviation of e'. For empirical measurements we take average among 100 runs. The theoretical value is determined from Lemma 2 with continuous Gaussian distribution.

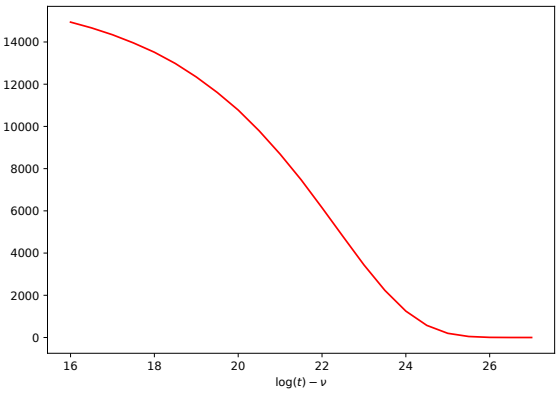

Figure 4: Average weight of e' among 100 runs.

3.2.2 Experiments on the empirical noise estimation

We now shift our attention to empirical noise estimation as recommended by OpenFHE. The attack scenario is the same as in Section 3.2.1, but now we assume that the user with secret key estimates the noise for $g_t(\cdot)$ for some small t, say $t = 15$, expecting the server to do a few additions. The ad-

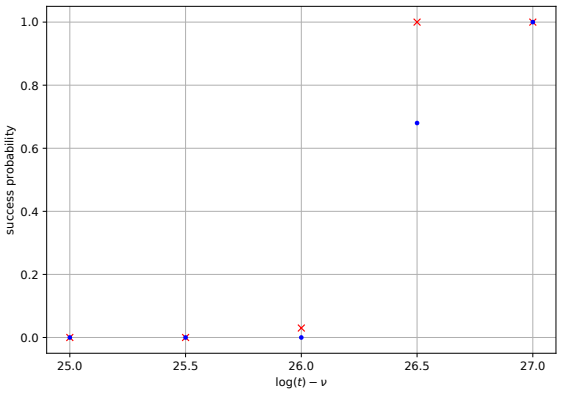

Figure 5: Empirical probability of successful key recovery attack: each data point based on 100 runs. Blue dots correspond to the case without post-processing, i.e. when the noise e' is zero, while red crosses show the probability of obtaining e' with weight less or equal 2, which allows for simple post-processing.

versary, however, computes $g_t(\cdot)$ for $t = 2^{45}$ implementing g_t via g'_t. Upon receiving the decryption result, the adversary can effortlessly recover the secret s by computing $s = a^{-1}b'$. Note that the switch from average-case to empirical noise estimation in the described scenarios allows the adversary to reduce t from 2^{57} to 2^{45} for the straightforward attack without post-processing when targeting parameters from Table 1.

The required value of $\log t$ increases with the value of the statistical parameter ν. The scheme is using $\nu = 30$, therefore, even if we assume that the estimated noise is low, the starting value for t remains relatively high. Despite this, the attack can be more efficient than those discussed in Section 3.2.1. With the same computer platform, the adversary still requires less than three seconds to prepare the ciphertext for decryption and about one minute for key recovery.

If we consider HElib, the attack described in Section 3.2.1 is not successful. That is because HElib keeps track of the error bound for the ciphertext. Most importantly, the error bound estimation employs worst-case analysis. This means that the noise after g_t with the same ciphertexts and the added noise during decryption have the similar standard deviation. However, the documentation of HElib suggests the usage of the function ctxt.bumpNoiseBound in case when the estimated noise is much larger than the real one, determined during the experiments. In other words, the usage of this function can transform the worst-case noise estimation into empirical noise estimation, thus potentially making the mentioned attack possible. We warn about the dangers of such function and relying on the average-case estimations since an attacker may not necessarily adhere to the underlying assumptions of the estimation.

4 On deterministic Gaussian noise for fresh ciphertext

In the conclusion section of [23], it was suggested to limit the number of decryption calls to 1 per ciphertext by simply replacing the seed of the pseudorandom function for the additional noise with the ciphertext and key derived from the decryption key. They claim that this proposed countermeasure can prevent an attack where the adversary makes the noise arbitrarily small by using a sufficiently large (still polynomial) number of calls for decrypting the same ciphertext. This countermeasure has been implemented in the HElib library. The rounding protection employed in Lattigo can be regarded as a variant of adding deterministic noise. In [9], Cheon, Hong, and Kim made similar claims, stating that "..an adversary can query the decryption only for fresh ciphertexts, one may choose much smaller additional noise..". However, we will now demonstrate that the countermeasure involving deterministic noise generation does not provide additional security.

The new idea. Our novel observation reveals that the secret noise e of a ciphertext c may be exposed through querying decryption outputs of ciphertexts as a function incorporating c, rather than solely through the decryption outputs of the exact ciphertext c. Consequently, we generate multiple ciphertexts derived from c and obtain corresponding decryption outputs to gather information about the secret noise e. For example, for a ciphertext c which is an encryption of all zeros, we submit ciphertexts of $t \cdot c$ for decryption, with varying values of t. This approach yields the noise $t \cdot e + \varepsilon(t \cdot c, s)$ for a specific integer t. As t changes, the pseudorandom generator's seed alters. The error $\frac{\varepsilon(t \cdot c, s)}{t}$ remains random, ultimately allowing for the acquisition of multiple approximate samples of e to minimize the additional noise to an arbitrarily small amount.

The ciphertexts $t \cdot c$ can be derived by homomorphically evaluating the scalar multiplication of c by t or the addition gate of $g_t(c, \ldots, c)$. As detailed in Section 3, estimating the noise size of $g_t(\cdot)$ using an average-case approach enables a more efficient attack on the scheme. We now illustrate that even with worst-case noise size estimation, incorporating deterministic noise for fresh ciphertexts fails to provide extra protection. A prime example is the current HElib implementation; when worst-case noise estimation with no empirical noise setting is employed, the standard deviation of $\varepsilon(t \cdot c, s)$ is equal to the one of $t \cdot e$, and, subsequently, the error $\frac{\varepsilon(t \cdot c, s)}{t}$ exhibits the same standard deviation as e. From this point forward, we assume that noise is estimated in the worst-case manner and modify our notation accordingly.

As described in Algorithm 1, we denote $c_0 := (a, -as + e)$ a ciphertext encrypting zero, and for $i > i_0$, $c_i = (i \cdot a, -i \cdot as + i \cdot e)$ a fresh ciphertext of zero, which is the homomorphical multiplication of c_0 by i. With a raw decryption query of c_i,

Algorithm 1 Key recovery attack on noise-flooding countermeasure with deterministic noise generation.

Input: Lattice parameters $(n, \log q)$, initial scaling factor Δ_0
Sample $(\mathsf{sk}, \mathsf{pk}, \mathsf{ek}) \leftarrow \mathsf{KeyGen}(n, \log q, \Delta_0)$
Encrypt $c_0 \leftarrow \mathsf{Enc}_{\mathsf{pk}}(\mathsf{Encode}(\mathbf{0}; \Delta_0))$
$\hat{z} \leftarrow \mathbf{0}$
for $i_0 \le i < \gamma + i_0$ **do**
    Homomorphically evaluate $c_i \leftarrow g_i(c_0, c_0, ...c_0)$
    Decrypt $z_i \leftarrow \mathsf{DecForShare}_{\mathsf{sk}}(c_i)$
    $z_i \leftarrow \frac{1}{i} z_i$
    $\hat{z} \leftarrow \hat{z} + \frac{1}{\gamma} z_i$
end for
$m' \leftarrow \mathsf{Encode}(\hat{z}; \Delta_0)$
Compute $b' \leftarrow m' - b \in R_q$, where $(a, b) = c_0$ ▷ $b' \simeq a \cdot s + X_\gamma$
if POST-PROCESSING $= 1$ **then**
    Return $s' := \mathsf{PostPro}(a, b')$, where $\mathsf{PostPro}(\cdot)$ represents a post-processing procedure, which could be enumeration or lattice reduction methods
else
    Return $s' := a^{-1} \cdot b'$ for the trivial attack when $X_\gamma = 0$ with high probability
end if

an adversary can passively get $i \cdot e$. If we add a noise $\varepsilon(c_i, s)$ issued from a pseudorandom generator applied to (c_i, s) to hide this error, the attacker will get an approximation of $i \cdot e + \varepsilon(c_i, s)$.

We denote $z_i \leftarrow \mathsf{DecForShare}_{\mathsf{sk}}(c_i)$ the result from the decryption query followed by noise flooding and decoding. From these observations, an attacker can compute $z'_i = \frac{1}{i} z_i$, compute the empirical mean by $\hat{z} = \sum_{i=1}^{\gamma} \frac{1}{\gamma} z'_i$ and encode it to have

$$\mathsf{Encode}(\hat{z}) \simeq \Delta \varphi^{-1}\left(\frac{1}{\gamma}\sum_{i=1}^{\gamma} z'_i\right) \simeq \frac{\Delta}{\gamma}\sum_{i=1}^{\gamma} \varphi^{-1}(z_i) = e + X_\gamma$$

with

$$X_\gamma \simeq \frac{1}{\gamma}\left(\sum_{i=1}^{\gamma} \frac{1}{i}\varepsilon(c_i, s)\right)$$

The value X_γ is the sum of independent centered Gaussian noises of the same standard deviation so it behaves as a centered Gaussian noise with a smaller variance. Doubling γ divides the variance by two. To have access to η bits of e with overwhelming probability, the attacker will only need to have $\gamma = \Theta(\eta^2)$ decrypted results.

Contrastingly, without applying the countermeasure of deterministic noise generation for fresh ciphertexts, each query introduces a fresh noise with a standard deviation equal to that of e, equivalent to adding noise of $\frac{\varepsilon(i \cdot c, s)}{i}$. To recover η bits of the secret e, we still need $\gamma = \Theta(\eta^2)$ decrypted outputs.

In summary, the new method illustrates that employing deterministic noise for fresh ciphertexts offers no additional protection.

	n	$\log q$	precision	plaintext slots
HElib	2^{13}	108	20	2^{12}

Table 2: The targeted parameters used in the experiments on HElib.

4.1 Application to HElib

We implemented the attack described in Algorithm 1 for HElib. Secret key coefficients in this library are sampled from the ternary set, where the probability to sample 0 is $1/2$, and the rest probability mass is equally split between 1 and -1. Consequently, the expected noise of a fresh ciphertext is given by $\sigma_1 = 3.2\sqrt{n+1}$. Since HElib uses worst-case estimation for the noise and due to canonical embedding we have $\sigma_{1,\text{est}} \simeq 3.2(\sqrt{2n \ln n} + 1)$. At the end of the algorithm the standard deviation of X_γ is approximately

$$\sigma_{\mathsf{attack}} = \frac{\sigma_{1,\text{est}}}{\sqrt{\gamma}}.$$

For our experiments, we selected parameters according to Table 2 to ensure a desired level of security, specifically, the overall security level is more than 128 bits, as outlined in [3]. We compared the theoretical value of σ_{attack} with the actual values obtained during our experiments. Fig. 6 presents a graphical representation of these results. It is evident from the figure that our experimental data aligns closely with the theoretical predictions, validating the correctness of the results in Section 4.

We provide an overview of the implications of our attack on the HElib library. Given that HElib has not implemented any updates incorporating the countermeasure through differential privacy [24], it lacks IND-CPA$^{\mathsf{D}}$ secure. On the other hand, attack strategy detailed in this section requires millions of decryption queries to successfully retrieve the secret key when the worst-case noise bound for each ciphertext is dynamically updated. Consequently, when noise estimation is executed in a worst-case manner, the encryption scheme maintains its KR$^{\mathsf{D}}$ security. Last, the attack discussed in Section 3.2.2 could work when targeting implementations with the empirical noise estimation method of invoking the function ctxt.bumpNoiseBound to manually adjust the noise level utilized in the decryption function for sharing.

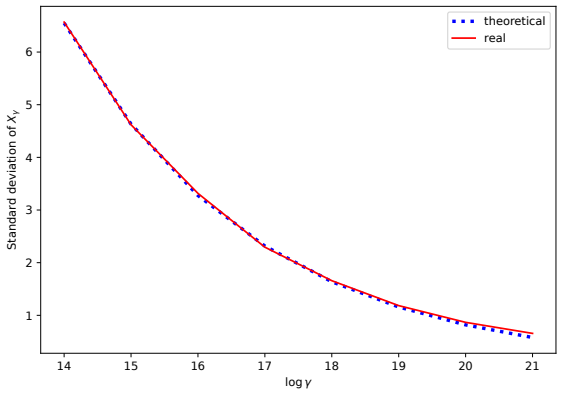

Figure 6: Standard deviation of X_γ according to the prediction and determined experimentally.

5 Concluding remarks

In this paper, we have proposed new key-recovery attacks on Approximate Homomorphic Encryption schemes that use noise-flooding countermeasures based on non-worst-case noise estimation, which are implemented to attain IND-CPA^D security. We illustrated the attack process using the recent implementation of the OpenFHE library and showed how to recover the secret key with a single decryption output. Furthermore, we discussed the security implications of our attack on the HElib implementation, which allows the use of empirical noise estimation. As an additional finding, we revealed that using a pseudorandom generator to create deterministic noise in noise-flooding countermeasures does not enhance security.

Mitigation and future works. Our research underscores the importance of employing worst-case noise estimation in noise-flooding countermeasures. By adopting the security bounds proposed in [24], which stem from differential privacy, and implementing a worst-case noise estimation strategy, our attack can be thwarted. Nevertheless, the application of such countermeasures can lead to a considerable reduction in performance, emphasizing the need to investigate more efficient countermeasures in future work.

Although one could formulate defenses against our attacks that employ the function $g_t(\cdot)$ – for instance, by limiting the acceptable average-case noise bound for ciphertexts, thus disallowing large t values conducive to key recovery – such countermeasures often incur significant performance costs. Moreover, they may prove ineffective against adversaries who craft new evaluation functions for emerging passive attacks. It remains an intriguing question as to whether we can develop a more efficient implementation using average-case noise estimation, while still preserving the scheme's IND-CPA^D security (or perhaps only the KR^D security).

Terrapin Attack: Breaking SSH Channel Integrity By Sequence Number Manipulation

Abstract

The SSH protocol provides secure access to network services, particularly remote terminal login and file transfer within organizational networks and to over 15 million servers on the open internet. SSH uses an authenticated key exchange to establish a *secure channel* between a client and a server, which protects the confidentiality and integrity of messages sent in either direction. The secure channel prevents message manipulation, replay, insertion, deletion, and reordering. At the network level, SSH uses the *Binary Packet Protocol* over TCP.

In this paper, we show that as new encryption algorithms and mitigations were added to SSH, the SSH Binary Packet Protocol is no longer a secure channel: SSH channel integrity (INT-PST, aINT-PTXT, and INT-sfCTF) is broken for three widely used encryption modes. This allows *prefix truncation attacks* where encrypted packets at the beginning of the SSH channel can be deleted without the client or server noticing it. We demonstrate several real-world applications of this attack. We show that we can fully break SSH extension negotiation (RFC 8308), such that an attacker can downgrade the public key algorithms for user authentication or turn off a new countermeasure against keystroke timing attacks introduced in OpenSSH 9.5. Further, we identify an implementation flaw in AsyncSSH that, together with prefix truncation, allows an attacker to redirect the victim's login into a shell controlled by the attacker.

We also performed an internet-wide scan for affected encryption modes and support for extension negotiation. We find that 71.6% of SSH servers support a vulnerable encryption mode, while 63.2% even list it as their preferred choice.

We identify two root causes that enable these attacks: First, the SSH handshake supports optional messages that are not authenticated. Second, SSH does not reset message sequence numbers when activating encryption keys. Based on this analysis, we propose effective and backward-compatible changes to SSH that mitigate our attacks.

1 Introduction

Secure Shell (SSH). While TLS is commonly used to secure user-facing protocols such as web, email, or FTP, SSH is used by administrators to deploy and maintain these servers, often with high privilege (root) access and a large attack surface for lateral movement within an organization's infrastructure. SSH was developed by Tatu Ylonen in 1995 as a secure alternative to telnet and rlogin/rcp and has since become a critical component of internet security.

In 1996, SSHv2 was developed to fix severe vulnerabilities in the original version. In February 1997, the IETF formed the SECSH working group to standardize SSHv2. After a decade, it published five core RFCs [29–33]. SSHv2 provides cryptographic agility and protocol agility without breaking backward compatibility. Since its original release, dozens of standardized and informal updates to the protocol have been published. Because of this, SSHv2 remains relevant after 25 years without major redesign, but it has also become difficult to analyze. There is a significant risk that these extensions of SSH interact to undermine its security goals.

SSH Connections. An SSH connection between a client and a server begins with the *Transport Layer Protocol* [33], which defines the handshake messages for key exchange and server authentication and how messages are exchanged over TCP using the *Binary Packet Protocol* (BPP). After the handshake, SSH provides a *secure channel*[1] for application data. At the application level, the client chooses a sequence of *services* to run. In practice, the client will run precisely two services: the *Authentication Protocol* [30] for user authentication with a password or public key, followed by the *Connection Protocol* [31] for the bulk of SSH's features like terminal sessions, port forwarding, and file transfer.

[1] We note that by *channel*, we refer to the integrity-protected, encrypted byte stream at the transport level, not the SSH data channels from the connection protocol. Multiple SSH data channels can be multiplexed over the same secure transport channel.

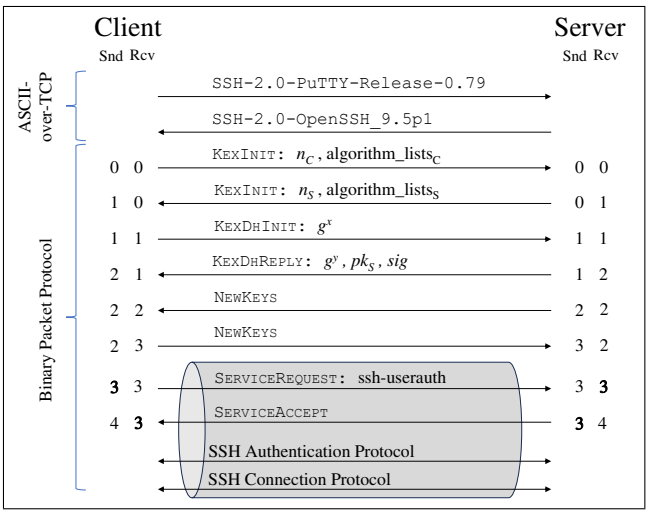

Figure 1: Typical SSH handshake using a finite-field Diffie-Hellman key exchange. Included sequence numbers are implicit and maintained by the BPP. Snd denotes the counter for sent packets and Rcv for received packets. Sequence numbers verified using authenticated encryption are in **bold**.

1.1 SSH Channel Security

In this work, we focus on the integrity of the SSH handshake and the resulting secure channel, as shown in Figure 1. After an initial exchange of version information directly over TCP, the BPP exchanges *packets*, each containing precisely one *message*. Initially, the BPP is used without encryption or authentication for the duration of the handshake until the NewKeys message. Afterward, the encryption and authentication keys are used to form a secure channel, intending to protect the confidentiality and integrity of the *ordered stream of all following messages*. Note that technically, the secure channel consists of two separate cipher streams, one for each direction, and that the order of message arrival is only guaranteed for each direction separately.

Message Authentication Codes. As SSH is an interactive protocol, the integrity of each packet must be verified when it is received so that it can be promptly processed. For this, the BPP appends a Message Authentication Code (MAC) to each packet. A cipher mode and a MAC form an authenticated encryption scheme [5]. SSH historically uses *Encrypt-and-MAC* (EaM), where the MAC is computed over the plaintext, but this is vulnerable to oracle attacks [2]. Later, *Encrypt-then-MAC* (EtM) was added, where the MAC is computed over the ciphertext instead. SSH has recently adopted the AEAD ciphers AES-GCM and ChaCha20-Poly1305, where ciphertext integrity is built into the encryption scheme [43].

A Trivial Example: Suffix Truncation Attacks. Note that a per-packet MAC cannot fully protect the channel's integrity, as packets are verified and decrypted before the end of communication has been seen. This allows for a trivial *suffix truncation attack*, where the attacker interrupts the message flow at some point during the communication. This is an inherent limitation of interactive protocols and an accepted trade-off in the design of SSH, but also, e.g., the TLS Record Layer. Although this attack cannot be prevented, it can be detected by requiring "end-of-communication" messages as the last messages in both directions. TLS defines a "close_notify" alert for this purpose [42]. Although SSH also defines a Disconnect message to indicate the end of the secure channel, this message is optional, unidirectional, and not described as security-critical in the standard.

Implicit Sequence Numbers. If the MAC was only computed over the payload of each packet, an attacker could still delete, replay, or reorder packets. Therefore, a *sequence number* is included in the MAC computation, corresponding to the position of the message in the stream. Each peer maintains two counters (starting at 0), one for each direction. The Snd counter is incremented after a packet has been sent, and the Rcv counter is incremented after a received packet has been processed. Once the secure channel has been established, the current value of Snd is used to compute the MAC of an outgoing packet, and the current value of Rcv is used to verify the MAC of an incoming packet. If packets in the secure channel are deleted, replayed, or reordered, the sequence numbers get out of sync, and MAC verification will fail.

Because TCP is a reliable transport, accidental reordering of SSH packets cannot occur on the network. Thus, SSH (like other TCP-based protocols) uses *implicit sequence numbers* that are not transmitted as part of the packet.

Security Guarantees of Secure Channels. For TLS, the security guarantees of the Record Layer were formalized as stateful length-hiding encryption [39], with the state mainly consisting of the implicit sequence number. The security of the BPP and implicit sequence numbers was analyzed by Bellare et al. in [4] and later refined and extended by Paterson and Watson [40] and Albrecht et al. [1]. These works define, in slightly idealized scenarios, the following informal security goal for a secure channel:

> When a secure channel between A and B is used, the data (or message) stream received by B should be identical to the one sent by A and vice versa (INT-PST, aINT-PTXT in [17]).

Within their idealizations, all three works confirm that the BPP is indeed a secure channel. The difference between the models is that Paterson and Watson [40] also included the encrypted length field of the Encrypt-and-MAC modes, while Albrecht et al. [1] considered the more recent cipher modes ChaCha20-Poly1305, AES-GCM, and generic Encrypt-then-MAC. Our

attacks show that the models underlying the proofs in [1] are only partially accurate. We will explain the discrepancies between the proofs and our findings in Section 2.

1.2 Overview of Our Attacks on SSH

In this paper, we show that SSH fails to protect the integrity of the encrypted message stream against meddler-in-the-middle (MitM) attacks. More precisely, we present novel *prefix truncation attacks* against SSH:

> We show that the SSH Binary Packet Protocol is *not* a secure channel because a MitM attacker can delete a chosen number of integrity-protected packets from the beginning of the channel in either or both directions without being detected (Figure 2).

Attacker Model. We consider a MitM attacker who can observe, change, delete, or insert bytes at the TCP layer. We do *not* assume that the attacker can break the confidentiality of the session keys, i.e., the attacker has no information about the derived encryption keys, MAC keys, or IV. However, we do assume that the attacker can determine the length of the messages to be deleted even if the length field is encrypted. We discuss the practicality of this in Section 4.3. The rogue session attack presented in Section 6.2 further assumes the attacker has an account on the same host as the victim.

As for the connection, we assume that the server is correctly authenticated (i.e., the client recognizes the server's host key) and that a vulnerable encryption mode has been negotiated. See Table 1 for a list of vulnerable encryption modes.

Prefix Truncation Attacks. While our attacks on SSH are novel, the idea of prefix truncation attacks against network protocols by sequence number manipulation is not. To the best of our knowledge, the first and only description of such an attack is by Fournet (on behalf of miTLS) in an email to the TLS working group in 2015, targeting a draft version of TLS 1.3 [18]. Fournet's attack increases sequence numbers in TLS by message fragmentation rather than message injection and remains theoretical, as *"prefix truncations will probably cause the handshake to fail."* Subsequently, the draft was modified, and no prefix truncation attacks against the final version of TLS 1.3 are known. In contrast, we present the first real-world, practical prefix truncation attack against a mature, widely used protocol.

Root Cause Analysis. Our results depend on two technical observations about how SSH protects the integrity of the handshake and channel:

1. *SSH does not protect the full handshake transcript.* Although server authentication uses a signature to verify the integrity of the handshake, the signature is formed over a fixed list of handshake messages rather than the complete transcript. This gap in authentication allows an attacker to insert messages into the handshake and thereby manipulate sequence numbers.

2. *SSH does not reset sequence numbers at the beginning of the secure channel.* Instead, SSH increases sequence numbers monotonically, independent of the encryption state. Any manipulation of sequence numbers before the secure channel carries over into the channel.

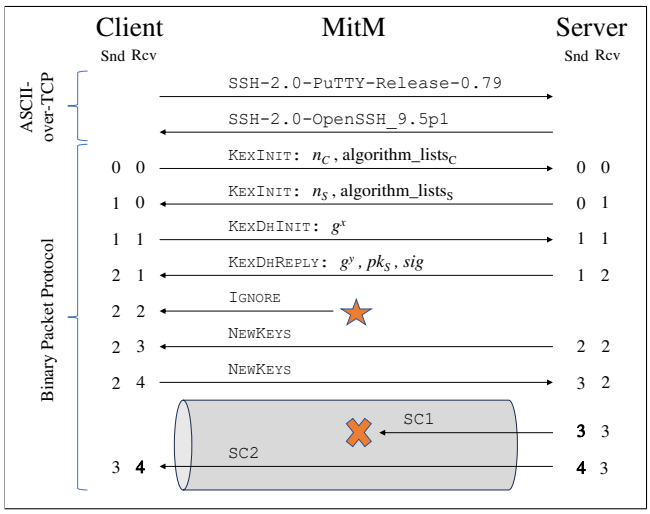

Figure 2: A novel prefix truncation attack on the BPP. The server sends SC1 and SC2, but the client only receives SC2.

Based on these two key observations, we present a series of novel attacks on SSH that increase in complexity and impact.

Sequence Number Manipulation. We show that an attacker can *increase the receive counters* of the server and the client by inserting messages into the handshake. Although not required for any of our attacks, we also show that, for some implementations, an attacker can *fully control the receive and send counters*, setting them to arbitrary values (Section 4.1).

A Prefix Truncation Attack on the BPP. An attacker can use sequence number manipulation to *delete a chosen number of packets at the beginning of the secure channel*. Neither the client nor the server detects this prefix truncation, consequently breaking the channel integrity of SSH (Section 4.2).

Extension Negotiation Downgrade Attack. As a practical example, we show an attack that uses prefix truncation to *break extension negotiation* [9], thereby downgrading the security of the connection. The attacked client might mistakenly believe that the server does not support recent signature algorithms for user authentication or does not implement certain countermeasures to attacks (Section 5.2). Specifically,

the attacker can turn off protection against keystroke timing attacks in the recently released OpenSSH 9.5.

Rogue Extension Attack and Rogue Session Attack. As another example, we show two attacks on the AsyncSSH client and server. In the first attack, *the victim's extension info message is replaced* with one chosen by the attacker (Section 6.1). For the second attack, the attacker must have a user account on the same server as the victim. The attacker injects a malicious user authentication message so that *the victim logs into a shell controlled by the attacker* rather than the victim's shell, thereby giving the attacker complete control over the victim's terminal input (Section 6.2). These attacks combine prefix truncation with implementation flaws in the AsyncSSH library.

Limitations. Our attacks critically depend on the SSH encryption mode negotiated between the client and the server. The attack works best with the AEAD cipher ChaCha20-Poly1305 (added in 2013). The attack also works with any EtM mode (added in 2012), although the success probability depends on the cipher mode negotiated. CBC-EtM can be exploited with a significant probability, while the exploitability of CTR-EtM is low. On the other hand, CBC-EaM, CTR-EaM, and GCM modes are not affected. See Section 4.4 for a complete analysis.

In an internet-wide scan, we show that despite these limitations, 71.6% of all SSH servers on the internet support an affected encryption mode, and 63.2% even list it as their preferred choice (Section 7).

1.3 Our Contributions

We contribute the following novel results:

- An analysis of the integrity of SSH channels, where we identify two previously unknown flaws in the SSH specification, namely gaps in the handshake authentication and the use of sequence numbers across key activation.
- A novel prefix truncation attack on SSH channel integrity, where we show that an attacker can manipulate the sequence numbers and delete several messages from the beginning of the secure channel.
- A first security analysis of SSH extension negotiation, including a novel downgrade attack that disables extension negotiation completely. Thus, support for some public key signature algorithms or, with OpenSSH 9.5, protection against keystroke timing attacks can be disabled.
- As a practical demonstration, two novel attacks on AsyncSSH. First, a rogue extension attack, where the attacker can insert a chosen extension negotiation message. Second, a rogue session attack that allows the attacker to log the victim into an attacker-controlled shell. Both escalate implementation flaws in AsyncSSH using the prefix truncation attack.
- An internet-wide scan with up-to-date information on the distribution of SSH encryption modes and extensions.

Artifacts. Proof-of-concept implementations for our attacks and the aggregated results of our internet-wide scan are available under the Apache-2.0 open-source license. See:
https://github.com/RUB-NDS/Terrapin-Artifacts

Ethics Consideration and Responsible Disclosure. We disclosed our findings to 33 vendors of SSH implementations, including OpenSSH and AsyncSSH, in October and November 2023, followed by a public disclosure on December 18th, 2023. As of February 2024, 28 vendors have published patches implementing a backward-compatible countermeasure proposed by OpenSSH. The general protocol flaw has been assigned CVE-2023-48795 (CVSSv3 5.9), while the implementation flaws in AsyncSSH were assigned CVE-2023-46445 (Rogue Extension Negotiation; CVSSv3 5.9) and CVE-2023-46446 (Rogue Session Attack; CVSSv3 6.8). To estimate the adoption rate of the countermeasure, we scanned the IPv4 address space on January 5th, 2024, indicating that more than 3.4M servers were patched.

We provide an opt-out option and an email address for inquiries about our internet-wide scans. Additionally, we employ a block list to exclude networks that opted out of previous scans. Scan results are solely published in aggregated form, without any information that could identify individual servers or networks.

2 Related Work

Secure Channels. In 2001, Canetti and Krawczyk [12] established the first model for secure channels, which only requires protection against adversarial insertion of messages. Paterson et al. [39] defined stateful length-hiding authenticated encryption (sLHAE) to model the TLS record layer as a secure channel. This definition was used in [23, 24] to define authenticated and confidential channel establishment (ACCE) to analyze the TLS handshake and record layer as a whole. Bellare et al. [4] used stateful authenticated decryption to define a security notion for SSH that is directed against replay and out-of-order delivery attacks (INT-sfCTXT). Paterson and Watson [40] later refined this work to cover buffered decryption (INT-BSF-CTXT). Albrecht et al. [1] further refined and extended this definition to cover ciphertext fragmentation attacks more generally (INT-sfCTF). Generalizing the work on TLS and SSH, Fishlin et al. [17] defined, among other notions, plaintext integrity for generic data and (atomic) message streams (INT-PST, aINT-PTXT).

Our attacks show that SSH BPP, when instantiated with ChaCha20-Poly1305, CBC-EtM, or CTR-EtM, does not provide integrity of plaintext or ciphertext (message) streams (INT-PST, aINT-PST, INT-sfCTF) as defined in [1, 17].

Truncation Attacks. Suffix truncation attacks against web services using TLS have been demonstrated by Smyth and Pironti in [44]. A prefix truncation attack against a draft version of TLS 1.3 was described by Fournet (on behalf of miTLS) in an email to the TLS working group in 2015 [18]. Fournet's attack increases TLS sequence numbers by message fragmentation rather than injection to avoid breaking handshake authentication. The attack remained theoretical as *"prefix truncations will probably cause the handshake to fail."* As a countermeasure, the draft was changed back to reset sequence numbers to 0 when activating keys.

Attacks on SSH. The most severe attack on SSH was presented by Albrecht, Paterson, and Watson [2] in 2009. It exploited the encrypted length field, using the length of the ciphertext accepted by the server from the network as a decryption oracle for parts of a ciphertext block. In [40], this peculiarity of the BPP was formalized, and in [1] a variant of this attack was presented. Other attacks on SSH include a timing attack on SSH keystrokes by Song, Wagner, and Tian [45], a theoretical attack on SSH CBC cipher modes by Wei Dai [14], and a SHA-1 chosen prefix collision attack on the handshake transcript by Bhargavan and Leurent [8]. The weakness of some SSH host keys presented by Heninger et al. [20] was caused by a lack of entropy and faulty implementations and is not an inherent weakness of the protocol.

Formal Proofs for SSH. The SSH handshake was analyzed by Williams [47] and Bergsma et al. [7]. Bellare et al. [4] presented a generic security model for SSH BPP, and Paterson and Watson [40] a specific, more detailed one for CTR-EaM. Albrecht et al. [1] included security statements for ChaCha20-Poly1305, generic Encrypt-then-MAC, and AES-CTR in SSH, claiming the indistinguishability and integrity of the ciphertext. Careful analysis of their proofs reveals an essential assumption about SSH sequence numbers that does not hold. In particular, they assume that the sequence counters in the stateful encryption scheme are initialized to 0 on both sides, which is false for the cipher modes affected by our attack. This assumption is not apparent from the paper, which omits the pseudocode for the encryption schemes, but Hansen gives the missing parts in [19] (Alg. `ssh-ChaCha20-Poly1305-Gen` in Fig. 6.5 and Alg. `ssh-fgEtM-Gen` in Fig. 6.6 there). We note that this assumption is also present in [4] (Fig. 4 there).

Cadé and Blanchet [11] used the formal verification tool *CryptoVerif* [10] to prove the security of SSH server authentication and the secrecy of the session key in the computational model. The secrecy of messages in the channel cannot be shown due to the attack in [2]. However, they do mention that due to a limitation in the design of CryptoVerif, it cannot keep mutable internal states such as sequence numbers or counters. In their model, the sequence numbers are passed explicitly as arguments and are, therefore, under the attacker's control. The authors do not raise the issue of channel integrity. Other computer-aided proofs of server authentication and secrecy of the session key in the symbolic or computational model can be found in [13, 25], which also do not consider the integrity of the secure channel. For an overview of the field of computer-aided cryptography, see [3].

3 Background

SSH Handshake (Figure 1). To initiate an SSH connection, both peers exchange a version banner. The Binary Packet Protocol (see below) is used from the third message on but without encryption and authentication. In the KEXINIT messages, nonces and ordered lists of algorithms are exchanged: One list for key exchange, one for server signatures, and two (one per direction) each for encryption, MAC, and compression. For each list, the negotiated algorithm is the first algorithm in the client's list, which is also offered by the server.

In the KEXDHINIT and KEXDHREPLY messages, a finite-field Diffie-Hellman key exchange is performed. SSH also supports elliptic curves (ECDH) and hybrid schemes with post-quantum cryptography (PQC) as alternatives. The server authenticates itself with a digital signature as part of the handshake. The signature is computed over the contents of the previously exchanged messages in a specified order.

The Exchange Hash: A Partial Handshake Transcript. In contrast to TLS, SSH uses only a selection from the handshake transcript for authentication. The hash value computed from this selection is called *exchange hash* H, defined as

$$H = \mathrm{HASH}(V_C \,||\, V_S \,||\, I_C \,||\, I_S \,||\, K_S \,||\, X \,||\, K),$$

where HASH is the hash function of the negotiated key exchange, V_C and V_S are the version banners of the client and server, I_C and I_S are the KEXINIT messages, K_S is the server's public host key, and K is the shared secret derived from the key exchange. The value of X depends on the key exchange and contains a composition of negotiated parameters (if any) and the ephemeral public keys of the key exchange [33, Sec. 8]. Each field includes a length field defined by the encoding.

Although the exchange hash contains everything that may influence the negotiation of algorithms or computation of the shared secret, it excludes seemingly 'unimportant' messages or message parts, such as IGNORE messages and unrecognized messages. This authentication gap allows a MitM attacker to inject messages into the handshake.

Sequence Numbers. Each sequence number is stored as a 4-byte unsigned integer initialized to zero upon connection. After a binary packet has been sent or received, the corresponding sequence number Snd or Rcv is incremented by one. Sequence numbers are never reset for a connection but roll over to 0 after $2^{32}-1$. As sequence numbers are responsible for protecting against replay attacks, rekeying must occur at least once every 2^{32} packets [37, Sec. 6.1].

We illustrate the use of sequence numbers in Figure 1: After the banner exchange, the counters Snd and Rcv are initialized with $(0,0)$ on both sides. During algorithm negotiation and key exchange, sequence numbers are increased but not used in any MAC computation or verification. Only after keys are activated the secure channel is established, and sequence numbers are used for MAC computation and verification. For each BPP packet, the sequence numbers in bold must match at both peers; otherwise, the BPP packet is rejected.

SSH Binary Packet Protocol. The BPP is used to encrypt and authenticate messages. First, a message is prefixed by a 4-byte message length and a 1-byte padding length. Then, at least 4 bytes of padding are added to the message so that the total length is a multiple of the block size or 8, whatever is larger. On the secure channel, the packet is encrypted by the cipher mode, and a MAC is added. The details depend on the authenticated encryption scheme, which uses an implicit initialization vector $\mathrm{IV}_{\mathrm{KDF}}$ derived from the session key.

CBC-EaM [33] (Figure 3a) is part of the original SSH specification. The MAC is computed over the implicit sequence number and the packet plaintext. The IV of the first packet is $\mathrm{IV}_{\mathrm{KDF}}$, and IV chaining is used (i.e., the IV of packet i is the last ciphertext block of packet $i-1$).

CBC-EtM [36] (Figure 3b) was added to OpenSSH in 2012. Here, the packet length is *not* encrypted to allow checking the MAC before decryption. The MAC is computed over the sequence number, the unencrypted packet length, and the ciphertext. The IVs are handled as with CBC-EaM.

CTR [37] mode was proposed by Bellare, Kohno, and Namprempre [4] as a countermeasure to attacks on CBC with IV chaining. $\mathrm{IV}_{\mathrm{KDF}}$ is used as the initial counter value and incremented after encrypting a plaintext block. CTR can be used with EaM or EtM, with identical implications for the length field and MAC computation as above.

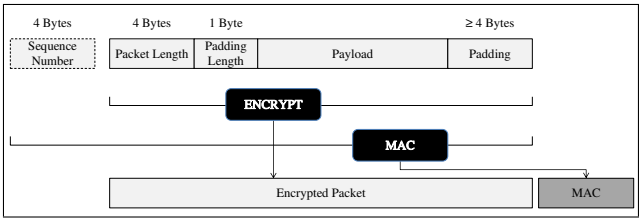
GCM [22] (Figure 3c) mode was specified by the NSA for Suite B-compliant SSH implementations [21]. Here, ciphertext integrity is part of the cipher mode. The length field is *not* encrypted (solely authenticated) to allow verification of the authentication tag before returning any plaintext. Internally, GCM uses a 12-byte nonce that is initialized to $\mathrm{IV}_{\mathrm{KDF}}$. The nonce is split into a 4-byte fixed value and an 8-byte invocation counter that is incremented by one for each message. The sequence number is not used but is always offset by a constant from the invocation counter.

ChaCha20-Poly1305 [34] (Figure 3d) was added to OpenSSH in 2013, inspired by a similar proposal for TLS by Langley and Chang [26, 27]. Here, two different encryption keys for the length field and the packet payload are derived, so the length field cannot be used as a decryption oracle for the payload. The MAC is computed over the concatenation of the two ciphertexts. Internally, the AEAD construction uses the sequence number as a nonce for each packet.

We note that the SSH specification says that the length field is encrypted [33, Sec. 6] and that the sequence number is used for integrity checks [33, Sec. 6.4]. This is only true for CBC-EaM, CTR-EatM, and ChaCha20-Poly1305. The modes CBC-EtM, CTR-EtM, and GCM do not encrypt the length field, and GCM also does not use the sequence number.

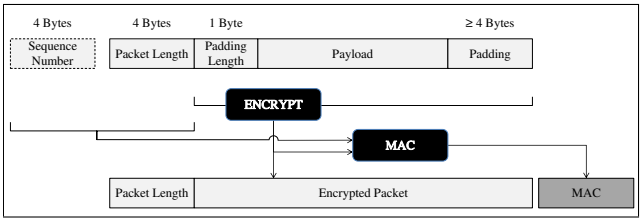
4 Breaking SSH Channel Integrity

In this section, we present a novel *prefix truncation attack* on SSH. The basic idea is that the attacker injects messages into the handshake to increase the implicit sequence number in one of the peers and then deletes a corresponding number of messages to that peer at the beginning of the secure channel. Two key insights about the SSH protocol enable this attack:



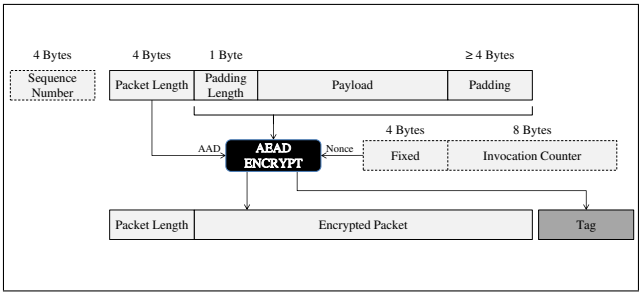
SSH Does Not Protect the Full Handshake Transcript. As detailed in Section 3, the exchange hash signed by the server during the handshake only authenticates some parts of the handshake transcript, while other parts are left unauthenticated. This allows an attacker to inject messages into the handshake, which cannot affect the key exchange but does affect the implicit sequence numbers of the peers.

SSH Does Not Reset Sequence Numbers at the Beginning of the Secure Channel. In SSH, sequence numbers are only incremented and never reset to 0, even when the encryption key changes. This allows an attacker to manipulate the sequence number counters in the secure channel before encryption and authentication keys are activated.

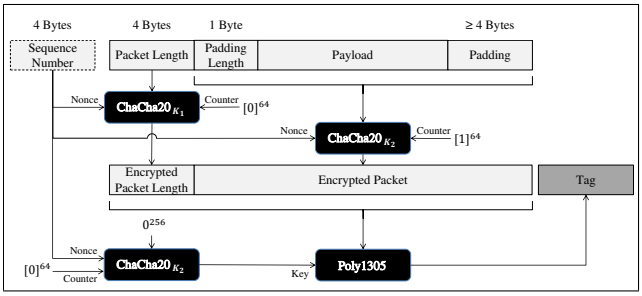


Comparison to Other Protocols. In IPsec/IKE, only a portion of the handshake transcript is signed, but unlike SSH, sequence numbers are reset to 0 when encryption and MAC keys are activated. In TLS, FINISHED messages are exchanged at the beginning of the secure channel to verify the integrity of the complete handshake transcript, and sequence numbers are reset to 0 after installing new keys. The Noise Protocol Framework fully secures the handshake transcript and uses a nonce as a sequence counter that is initialized to 0 after the handshake.

4.1 Sequence Number Manipulation



In this section, we first show how a MitM attacker can arbitrarily increase the receive sequence numbers C.Rcv and



(a) Encrypt-and-MAC [33] (diagram based on [2, Fig. 1]). The packet length is encrypted as part of the packet's plaintext. The sequence number is part of the input used to compute the MAC.

(b) Encrypt-then-MAC [36, Sec. 1.5] (diagram based on [41, Slide 37]). The packet length is not encrypted but authenticated as part of the MAC's input. The sequence number is used similarly to Encrypt-and-MAC.

(c) Galois/Counter Mode [22]. The packet length is not encrypted but authenticated as additional authenticated data (AAD). The sequence number is not used directly but is replaced with an invocation counter of constant offset.

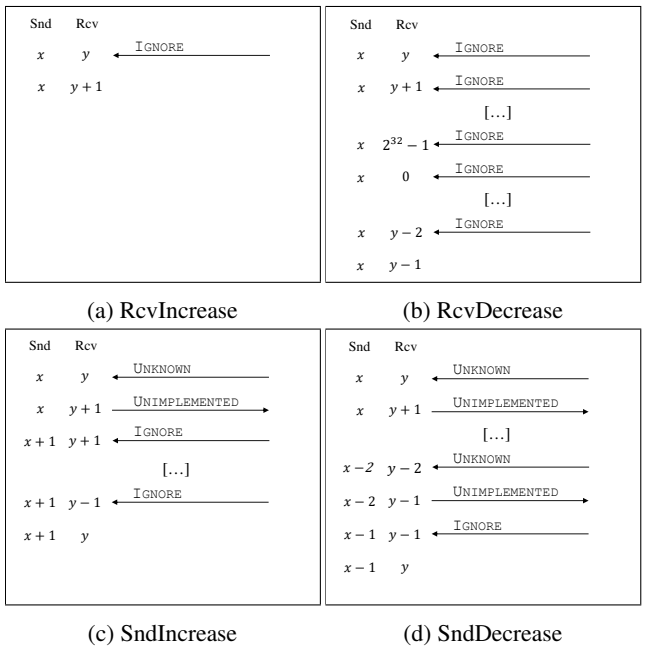
(d) ChaCha20-Poly1305 [34] (diagram based on [41, Slide 39]). The packet length is encrypted using a different key and authenticated as part of the Poly1305 input. The sequence number is encoded as an unsigned 64-bit integer to match the nonce length of ChaCha20.

Figure 3: Commonly used authenticated encryption schemes in the BPP of SSH.

S.Rcv in the client and the server during the handshake. This will be the basis for our prefix truncation attack and its applications, allowing the attacker to compensate for messages deleted from the secure channel.

Technique RcvIncrease (Figure 4a). A MitM attacker can increase C.Rcv (resp. S.Rcv) by N while not changing any other sequence number by sending N IGNORE messages to the client (resp. server).

The correctness is evident from the fact that the SSH standard requires for IGNORE that *"All implementations MUST understand (and ignore) this message at any time."* [33, Sec. 11.2]. The intended purpose of this message is to protect against traffic analysis, so it is considered a security feature, although there is no benefit from it during the handshake phase. We note that the attacker may also use any other message type that does not generate a response.



Other Modifications of Sequence Numbers. In addition, we found that an attacker can set the sequence numbers to arbitrary values by using the rollover after 2^{32} messages during the handshake. These advanced techniques require that the implementation allows handshakes with many messages, a large amount of data, and a long operating time. We also require a message that generates a response message but is otherwise ignored. Conveniently, the SSH standard requires this for all messages with unrecognized message IDs [38, Sec. 11.4]. Let UNKNOWN be a message with an unrecognized message ID.

Technique RcvDecrease (Figure 4b). A MitM attacker can decrease C.Rcv (resp. S.Rcv) by N while not changing any other sequence number by sending $2^{32}-N$ IGNORE messages to the client (resp. server).

A single IGNORE message is only 5 bytes, so it fits into a single block even for a 128-bit block cipher. Sending $2^{32}-N$ such messages transfers $\approx 2^{32} \cdot 16\text{B} \approx 69\text{GB}$ of data. Consequently, this technique can fail on implementations with timeouts or restrictions to the amount of data or the number of messages transferred during the handshake.

Technique SndIncrease (Figure 4c) and SndDecrease (Figure 4d). A MitM can increase C.Snd (resp. S.Snd) by N while not changing any other sequence number by sending N UNKNOWN and $2^{32}-N$ IGNORE messages to the client (resp. server) and deleting all generated UNIMPLEMENTED messages. Conversely, a MitM can decrease C.Snd (resp. S.Snd) by N while not changing any other sequence number by sending $2^{32}-N$ UNKNOWN and N IGNORE messages to the client (resp. server) and deleting all generated UNIMPLEMENTED messages.

Here, the total data transfer required is $\approx 69\text{GB}$ for SndIncrease and twice as much ($\approx 138\text{GB}$) for SndDecrease. Again,

(a) RcvIncrease (b) RcvDecrease

(c) SndIncrease (d) SndDecrease

Figure 4: Techniques for sequence number manipulation as a MitM in the SSH protocol. All techniques can target either client or server before the initial handshake concludes. The MitM deletes all generated UNIMPLEMENTED messages.

these techniques may fail on implementations that have timeouts or restrict the amount of data or number of messages exchanged during the handshake.

Evaluation. We verified all techniques successfully against PuTTY 0.79. Additionally, our experiments show that OpenSSH 9.5p1 recognizes a rollover of sequence numbers and terminates the connection, thus not affected by any technique but RcvIncrease. AsyncSSH 2.13.2 and libssh 0.10.5 allow for RcvIncrease but terminate the connection due to handshake timeouts before any advanced technique concludes. Dropbear 2022.83 disconnects on UNKNOWN messages instead of responding with UNIMPLEMENTED but allows Rcv to roll over, therefore being affected by RcvIncrease and RcvDecrease only.

4.2 Prefix Truncation Attack on the BPP

Single Message Prefix Truncation Attack. We assume the attacker wants to delete the first message SC1 sent from the server (Figure 2). The attack takes two steps:

1. The attacker uses the RcvIncrease technique to increase C.Rcv by one, e.g., by injecting an IGNORE message to the client before NEWKEYS.

2. The attacker deletes the first message SC1 sent by the server.

We first analyze this attack with regard to handshake authentication and sequence numbers. As the key exchange does not protect the handshake transcript from inserting IGNORE messages (Section 3), handshake authentication is not broken. Before the first step, we have C.Rcv = S.Snd. After the first step, we have C.Rcv = S.Snd + 1, but this manipulation is not detected during the handshake. After the second step, we have C.Rcv = S.Snd, and sequence numbers are back in sync.

It remains to be shown that the attacker can delete the message from the channel, which requires knowledge about the message's length, and that its deletion does not affect the MAC verification and decryption output for the following messages. Both aspects require careful analysis with respect to the used encryption mode, which will be given in Section 4.3 and Section 4.4. Here, we conclude by describing a straightforward generalization of the single message attack.

(N_S, N_C)-Prefix Truncation Attack. In a single attack, the attacker can generally delete an arbitrary number of N_S initial messages sent from the server and N_C initial messages sent from the client. This is straightforward: Instead of inserting one IGNORE message to the client before NEWKEYS, the attacker inserts N_S such messages to the client and N_C to the server. Consequently, instead of deleting the first message from the server, the attacker deletes N_S initial messages from the server and N_C initial messages from the client.

Note that the single message attack above is the specific case of a $(1,0)$-prefix truncation attack.

4.3 Determining the Byte-Length of Messages

To successfully delete packets from the secure channel, the attacker has to know their length. This is inherently true for encryption modes that do not encrypt the packet length field (any EtM mode, GCM). In the case of an encryption mode with an encrypted packet length field (any EaM mode, ChaCha20-Poly1305), the attacker may employ different strategies to determine the packet's length. One such strategy is to utilize knowledge about the plaintext if the length of the first few messages inside the secure channel is either fixed (for example, SERVICEACCEPT) or can be measured within a single connection ahead of time (for example, EXTINFO). This approach was used for all attacks described here. More advanced strategies may exploit TCP segment sizes and timings, as well as the message order of the SSH protocol. For example, an attacker may delay all encrypted traffic by the server until after the client's SERVICEREQUEST message has been processed to determine the length of the EXTINFO message. Here, we assume that the attacker always knows the lengths.

4.4 Analysis of Encryption Modes

In this section, we analyze which encryption modes our attacks affect and if they can be exploited in a real-world sce-

Authenticated Encryption Mode		Specification	Enc. State	Dec. State	Affected	Exploitable	Ref.
Encrypt-and-MAC	CBC	[33]	(IV, **Snd**)	(IV, **Rcv**)	✗	○	Section 4.4.1
	CTR	[33, 37]	(ctr, **Snd**)	(ctr, **Rcv**)	✗	○	Section 4.4.1
Encrypt-then-MAC	CBC	[33, 36]	(IV, **Snd**)	(IV, **Rcv**)	✓	◐	Section 4.4.3
	CTR	[36, 37]	(ctr, **Snd**)	(ctr, **Rcv**)	✓	◐	Section 4.4.3
GCM		[22]	$ctr_{Invocation}$	$ctr_{Invocation}$	✗	○	Section 4.4.1
ChaCha20-Poly1305		[34]	**Snd**	**Rcv**	✓	●	Section 4.4.2

Table 1: Authenticated encryption modes, corresponding specification documents, and their exposure to prefix truncation in the BPP of SSH. The initial value of state variables printed in bold purple can be chosen by the attacker, cf. Section 4.1. Full control of either state enables perfect prefix truncation (●, ChaCha20-Poly1305). Partial control may lead to limited exploitability, depending on the inner workings of the authenticated encryption mode (◐, Encrypt-then-MAC).

nario (see Table 1). An encryption mode is *affected* if, after prefix truncation, all following packets on the secure channel are decrypted, i.e., an AEAD mode does not generate the distinguished symbol INVALID or a composed mode successfully verifies the MAC. Note that we allow decryption to a different plaintext for probabilistic attacks. To capture this, we define an encryption mode as *exploitable* for an attack if the message stream after decryption is well-formed and supports that attack. If the attack's success probability is less than 1, we say the attack has *limited exploitability*.

4.4.1 Not Affected

GCM. GCM [22] mode does not use the implicit sequence number. Instead, it uses an invocation counter, initialized to $\mathrm{IV}_{\mathrm{KDF}}$, and incremented after each message. The authors justify this by stating that the resulting nonce is always a fixed offset from the sequence number. By deviating from the SSH standard, GCM stops our attack, as the attacker cannot manipulate the invocation counter during the handshake.

CBC-EaM and CTR-EaM. CBC uses IV chaining, and CTR uses a key stream. When the attacker deletes any prefix of the ciphertext in either mode, the first ciphertext block received will be decrypted as pseudorandom. Because EaM computes the MAC over the plaintext, MAC verification will fail with a probability close to 1, thwarting our attack.

4.4.2 Affected And Perfectly Exploitable

ChaCha20-Poly1305. ChaCha20-Poly1305 [34] directly uses the sequence number in its internal key stream derivation, which makes it vulnerable to our prefix truncation attack. All messages following the truncated prefix are decrypted to their original plaintext because the integrity check of the AEAD cipher is done over the ciphertext and the sequence number, which the attacker has manipulated to match. Under the assumption that the attacker can correctly guess the packet length, the prefix truncation attack always succeeds.

Note that the fault is not with ChaCha20-Poly1305 as an AEAD encryption scheme but with its integration into the SSH secure channel construction.

4.4.3 Affected With Limited Exploitability

CTR-EtM. With CTR-EtM, the MAC is computed over the unencrypted length, the sequence number, and the ciphertext. So, removing some packets from the beginning of the channel does not cause a MAC failure, and cryptographically, the attack succeeds. However, CTR uses a block counter initialized to $\mathrm{IV}_{\mathrm{KDF}}$, which increments after each block. After prefix truncation, the key stream is desynchronized, so *all* following ciphertexts are decrypted as pseudorandom packets. Each corrupted packet has a significant probability of causing a critical failure, eventually stopping our attack.

Remark: Decryption Oracle for CTR-EtM Using Prefix Truncation. For CTR-EtM, prefix truncation of k blocks (which exactly contain one or more messages) provides a very limited *decryption oracle* on the ciphertext $c_1, \ldots, c_k$ where $c_i := \mathrm{Enc}(\mathrm{IV}_{\mathrm{KDF}} + \mathrm{i}) \oplus p_i, 1 \leq i \leq k$. After deleting the first k blocks, MAC verification for the following message of length l blocks will succeed because the length, sequence number, and ciphertext are correct. The blocks $c_{k+1}, \ldots, c_{k+l}$ will be decrypted as $p'_j := \mathrm{Enc}(\mathrm{IV}_{\mathrm{KDF}} + \mathrm{j}) \oplus c_{k+j}, 1 \leq j \leq l$, and processed as a pseudorandom SSH message SC1'. Due to format oracle side channels in SSH at the BPP layer, e.g., the padding length, but also at the protocol layer, e.g., if a message is ignored or triggers a response, the attacker can get some information about the bits in p'_j. This reveals information about the first l key stream blocks, and thus also about $p_1, \ldots, p_l$, potentially leaking confidential information like passwords in user authentication. If processing SC1' does not cause a critical failure, the attack can even continue, revealing more about the following key stream and, thus, plaintext. Exploiting this requires a careful study of format oracles in SSH, which is outside the scope of this work.

CBC-EtM. With CBC-EtM, the MAC is computed from the unencrypted length, the sequence number, and the ciphertext. The IV is not required because $\mathrm{IV}_{\mathrm{KDF}}$ is implicit, and all other IVs are authenticated before use. Consequently, prefix truncation does not cause a MAC failure, and cryptographically, the attack succeeds. Nevertheless, we need to consider the impact that IV chaining has on the immediately following packet to see if this attack is practically exploitable.

Recall that the decryption of the first block is $p_1 := \mathrm{Dec}(c_1) \oplus \mathrm{IV}_{\mathrm{KDF}}$, and for block i, it is $p_i := \mathrm{Dec}(c_i) \oplus c_{i-1}$. We assume the attacker uses prefix truncation to remove blocks $c_1, \ldots, c_k$. The following block c_{k+1} will now be decrypted as $p'_1 := \mathrm{Dec}(c_{k+1}) \oplus \mathrm{IV}_{\mathrm{KDF}}$. We are interested in how SSH implementations process the resulting pseudorandom block p'_1 as the first block in the decrypted packet. Intuitively, it should result in a corrupted packet that causes a critical failure.[2]

Surprisingly, there is a significant probability that the attack can continue, although it is highly implementation-dependent. For a corrupted packet, there are four possible outcomes:

1. *Critically Corrupt:* If corruption is detected at the BPP or application level, e.g., if a length field exceeds the packet length, the connection should be closed.

2. *Marginally Corrupt:* If the packet happens to be similar enough to the original, e.g., if the corruption is limited to optional fields, it should be processed without error and have the same effect as the original would have had.

3. *Evasively Corrupt:* If the packet is well-formed (i.e., has valid padding length) but has an unrecognized message ID, an UNIMPLEMENTED response must be sent, and the connection continues normally [33, Sec. 11.4].

4. Any other case not covered above, in particular, recognized messages different from the original.

Clearly, the first outcome stops any attack from going forward. However, the second, third, and fourth outcomes may be beneficial for the attacker. We will now present two instructive scenarios for outcomes two and three, and estimate the success probability of an attack relying on that outcome. Later, we will verify these estimates experimentally.

Scenario 1: CBC-EtM Prefix Truncation Of a Single Message, Second Message Has Format Flexibility. In this scenario, the attacker wants to remove the first message, and the second (corrupted) message needs to be functionally preserved but has some format flexibility. For example, the second message might be SERVICEACCEPT (see Section 5.2), which is mandatory to start user authentication. The encrypted part of the packet looks like this, where p is the padding length, m is the message ID, and n is the service name length:

p	m	n	Service Name
0e	06	00 00 00 0c	s s h - u s e r a u
t h		Random Padding	

The probability that the first block decrypts exactly as shown is only 2^{-128} for a 128-bit block cipher. However, for some clients, the service name string is optional. These clients accept a 1-byte message with $p = 30$ (`0x1E`) and $m = 6$ as *marginally corrupt*, which has a success probability of 2^{-16}, independent of the block size.

Although SERVICEACCEPT may be a lucky case (for the attacker), there are structural reasons for this result: First, SSH messages are often short and can be smaller than a single block. Second, the padding is random and cannot be verified. Third, some messages have redundant fields that implementations ignore (e.g., the service name above).

We experimentally verified that OpenSSH, Dropbear, PuTTY, and libssh allow empty SERVICEACCEPT messages from the server, enabling this attack. At the same time, AsyncSSH is strict by requiring the correct service name.

Scenario 2: CBC-EtM Prefix Truncation Attack On More Than One Message. In this scenario, we assume the attacker wants to remove the first $N > 1$ messages and preserve all the following messages perfectly. Then, the attacker can use prefix truncation to delete the first $N-1$ messages and take a bet on the N-th message to be *evasively corrupt*.

Let ℓ be the length of the ciphertext of the N-th message, with padding length p, message ID m, and random padding. The attack succeeds regardless of the content of the corrupted packet as long as it is well-formed and unrecognized: A packet is *well-formed* if $4 \le p \le \ell - 2$ (accounting for the padding length and message ID). A packet is *unrecognized* if m is a message ID not known by the implementation.

Because the message is well-formed, it is not rejected at the BPP layer. Furthermore, because the message is unrecognized, the peer must respond with UNIMPLEMENTED and otherwise ignore it [33, Sec. 11.4], so our attack succeeds.

The probability that a packet is well-formed depends on ℓ. The padding length is between 4 and 255, and ℓ is a multiple of $\max(8, \text{block size})$, so the number of valid padding length values is $\min(252, \ell - 5)$ out of 2^8.

The probability that a packet is unrecognized depends on the size of the set U of unrecognized message IDs in the implementation. The attack requires at least one unknown message ID. Through source code review, we identified 43 IDs that are in active use, so we estimate up to 213 unknown message IDs out of 2^8.

In total, we estimate a success probability of $\min(252, \ell - 5) \cdot |U| \cdot 2^{-16}$. Assuming a block size of at least 128-bit (i.e.,

[2] Similarly to CTR-EtM, any format oracle side channel for p'_1 reveals a relationship between $\mathrm{IV}_{\mathrm{KDF}}$ and p_{k+1} via $\mathrm{IV}_{\mathrm{KDF}} \oplus p_{k+1} = c_k \oplus p'_1$, which is a marginal information leak for the (secret) IV given information on p_{k+1}, and vice versa. Again, we do not explore this further here.

$\ell \geq 16$), we estimate that the success probability of this attack is between $11 \cdot 2^{-16} \approx 0.0002$ ($\ell_{\min} = 16, |U_{\min}| = 1$) and $252 \cdot 213 \cdot 2^{-16} \approx 0.8190$ ($\ell_{\max} \geq 252, |U_{\max}| = 213$) for vulnerable implementations. Our experiments show success probabilities from 0.0003–0.8383, in good agreement with our analysis (Section 5.2). Increasing the block size increases the lower bound, while the upper bound stays the same.

5 Breaking SSH Extension Negotiation

While the fact that BPP does not implement a secure channel is troublesome enough, exploiting this vulnerability requires an analysis of the SSH protocol after the handshake, i.e., the SSH authentication protocol.

As our attack achieves prefix truncation, it is natural to ask which SSH messages can occur at the beginning of a secure channel. Historically, the first messages exchanged are SERVICEREQUEST and SERVICEACCEPT. Removing either causes the connection to go stale, as the client will not begin the user authentication. Then, our attack, while cryptographically successful, fails at the application layer.

However, the SSH Extension Negotiation mechanism [9] introduces a new message, EXTINFO, which can occur immediately after NEWKEYS as the first message on the secure channel. Some of the extensions that can be negotiated are security-relevant, providing an attack surface for our prefix truncation attack and raising its impact.

In this section, we will first describe SSH Extension Negotiation and then demonstrate how an attacker can downgrade the security of a connection by removing the EXTINFO message from the secure channel in a prefix truncation attack.

5.1 SSH Extension Negotiation

Even though the original SSH RFCs were designed with extensibility in mind, they do not provide any mechanism to negotiate protocol extensions securely. RFC 8308 [9] closes this gap. The RFC describes a signaling mechanism enabling extension negotiation, the extension negotiation mechanism itself, and a set of initially defined extensions.

Support for extension negotiation is signaled as part of the KEXINIT message. The structure of the message is not altered, and the reserved field is not used to avoid compatibility issues. Instead, each peer may include an indicator name within the list of key exchange algorithms. The indicator name differs depending on the role of the peer (`ext-info-c` vs. `ext-info-s`) to avoid accidental negotiation.

Whenever a peer signals support for extension negotiation, the other side may send an EXTINFO message as the first message after NEWKEYS. Additionally, the server can send a second EXTINFO later to authenticated clients to avoid disclosing extension support to unauthenticated clients. Each EXTINFO message can contain several extension entries. Negotiation requirements are defined on a per-extension level.

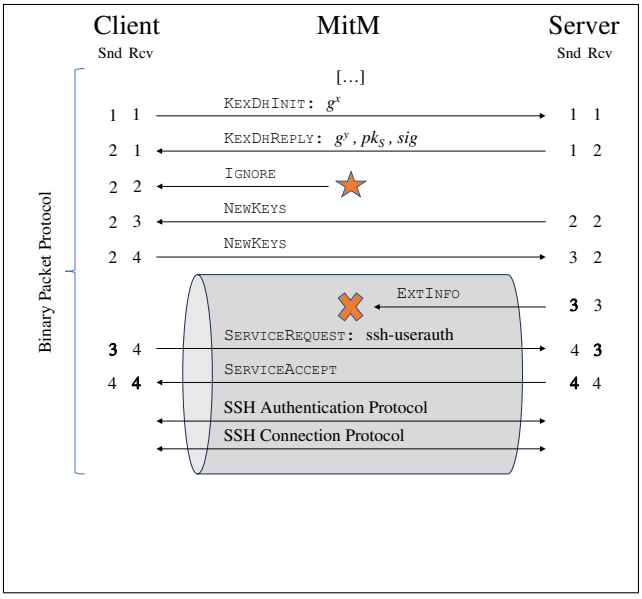
RFC 8308 defines an initial set of four protocol extensions, and vendors have proposed and implemented additional extensions. We detail those relevant to our attacks here.[3]

`server-sig-algs` [9] is a server-side extension that informs the client about all supported signature algorithms when using a public key during client authentication.

`publickey-hostbound@openssh.com` [35,36] is a server-side extension to advertise support for host-bound public key authentication, which deviates from public key authentication by also covering the server's host key. This allows the enforcement of per-key restrictions when generating the signature outside the SSH client (i.e., when using SSH Agent).

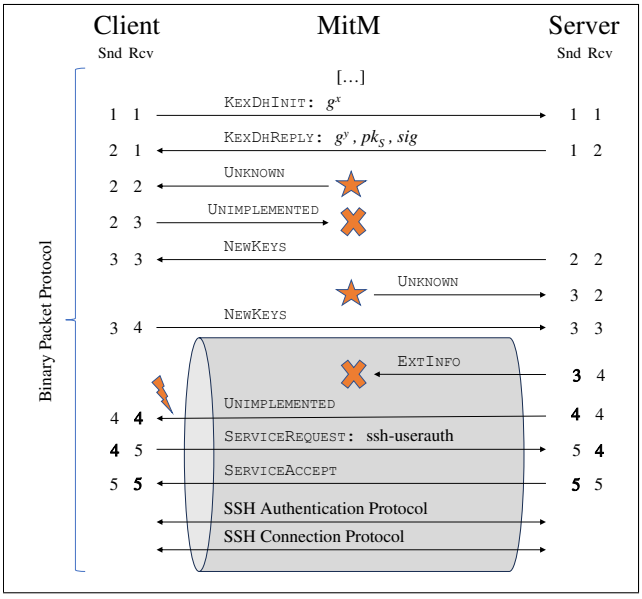
`ping@openssh.com` [36] is a server-side extension to advertise support for a transport-level ping message similar to the Heartbeat extension in TLS [46].

5.2 Extension Downgrade Attack



We now show how the prefix truncation attack can be applied to delete the EXTINFO message sent by the client, server, or both parties without either noticing. Our attack differs depending on the encryption mode. For ChaCha20-Poly1305, we can use the basic attack strategy. For CBC-EtM, we show two strategies to generate additional messages in the secure channel so that the attacker can use the "evasively corrupt" outcome of Scenario 2 in Section 4.4.3.

Impact. Successfully performing the extension downgrade can directly impact the security level of the connection. Most notably, the recently introduced keystroke timing countermeasures by OpenSSH 9.5 will remain disabled when the server has not sent `ping@openssh.com`. Furthermore, stripping an EXTINFO containing the `server-sig-algs` extension can lead to a signature downgrade during client authentication, as the client has to resort to trial-and-error instead.



Extension Downgrade for ChaCha20-Poly1305. The downgrade attack for ChaCha20-Poly1305 against the client is depicted in Figure 5a. It is identical to the single message prefix truncation attack from Section 4.2, with EXTINFO now taking the place of SC1 in Figure 2. If the attack should be directed against the server instead, a $(0,1)$-prefix truncation attack should be performed. This allows an attacker to delete any EXTINFO sent immediately after NEWKEYS.

While the server may send a second EXTINFO just before signaling successful client authentication, stripping the EXTINFO message sent after NEWKEYS renders most publicly specified extensions unusable. This is because they are either scoped to the authentication protocol, sent by the client only, or must be sent by both parties to take effect. Solely

[3] We excluded the following extensions because we consider them unrelated to our attacks: `no-flow-control`, `delay-compression`, `elevation`, `global-requests-ok`, `ext-auth-info`

(a) Extension Downgrade Attack for ChaCha20-Poly1305: The MitM injects an IGNORE message before the handshake concludes. The change in sequence numbers allows the MitM to strip the EXTINFO from within the secure channel.

(b) Extension Downgrade Attack for CBC-EtM: The MitM injects UNKNOWN before the NEWKEYS is sent by the client. As the server already sent NEWKEYS, the provoked UNIMPLEMENTED message will be sent within the secure channel after EXTINFO. The corrupted UNIMPLEMENTED message has a significant probability of being ignored (see Scenario 2 in Section 4.4.3).

Figure 5: Variants of the extension downgrade attack for ChaCha20-Poly1305 and CBC-EtM.

the `ping@openssh.com` extension may be sent in the second EXTINFO to enable keystroke timing countermeasures inside the connection protocol. However, OpenSSH 9.5 does not implement any facility to send a second extension negotiation message. As shown in Section 7, extensions scoped to the authentication protocol are the most common among SSH servers on the internet by a significant margin.

Extension Downgrade for CBC-EtM. In Figure 5b, we show how the attack can also work with CBC-EtM. Suppose an attacker injects an UNKNOWN message to the server after the server sends NEWKEYS and EXTINFO but before the client's NEWKEYS message (and also injects UNKNOWN to the client to realign sequence numbers). In that case, the server sends the response UNIMPLEMENTED as the second message in the secure channel immediately after the EXTINFO message. The attacker now wants to remove two messages from the channel and can benefit from the "evasively corrupt" in Scenario 2 in Section 4.4.3. The attacker removes EXTINFO from the secure channel, which causes the decryption of the first block of UNIMPLEMENTED to become pseudo-random. Because UNIMPLEMENTED messages are relatively small ($\ell = 16$ for AES), the upper estimate for the success probability is only $11 \cdot 213 \cdot 2^{-16} \approx 0.0358$.

However, the success probability can be increased significantly by exploiting the new ping extension in OpenSSH 9.5. To make use of this, the attacker replaces the UNKNOWN message sent to the server with a PING message containing at least 255 bytes of payload. As per specification, the server will reflect this data in the PONG response. This yields $\ell \geq 264$, maxing out the probability of the packet being well-formed. Consequently, the upper estimate for the success probability is now $252 \cdot 213 \cdot 2^{-16} \approx 0.8190$.

Evaluation. We successfully evaluated the attack in 10,000 trials on ChaCha20-Poly1305 and CBC-EtM against OpenSSH 9.5p1 and PuTTY 0.79 clients, connecting to OpenSSH 9.4p1 (UNKNOWN only) and 9.5p1. For CBC-EtM, our success rate in practice was 0.0003 (OpenSSH) resp. 0.0300 (PuTTY), improved to 0.0074 (OpenSSH) resp. 0.8383 (PuTTY) when sending PING instead of UNKNOWN.

6 Message Injection Attacks on AsyncSSH

Going beyond the SSH specifications, we now demonstrate how prefix truncation attacks can also be used to exploit implementation flaws. Specifically, we target AsyncSSH,[4] an SSH implementation for Python with an estimated 60k daily downloads.[5] We present two attacks that exploit weaknesses

[4] https://github.com/ronf/asyncssh
[5] https://pypistats.org/packages/asyncssh

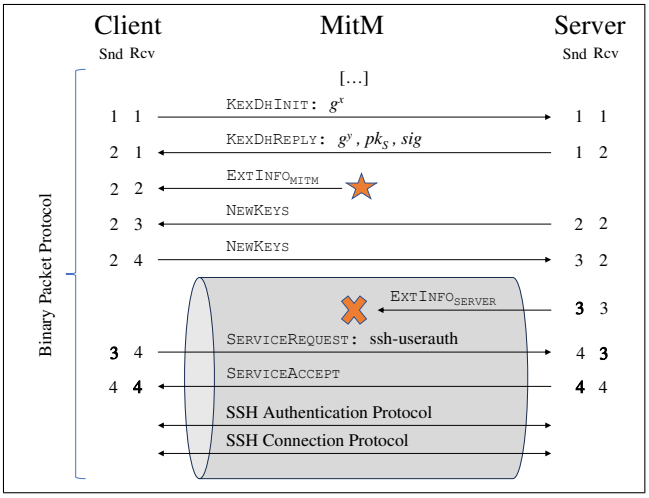


Figure 6: Rogue Extension Negotiation Attack on AsyncSSH: The MitM injects a malicious extension information message before the key exchange completes and deletes the server's ExtInfo message to account for the change in sequence numbers. This attack relates to the generic extension downgrade attack in Section 5.2.

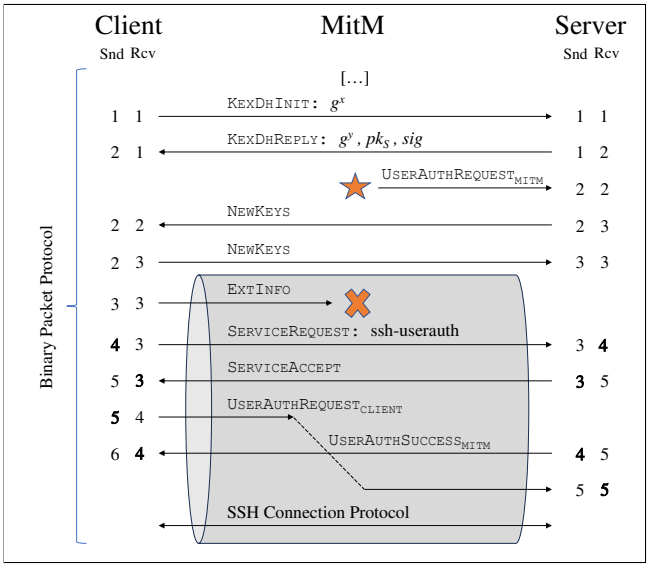

Figure 7: Rogue Session Attack on AsyncSSH: The MitM injects a malicious authentication request before the handshake is complete and deletes the client's ExtInfo message to account for the change in sequence numbers. By delaying the authentication request sent by the client, the MitM ensures that the malicious one is processed. Any additional authentication requests are silently ignored.

in handling unauthenticated messages during the handshake. These attacks are enabled by prefix truncation and sequence number manipulation.

Note that we describe these attacks only for ChaCha20-Poly1305. Adjusting them for CBC-EtM is straightforward, injecting appropriate Ignore and Unknown messages, but requires some of the advanced techniques described in Section 4.1. These advanced techniques only work against some SSH implementations.

6.1 Rogue Extension Negotiation Attack

The rogue extension negotiation attack targets an AsyncSSH client connecting to any SSH server sending an ExtInfo message. The attack exploits an implementation flaw in the AsyncSSH client to inject an ExtInfo message chosen by the attacker and a prefix truncation against the server to delete its ExtInfo message, effectively replacing it.

Impact. The attacker can replace the content of the ExtInfo message. AsyncSSH clients support the `server-sig-algs` and `global-requests-ok` extensions. Hence, the attacker can try to downgrade the algorithm used for client authentication by restricting the value of `server-sig-algs` to a subset of those supported by the server.

Attack Description. The attack is a variant of the extension downgrade attack in Section 5.2, but instead of Ignore, the attacker sends a chosen ExtInfo packet to the client. Similar to Ignore, ExtInfo does not trigger a response from the client. A correct SSH implementation should not process an unauthenticated ExtInfo message. However, the injected message is accepted due to flaws in AsyncSSH.

Evaluation. We successfully evaluated the attack against AsyncSSH 2.13.2 as a client, connecting to AsyncSSH 2.13.2.

6.2 Rogue Session Attack

The rogue session attack targets any SSH client connecting to an AsyncSSH server, on which the attacker must have a shell account. The attack's goal is to log the client into the attacker's account without the client being able to detect this.

Impact. With a successful attack, the attacker can gain complete control over the remote end of the SSH session. The attacker receives all keyboard input by the user, completely controls the terminal output of the user's session, can send and receive data to/from forwarded network ports, and can create signatures with a forwarded SSH Agent, if any. The result is a complete break of the confidentiality and integrity of the secure channel, providing a strong vector for a targeted phishing campaign against the user. For example, the attacker can display a password prompt and wait for the user to enter the password, elevating the attacker's position to a MitM at the application layer and enabling impersonation attacks.

Attack Description. The messages exchanged during the attack are depicted in Figure 7. The attacker injects a chosen USERAUTHREQUEST before the client's NEWKEYS. This request must be a valid authentication request containing the credentials of the attacker. The attacker can use any authentication mechanism that does not require exchanging additional messages between client and server, such as `password` or `publickey`. Due to a state machine flaw, the AsyncSSH server accepts the unauthenticated USERAUTHREQUEST message and defers it until the client has requested the authentication protocol.

To avoid a race condition between the USERAUTHREQUEST sent by the client and the USERAUTHREQUEST injected by the attacker, the attacker delays the client's USERAUTHREQUEST until after the server signals a successful authentication in response to the injected USERAUTHREQUEST. The AsyncSSH server silently ignores any additional authentication request after a successful authentication.

To complete the attack, the attacker has to fix the sequence numbers using one of two strategies (note that Figure 7 only shows the first strategy):

- Suppose the client sends an extra message before SERVICEREQUEST. In that case, the attacker can delete that message from the channel, effectively performing the (0,1)-prefix truncation attack with USERAUTHREQUEST instead of the usual IGNORE message.
- Alternatively, suppose the server sends an extra message before SERVICEACCEPT. In that case, the attacker can delete that message after injecting an additional UNKNOWN message to the client before NEWKEYS, triggering an UNIMPLEMENTED response that is deleted. This increases both C.Snd and C.Rcv, moving the send count deficit from the client to the server.

Evaluation. We successfully evaluated the attack against AsyncSSH 2.13.2 as a server, connecting to AsyncSSH 2.13.2 and OpenSSH 9.4p1.

7 SSH Deployment Statistics

To estimate the impact of the prefix truncation attacks, we scan for the SSH servers preferring or supporting any affected encryption mode. Similarly, to estimate the impact of the extension downgrade attack, we scan for servers sending EXTINFO messages.

Methodology. For scanning, we used ZMap [16] and ZGrab2 [15] on port 22 of the entire IPv4 address space. The scan was performed over two days in early October 2023, totaling 15.164M SSH servers.

As ZGrab2 cannot capture SSH extensions, we performed a complementary scan at the end of June 2023, using a custom tool, on a subset of 2^{20} open ports. The scan covered a total of 830k servers. All data relating to the use of extension negotiation in SSH is sourced from this scan.

Cipher Family	Preferred		Supported	
ChaCha20-Poly1305	8,739k	57.64%	10,247k	67.58%
AES-CTR	4,785k	31.56%	14,866k	98.04%
AES-GCM	1,219k	8.04%	10,450k	68.92%
AES-CBC	236k	1.56%	4,069k	26.84%
Other	147k	0.97%	-	-
Unknown / No KEXINIT	34k	0.23%	-	-
Total	15,164k	100%		

Table 2: Preferred SSH cipher families as of October 2023.

In SSH, the algorithm order of the client determines which algorithm is preferred. However, we cannot scan for actual client use. Assuming that servers and clients are bundled in a single product and share algorithm preference and support, we use the server's lists as a surrogate, as was also done in [1].

Symmetric Encryption Algorithms. In Table 2, we show the number of servers that prefer and support various encryption modes. A cipher is preferred if it is placed first in the list of supported algorithms.

We find that, by far, the most preferred encryption cipher is ChaCha20-Poly1305, with 57.64% listing this algorithm first. This is followed by AES-CTR (31.56%) and, with some distance, by AES-GCM (8.04%) and AES-CBC (1.56%).

Authenticated Encryption Modes. As non-AEAD ciphers must be combined with a MAC, we also evaluate which *authenticated* encryption modes the servers prefer and support. The numbers for the AEAD modes ChaCha20-Poly1305 (57.64%) and GCM (8.04%) are identical to those for encryption modes, as the MAC is already integrated. Preference for CTR modes is split between a majority for CTR-EaM (26.14%) and a minority for CTR-EtM (5.46%). Preference for CBC modes is mostly CBC-EaM (2.37%), while preference for CBC-EtM (0.09%) is marginal.

In summary, 63.2% of all servers prefer an authenticated encryption mode affected by our attacks.

Looking at the support for authenticated encryption modes vulnerable to our attacks, we find that 67.58% of all servers support ChaCha20-Poly1305, while 17.24% support CBC-EtM. In total, 71.6% support at least one affected mode.

SSH Extensions. We also looked at SSH extensions offered by servers before user authentication; see Table 4. We can see that 76.81% of all servers send the `server-sig-algs` extensions to indicate support for better signature schemes for client public key authentication. Furthermore, 8.8% send the `publickey-hostbound` extension, improving security

AE Mode	Preferred		Supported	
ChaCha20-Poly1305	8,739k	57.64%	10,247k	67.58%
CTR-EaM	3,964k	26.14%	4,200k	27.70%
GCM	1,219k	8.04%	10,450k	68.92%
CTR-EtM	828k	5.46%	10,685k	70.46%
CBC-EaM	359k	2.37%	1,585k	10.46%
CBC-EtM	14k	0.09%	2,614k	17.24%
Other	2k	0.01%	-	-
Unknown / No KEXINIT	36k	0.24%	-	-
Total	15,164k	100%		

Table 3: Distribution of supported authenticated encryption modes as of October 2023.

Extension name	Times Offered	
`server-sig-algs`	637,466	76.81%
`publickey-hostbound@`	73,040	8.80%
`delay-compression`	283	0.03%
`no-flow-control`	283	0.03%
`global-requests-ok`	283	0.03%

Table 4: SSH extensions offered by servers after the initial handshake, `@openssh.com` abbreviated to `@`. Extensions sent by servers upon successful client authentication are not included.

for authentication using SSH agent. Both extensions provide opportunities for downgrade attacks, as their absence can weaken the strength of the authentication.

8 Suggested Countermeasures

As a stop-gap measure, the affected cipher modes can be turned off. Widely supported alternatives are AES-GCM or AES-CTR. However, the root cause analysis shows that the underlying issues lie in the SSH specification. We therefore suggest two changes to the specification.

Sequence Number Reset. Resetting sequence numbers to zero when encryption keys are activated ensures that sequence number manipulations during the handshake can no longer affect the secure channel. Unfortunately, sequence number reset is a major break in compatibility. To avoid connection failures due to one-sided sequence number resets, we suggest that an implementation signals the support for this countermeasure by including an identification string in the list of supported key exchange algorithms. The SSH extension negotiation mechanism is already employing this method. If and only if both peers signal support for this countermeasure, the sequence numbers will be reset.

In response to our findings, OpenSSH implemented this behavior as part of their so-called "strict kex" countermeasure [36, Sec. 1.10]. In addition to resetting sequence numbers, "strict kex" mandates that unexpected or unknown messages during the initial key exchange must lead to the connection's termination. An unexpected message in this context is any message that is not strictly required for key exchange. "strict kex" has since been adopted by various vendors to ensure interoperability between SSH implementations.

Full Transcript MAC. Authenticating the full handshake transcript, as seen by the client and server, can detect attempts of handshake manipulation by a MitM attacker, including sequence number manipulation through our techniques. It is impossible to extend the scope of the existing exchange hash, as the server signature is transmitted before the new keys are taken into use. Therefore, any messages sent after the key exchange but before NEWKEYS cannot be included. We suggest that both peers send a MAC authenticating the entire transcript at the start of the channel, similar to TLS Finished messages. Signaling support should be done as above. However, the transcript must be carefully canonicalized. While client and server messages are sequential, they can interleave asynchronously, leading to transcript variations. Also, the protocol must be extended to define the algorithm, encoding, and position of the transcript MAC. Thus, securing the handshake is more complex than resetting the sequence number.

Relationship to Formal Proofs. Both countermeasures have a common goal: Align the SSH standard with expectations for stateful encryption schemes from formal models for the BPP presented in [1,4]. A sequence number reset achieves this directly by initializing the sequence numbers to zero, as in the models. On the other hand, verifying the full transcript hash forces the sequence number in the stateful encryption and decryption methods to be synchronized by the sender and receiver. Although the sequence numbers are then not initialized to zero, each pair is nevertheless initialized to a common value out of the attacker's control. The existing models could then be adjusted in the following way: If $T_C, T_S \in \{0,1\}^*$ are the (canonicalized) transcripts of the SSH handshake as seen by the client and the server, and $M_{CS}, M_{SC} : \{0,1\}^* \mapsto \mathbb{N}$ are functions counting the messages from the client to the server and vice versa in a transcript, then sequence numbers in the stateful encryption and decryption modes are initialized to:

$$\mathsf{C.Snd} = M_{CS}(T_C), \qquad \mathsf{C.Rcv} = M_{SC}(T_C),$$
$$\mathsf{S.Snd} = M_{SC}(T_S), \qquad \mathsf{S.Rcv} = M_{CS}(T_S).$$

Authenticating the transcript then ensures that $T_C = T_S$, and thus $\mathsf{C.Snd} = \mathsf{S.Rcv}$ and $\mathsf{C.Rcv} = \mathsf{S.Snd}$, before the first messages in the secure channel are encrypted or decrypted. Authenticating the handshake transcript has the added benefit that the handshake could be analyzed in a "matching conversations"-based security model [23, 24].

Other Issues. We suggest that SSH specifies "end-of-communication" messages to detect suffix truncation attacks. Also, AsyncSSH should be hardened to disallow unauthenticated, application-layer messages during the SSH handshake. In response to our findings, the state machine of AsyncSSH was improved in version 2.14.1 to mitigate our attacks.

9 Future Work

Formally, SSH BPP security was modeled as stateful decryption [1, 4, 40]. Implicitly, this state was associated with SSH sequence numbers, and it was assumed that an adversary could not manipulate this state. These models can be extended in two directions: (1) Include a broader definition of state. By including chained IVs, key stream state, and GCM invocation counters, these models can be used to show why certain cipher modes resist our attacks and that they indeed achieve INT-PST security. (2) Introduce a novel adversarial query, `ModifyState`, to model the attacks described here.

Our attack combines weaknesses in the SSH handshake with weaknesses in the encrypted channel. Earlier work analyzed these separately, leading to small models. To find our attack automatically, models of SSH for computer-aided proofs could (1) model the handshake as well as the BPP together, (2) keep track of sequence numbers in the BPP, including the handshake, which requires modeling integer numbers that can overflow as the internal state, (3) model seemingly unimportant messages like IGNORE, and (4) consider each encryption mode separately. The properties to verify should include strong security notions such as INT-aPTXT [17].

Applying state learning to implementations also has the potential to find our attacks automatically in the future, although it suffers from a combinatorial explosion in the number of messages (see Section 5.1 in [28]). Messages like IGNORE and EXTINFO need to be included in the alphabet to find our attacks, and an active MitM attacker has to be considered.

10 Conclusion

We have shown that the complexity of SSHv2 has increased over its 25 years of development to a point where the addition of new algorithms and features has introduced new vulnerabilities. The root cause analysis has shown that the potential for our attacks was already present in the original specification. Handshake transcripts were never fully authenticated, and sequence numbers were never reset to 0. However, as new authenticated encryption modes and extension messages were added, these weaknesses grew into exploitable vulnerabilities.

We introduced novel sequence number manipulation and prefix truncation attacks for secure channels, which invalidate the INT-aPTXT [17] security of SSH BPP for certain ciphers. We extended these vulnerabilities to real-world exploits like disabling SSH extension negotiation. This yields novel insights into the complex interplay between a practical security mechanism (sequence numbers) and abstract security notions (INT-PTXT vs. INT-CTXT, [6]).

Our close look at the extension negotiation mechanism reveals its design weaknesses: First, sending EXTINFO is optional even if both parties signal support for extension negotiation during the handshake. Second, EXTINFO cannot be used to change the SSH handshake itself, e.g., to implement the countermeasures proposed in this paper. However, it outperforms extension negotiation within the KEXINIT in aspects of privacy as protocol extension can be negotiated securely, i.e., privately, similar to encrypted extensions in TLS 1.3. As a consequence, extension negotiation within the KEXINIT should be strictly limited to extensions affecting the SSH handshake. Protocol extensions affecting the user authentication or application layer should be negotiated through the extension negotiation mechanism.

Although we suggest backward-compatible countermeasures to stop our attacks, the security of the SSH protocol could benefit from a redesign from scratch. The redesign process could be inspired by that of TLS 1.3, which brought implementers together with experts in protocol analysis and formal verification [3]. This could simplify the protocol while preserving and/or achieving desired security notions for SSH, which may differ from those of TLS. For example, while the privacy of client authentication and extension negotiation are relatively new features for TLS, they are already present in SSH and should thus be preserved in a redesign.
